The **heart** [cor] is a hollow organ principally composed of muscle, the **myocardium.** It is lined internally by **endocardium** which is continuous with the intima of the blood-vessels. Externally, it is covered by the **epicardium,** a serous membrane continuous with the serous lining of the pericardium. The form of the heart, when removed from the body without previous hardening, is that of a fairly regular truncated cone. The **base** [basis cordis] is poorly circumscribed but corresponds, in the general way, to the area occupied by the roots of the great vessels and the portion of the heart-wall between them. The base of the heart is held in position chiefly by the great vessels, which are attached to the pericardium. It is not fixed, however, for during systole the base performs a greater excursion than does the apex. The remainder of the organ is capable of free movement within the pericardial cavity.

The interior of the heart is longitudinally divided into right and left cavities by a septum passing from base to apex. Each cavity is subdivided into an **atrium** [atrium cordis] and a **ventricle** [ventriculus cordis], the former receiving the ultimate venous trunks and the latter giving rise to the main arteries. Thus the left atrium receives the four pulmonary veins, and the right atrium the superior and inferior vena cava and the coronary sinus; the aorta issues from the left ventricle and the pulmonary artery from the right. The ventricles, which constitute the major portion of the heart, may be recognised by their very thick walls. The atria have thinner walls and are less capacious than the ventricles; projecting from each is a diverticulum or **auricle** [auricula cordis]. The auricles (which receive their name from their resemblance to dog's ears) partially embrace the roots of the pulmonary artery and aorta.

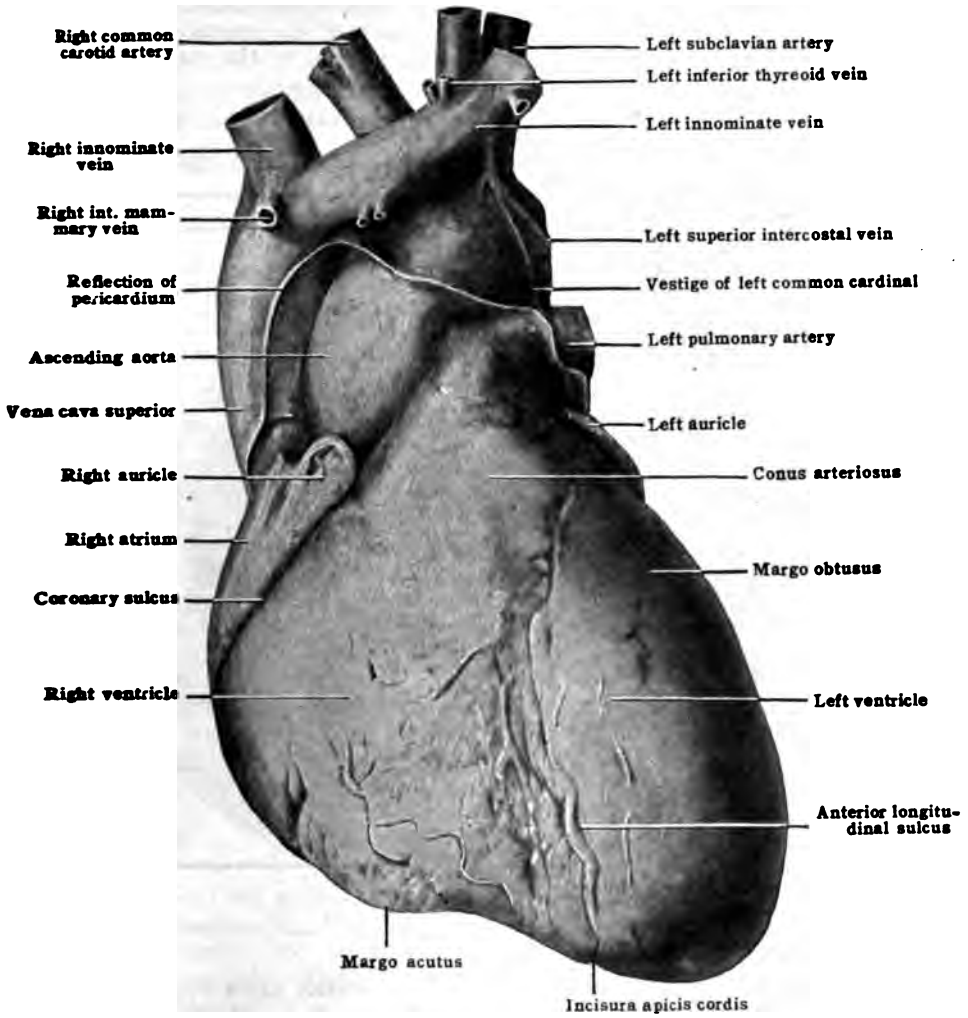
Orientation of the heart.—The apex of the heart [apex cordis] points forward, to the left and downward. The base is directed backward, to the right and upward The longitudinal axis of the heart forms an angle of about 40° with the horizontal plane and also with the median sagittal plane of the body.

The long axis of the heart is therefore slightly more horizontal than vertical, and slightly more anteroposterior than transverse, and the atria are posterior to, rather than above the ventricles. To arrive approximately at the direction of the longitudinal axis of the heart, it is necessary to select the central point of the base. By cutting the vessels short in several hearts, hardened by formalin before removal, a point immediately to the left of the left lower pulmonary vein was selected in determining the data above given. A steel pin was passed through this point to the apex cordis, and the angles controlled by frontal and transverse sections of the thorax. Mention of angular measurements of the axis of the heart could be found only in the

[illegible]-books of Testut and Luschka; the former gives 40° to the horizontal plane, the latter 60° to the midsagittal. Luschka's angle appears to be too large; but further investigation in this direction is desirable.

Size and weight.—The heart measures about 12.5 cm. (5 in.) from base to apex in the adult, and 8.7 cm. (3½ in.) at its broadest, and 6.2 cm. (2½ in.) at its thickest portion. In the male its weight averages about 312 gm. (eleven ounces), and in the female about 255 gm. (nine ounces). The weight of the heart forms approximately 0.55 per cent. of the total body-weight in the male of normal build and about 0.53 per cent. in the female; in emaciated individuals it usually weighs relatively more, and relatively less in the fat. The *volume* of the heart in diastole may be estimated during life in cubic centimeters by the use of the following formula,

FIG. 467.—STERNOCOSTAL SURFACE OF THE HEART.



0.53 A ¾, A being the X-ray silhouette of the diastolic area in square centimeters, after making due allowance for divergence of rays (Bardeen). The heart weight may be computed by multiplying 1/20 A ¾ by 0.0055.

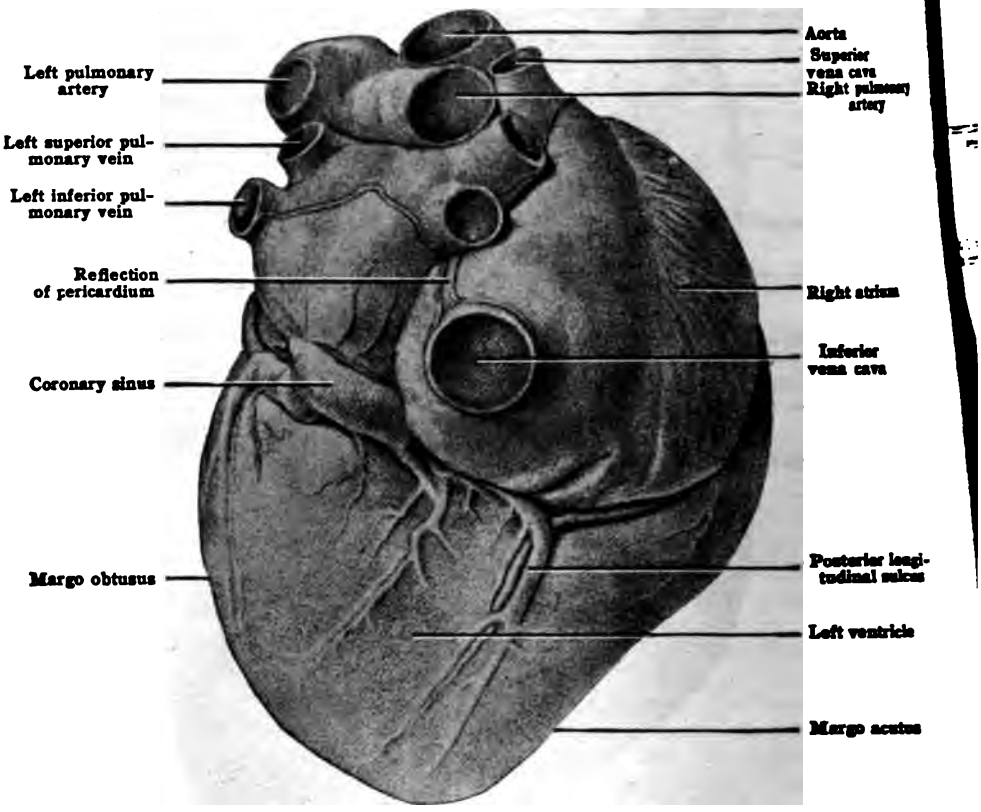
EXTERIOR OF THE HEART

In hearts which have been hardened by injection before removal from the body, the regularity of the heart-cone is disturbed by a well-marked triangular facet, imparted by contact with the diaphragm. This facet is the **diaphragmatic surface** [facies diaphragmatica], which is directed downward and slightly backward (fig. 468). It ends abruptly along a sharp margin extending from the apex toward the right. This margin is the **margo acutus** (fig. 467); it separates the diaphragmatic surface from the sternocostal surface. The other margin of the diaphragmatic surface is more rounded and shades gradually into the rounded

margo obtusus (fig. 467), which passes almost insensibly into the sternocostal surface. The convex **sternocostal** surface [facies sternocostalis] (fig. 467) is directed forward and somewhat upward and to the right, is triangular and bounded below by the margo acutus. To the left it goes over into the margo obtusus along a line extending from the apex of the heart to the root of the pulmonary artery. The **margo obtusus** corresponds to the rounded left side of the left ventricle.

The interventricular sulcus is a slightly marked groove indicating the separation of the ventricles upon the exterior of the heart. It lodges coronary blood-vessels and a moderate quantity of fat which can be seen through the epicardium. The part of this groove seen on the sternocostal surface is the **sulcus longitudinalis anterior.** It runs obliquely over the upper part of the margo obtusus on to the sternocostal surface. Crossing the margo acutus to the right of the apex

FIG. 468.—BASE AND DIAPHRAGMATIC SURFACE OF THE HEART. (After His.)



it is continuous with the **sulcus longitudinalis posterior** upon the diaphragmatic surface. The diaphragmatic surface is formed about equally by the right and left ventricles, and the sternocostal surface mainly by the right. Where the longitudinal sulcus crosses the margo acutus it produces a slight notch, the **incisura (apicis) cordis.**

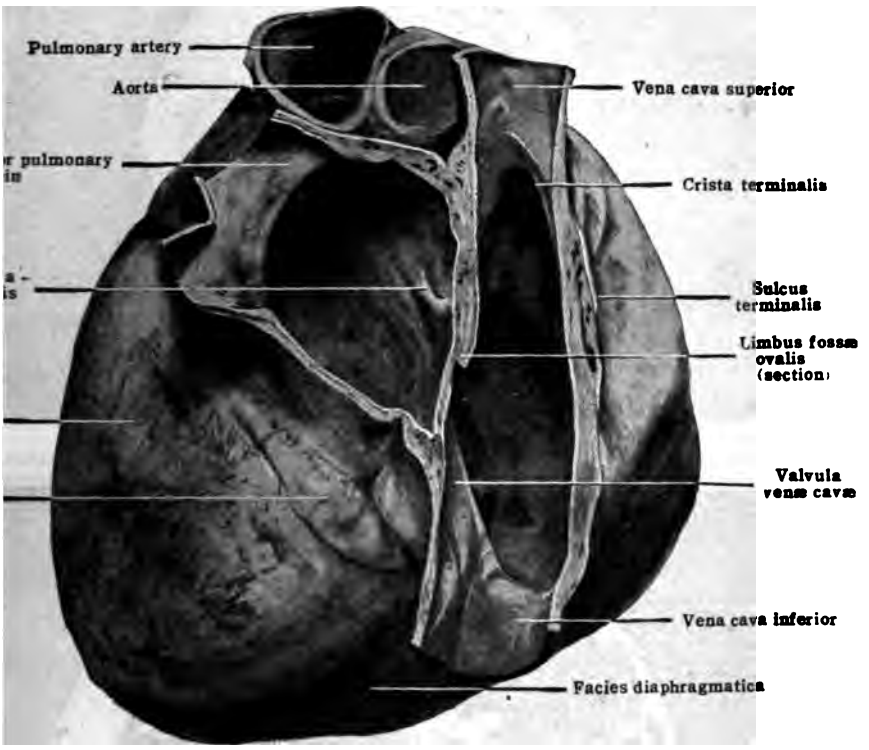
The atria are separated externally from the ventricles by the **sulcus coronarius.** This is a horseshoe-shaped groove well marked below and laterally, and interrupted above by the roots of the pulmonary artery and aorta. It lodges the coronary sinus, smaller coronary vessels and fat.

ATRIAL PORTION

The **atrial portion of the heart** is situated behind, and slightly to the right of and above, the ventricular portion. On the external surface, its separation into right and left atria is not indicated posteriorly, except in distended hearts (such as that shown in fig. 468); in these it is marked by a slight groove connecting the

s of the superior and inferior vena cava. The auricles are separated y by the deep notch which lodges the aorta and pulmonary artery. A ove on the back of the right atrium which connects the right sides of the and inferior vena cava, is the **sulcus terminalis** (figs. 468, 469). This s the right limit of what was, in the embryo, the sinus venosus. It also that the embryonic sinus venosus has become an integral part of the ht atrium. The superior and the inferior cava join the posterior part ht atrium above and below, respectively. The coronary sinus courses d, backward and to the right to enter the right atrium anteriorly to and t above the place of entrance of the inferior vena cava. The four pulmo- is run nearly transversely and somewhat forward into the right and left he left atrium.

G. 469.—ATRIA OPENED POSTERIORLY TO SHOW THE SEPTUM ATRIORUM.

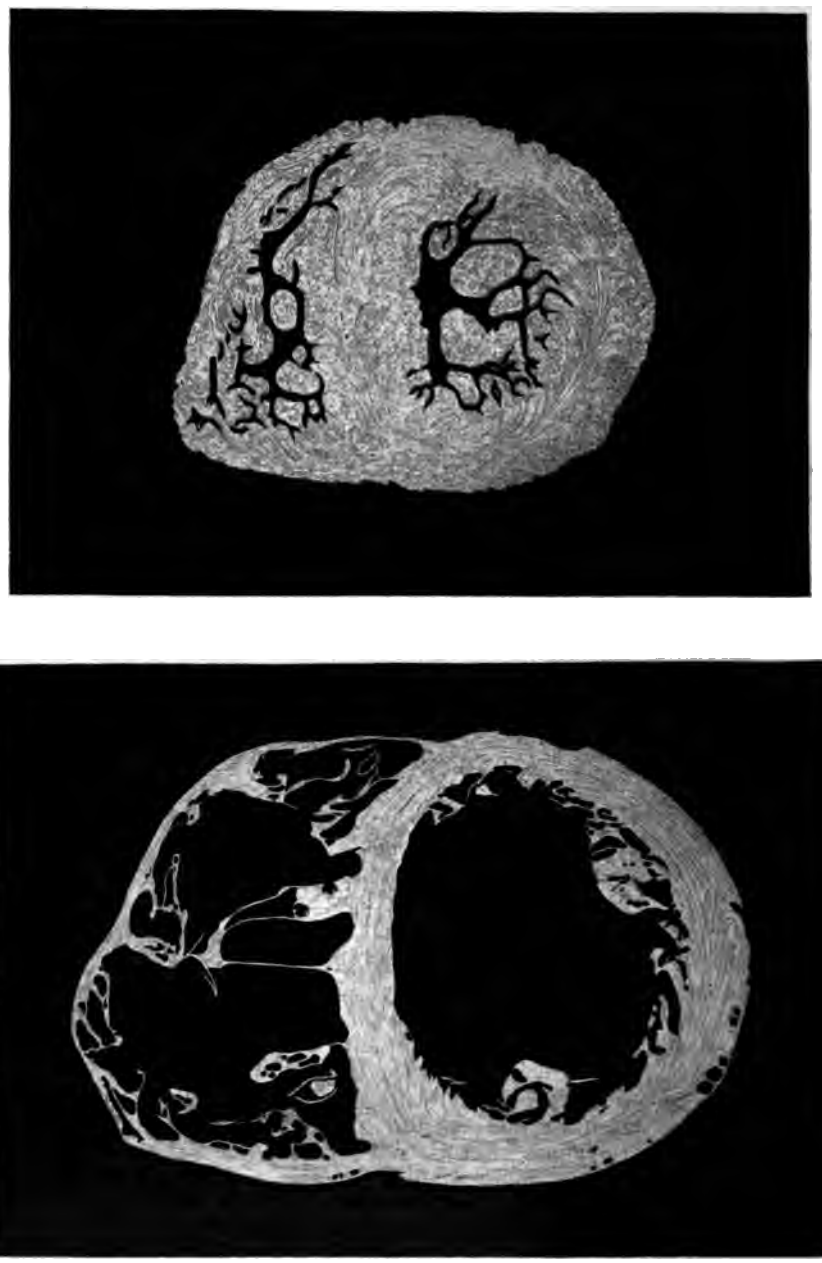


nterior of the atrial portion of the heart is divided into right and left y the **septum atriorum.** This septum is a composite structure, having eloped (see p. 567) in two independent parts, neither of which is a com- tum in itself. The two incomplete septa, however, partly overlap her so that, by lateral fusion at the time of birth, they together produce rvious structure of the adult heart (fig. 469). Of these septa, the first rmed is the **membranous septum** [pars membranacea septi atriorum]. ight of this is developed a muscular septum, the margin of which forms er part of the **limbus fossæ ovalis** of the adult right atrium. The margin mbranous septum is recognizable as a fold of endocardium on the septal he left atrium; it is called the **valvula foraminis ovalis.**

. the septal wall of the adult **right atrium** [atrium dextrum] (fig. 469), imme- bove the inferior cava is the **fossa ovalis,** of which the floor is formed by ibranous septum. Surrounding the fossa ovalis except below (indeed g the fossa) is the limbus fossæ ovalis which is continuous anteriorly and ith the **valvula venæ cavæ** (inferioris Eustachii). Anterior to the fossa the orifice of the coronary sinus, which is guarded by the **valvula sinus** (Thebesii) (fig. 472). Leading from the front of the atrium forward tly downward and to the left is the **ostium venosum** of the right ventricle

(right atrioventricular orifice) guarded by the tricuspid valve. Above and behind the venous ostium is the auricle, the exterior of which is in contact medially with the root of the aorta. To the right of the superior and inferior caval orifices there is a vertical ridge, the **crista terminalis,** which corresponds to the sulcus terminalis on the exterior (figs. 469, 472).

FIG. 470.—SECTION OF THE VENTRICLES IN SYSTOLE AND DIASTOLE. (After Krehl.)



The portion of the atrium bounded laterally by the crista terminalis and medially by t septum atriorum is smooth, the **sinus venarum;** in the embryo it is separated from the ati cavity proper by the right and left sinus valves. The crista terminalis marks the original l of attachment of the right sinus valve. The valve itself has disappeared, excepting the lo part which persists as the caval and the coronary valves. These valves vary in size considera in different specimens, and are frequently netlike from numerous perforations.

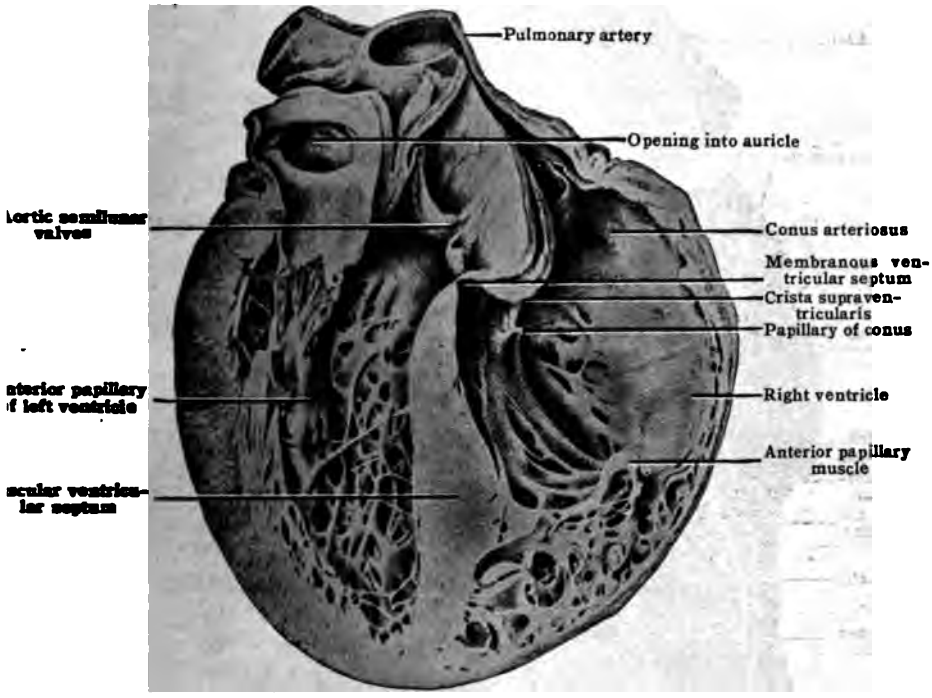
The conversion of a portion of a single valve into two separate parts, which meet at acute angle, is brought about by local blending between the sinus valve and an embryo

ucture called the sinus-septum. This septum is a ridge dividing the right horn of the sinus nosus from the transverse portion of the sinus (the coronary of the adult); it probably tributes somewhat to the formation of both the coronary and caval valves. The left sinus ve usually disappears by blending with the septum atriorum, becoming a part of the limbus ae ovalis; it occasionally remains partially separate in the adult.

The interior of the right auricle and of the portion of the atrium upon the teral side of the crista terminalis is thrown into ridges (**musculi pectinati**) by ominent bands of the atrial myocardium. The musculi pectinati end abruptly joining the crista. The orifice of the superior cava has no valve and is directed ownward and somewhat forward; below it, on the posterior wall of the atrium, ere has been described the **tuberculum intervenosum** (Loweri).

Apart from the posterior circumference of the superior cava itself and the limbus fossæ alis, the human heart appears to contain nothing in this region that could be described as a ercle. With regard to the segregation of the streams entering the fetal right atrium from

FIG. 471.—THE INTERIOR OF THE VENTRICLES, ANTERIOR HALF. (After His.)



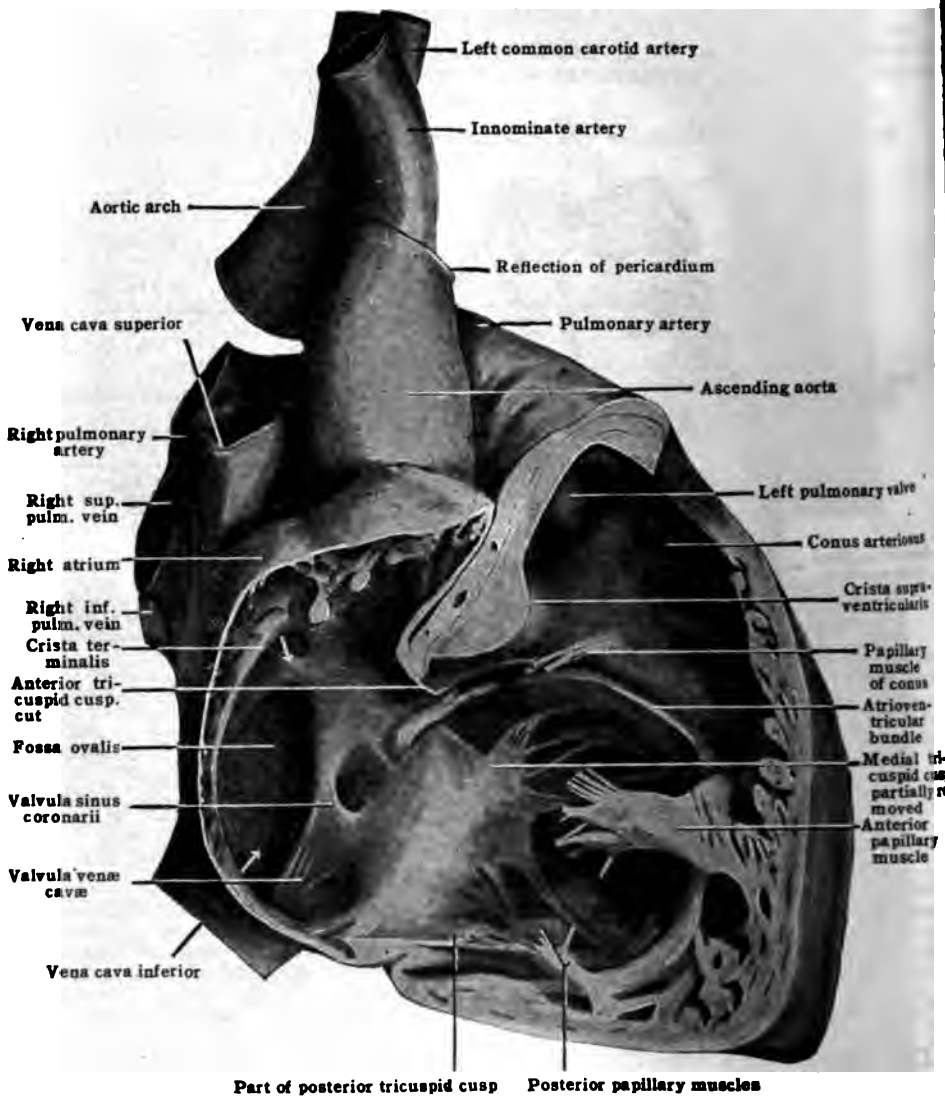
superior and inferior cava, respectively, in which the tubercle of Lower has been supposed articipate, it is to be noted that the fossa ovalis is just above (almost within) the inferior al orifice. In hearts well hardened before removal the inferior caval opening and the fossa lis occupy a diverticulum to the left of the remainder of the atrium. Between this diverdum and the atrium proper, the caval valve and the limbus fossæ ovalis form a prominent ge, better marked in the fetus than the adult. Opening into the right atrium, particularly n the septal and right lateral walls, are numerous *foramina venarum minimarum* (Thebesii).

The left atrium [a. sinistrum] (fig. 469) is situated upon the left side of, and newhat posteriorly to the right. It is behind the root of the aorta, and the t auricle lies to the left of the root of the pulmonary artery. Opening into the t atrium posteriorly, on the right and left sides, respectively, are the right and t upper and lower pulmonary veins. The valvula foraminis ovalis forms a ore or less distinct crescentric ridge on the septal wall (fig. 469). The valvula ay not be attached to the limbus fossæ ovalis, in which case there is a comunication between the two atria. This, however, does not necessarily lead to mixture of arterial and venous blood during life. The **ostium venosum** (atrioatricular orifice) of the left ventricle, guarded by the mitral valve, leads from e anterior part of the atrium forward and slightly downward and to the left. ie interior of the left atrium proper is smooth; in the auricle musculi pectinati well marked.

ATRIOVENTRICULAR VALVES

The **atrioventricular valves** (figs. 471–473, 475) are attached around the venous ostia of the ventricles in such a way as to give freely into the ventricles, but to prevent regurgitation of blood into the atria during ventricular systole. Each valve is continuous along its line of attachment, but its free edge is notched so as to produce an irregular margin; some of the notches are so deep as to partially divide the valve into cusps. The rght atrioventricular valve is commonly

FIG. 472.—INTERIOR OF THE RIGHT ATRIUM AND VENTRICLE.
The atrioventricular bundle is dissected out.

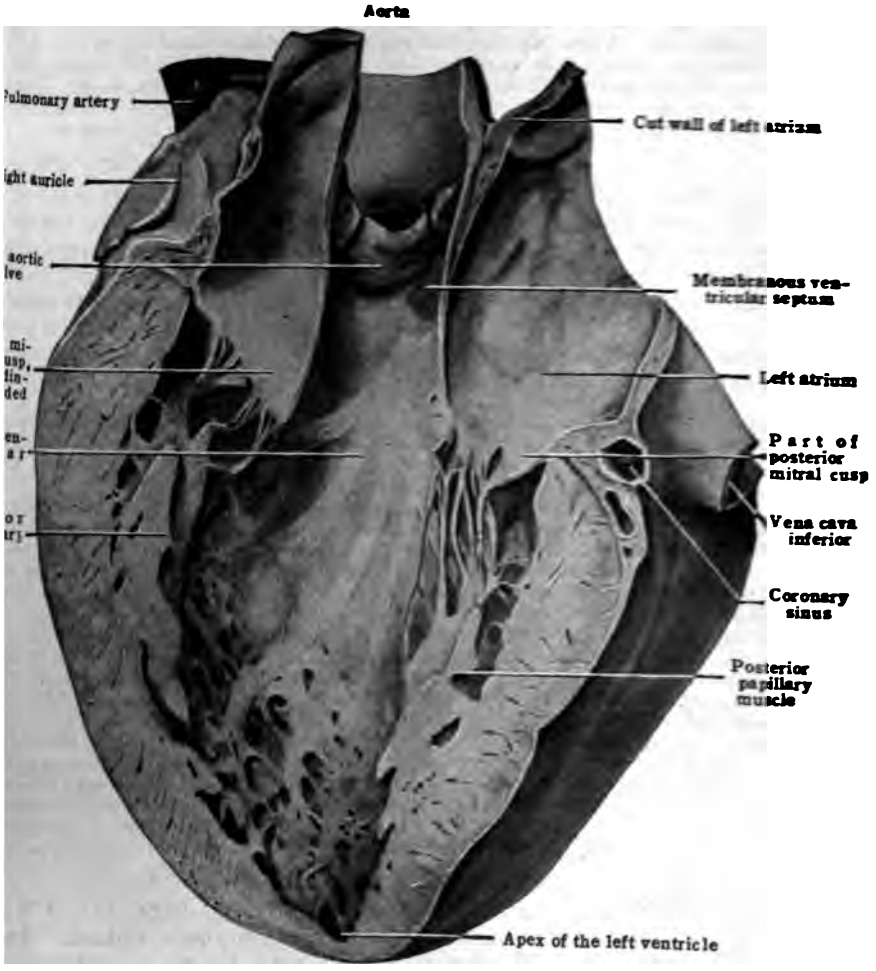


divided by three deep notches into three cusps; this valve is therefore called the **tricuspid** [valvula tricuspidalis]. The left is similarly divided into two cusps and is called the **bicuspid** [v. bicuspidalis] or **mitral.** The depth of the notches, however, is very variable and there may be an increase or (more rarely) a diminution in the number of cusps; the addition of subsidiary cusps is quite common. Each valve cusp is tied down to the **papillary muscles** [mm. papillares] of the ventricle by **chordæ tendineæ.** The latter are fibrous cords, generally branched, of varying thickness. The thinnest cords are attached to the free margin of the cusp; those of intermediate thickness to the ventricular surface a few millimeters from the free margin, and the thickest to the ventricular surface near the

ched margin. The valves are smooth and glistening on the atrial aspect, rough and fasciculated, from the attachment of the chordæ, on the ventricular aspect. The cusps of the *mitral valve* are called *anterior* and *posterior* ns of the *tricuspid, anterior, posterior* and *medial*. Each cusp receives chordæ n more than one papillary muscle and each papillary muscle sends chordæ to e than one cusp. The chordæ tendineæ of the mitral valve are thicker than se of the tricuspid (figs. 472, 473).

FIG. 473.—LEFT VENTRICLE AND PART OF THE ATRIUM.

Aorta is opened through the anterior cusp of the mitral valve. The plainly visible left limb of the atrioventricular bundle has been accentuated.



VENTRICULAR PORTION

ventricles form the greater part of the heart. In the adult the relation ventricles to one another is as follows. The left [ventriculus sinister] form of a narrow cone, the apex of which forms the apex of the heart. ht ventricle [ventriculus dexter] is crescentic in section and appears to be y wrapped around the right or lower wall of the left ventricle which forms tum ventriculorum (fig. 470). The **left ventricle** forms the margo ob- the heart, about half the diaphragmatic surface, and a small part of the ostal surface. The **right ventricle** forms about half the diaphragmatic and the major part of the sternocostal surface; it takes no share in the on of the apex of the heart.

interventricular septum [septum ventriculorum] is thick and muscular or a small area near the root of the aorta which is membranous [septum naceum *ventriculorum*]. *The latter* can be seen from the left ventricle

in the angle between the attached edges of the right and posterior aortic valves (fig. 473). The membranous septum is partly concealed on the right side by the medial cusp of the tricuspid valve which is attached to it near its upper end. The portion of the membranous septum above the attachment of the medial tricuspid cusp is therefore atrioventricular, since it intervenes between the right atrium and the left ventricle.

The membranous septum is the extreme lower part of the independent septum (s. orticum) which divides the aortic root from the pulmonary artery and conus arteriosus. The aortic septum partially subdivides, also, the right ventricle by separating the conus arteriosus from the remaining part of the interior. The relation borne by the part of the aortic septum which intervenes between the conus arteriosus and aortic root to the septum ventriculorum is well shown by His, in fig. 471.

The greater part of the interior of both ventricles is thrown into ridges by myocardial bundles of large size. These fasciculi [**trabeculæ cordis**] either stand out in relief only, or, by being undermined, form bands enveloped by endothelium. A careful examination of the endocardium of fresh hearts will reveal a plexiform network of **Purkinje fibers.** These fibers, belonging to the atrioventricular conducting system, become visible to the naked eye when the endocardium has been exposed to the air long enough to become partially dry.

The wall of the **right ventricle** [ventriculus dexter] (figs. 471, 472) is much thicker than that of the atria, but not so thick as that of the left ventricle. The upper and anterior part of the right ventricle lies in front of the root of the aorta. This portion of the ventricle is called the **conus arteriosus** and is separated from the remainder of the right ventricle by a muscular spur which extends from the back of the conus to the right venous ostium. The spur is the **crista supraventricularis;** its relation to the partition between the conus and aorta, and to the septum membranaceum, shows that it forms part of the embryonic aortic septum (see morphogenesis of the heart).

Two papillary muscles in the right ventricle are constant in position, the large **anterior papillary muscle,** and the small **papillary muscle of the conus** (Luschka). The anterior papillary is situated on the sternocostal wall, near the junction of this with the septal wall. The papillary of the conus is placed just below the septal end of the crista supraventricularis. The **posterior papillary muscles** form an irregular group springing from the diaphragmatic wall of the ventricle. Some of the chordæ tendineæ stretch directly from the septal wall (with or without small muscular elevations at their bases) to the medial cusp of the tricuspid valve. The chordæ tendineæ from the anterior papillary go to the anterior and posterior cusps; those from the conus papillary to the medial and anterior, and those from the posterior papillary muscles to the medial and posterior cusps of the tricuspid valve, respectively.

A band of myocardium is often found to extend from the septal wall of the right ventricle to the anterior papillary muscle; this is the **moderator band,** which contains a part of the right limb of the atrioventricular bundle. If the moderator band joins the anterior papillary near its base, as it frequently does, it is difficult to distinguish it from the trabeculæ cordis which ordinarily occupy this situation.

The term moderator band was originally applied to this bridge or band of muscle under the impression that it prevented overdistention of the ventricle. Since the discovery of the conducting system of the heart it has been known that there is always a band which conducts the right limb of the atrioventricular bundle from the septum to the anterior papillary muscle. Whether the band is isolated from the other trabeculæ, and therefore readily recognizable, appears to depend somewhat upon the relation of the base of the papillary muscle to the septum ventriculorum.

The wall of the **left ventricle** [ventriculus sinister] (figs. 471, 473) is very thick except at the extreme apex, and at the membranous septum. In the left ventricle are two large papillary muscles, generally known as **anterior and posterior;** both send chordæ tendineæ to each cusp of the mitral valve. On the septal wall of the ventricle the left limb of the atrioventricular bundle can usually be seen as a broad, flattened band beneath the endocardium. The band appears just below the septum membranaceum and divides into strands which go to the two papillarly muscles. The strands in many places bridge across part of the ventricle to reach the papillary muscles, covered only by tubes of endocardium.

These bridging strands connecting the papillary muscles with the septum ventriculorum, which were formerly called 'false chordæ tendineæ,' are exactly comparable to the moderator band of the right ventricle which occasionally consists of atrioventricular bundle and endocardium only.

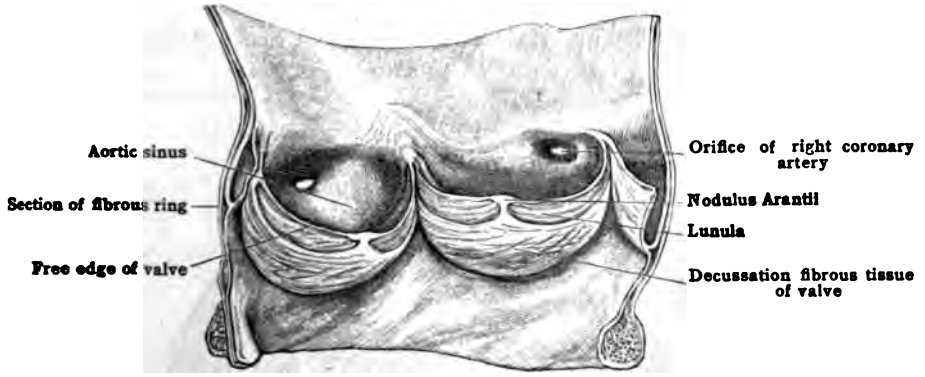
SEMILUNAR VALVES

The **semilunar valves** [valvulæ semilunares] guard the arterial ostia of the ventricles. The aortic ostium is directed upward and slightly forward and to the

ght; the pulmonary backward and slightly upward and to the left. Each valve, of which there are three to each ostium, is a pocket-like fold of endocardium strengthened by fibrous tissue (fig. 474). The free edge of each valve is directed away from the ventricle, so that excess of pressure within the great vessels brings the three valves of either ostium into mutual apposition. In the middle of the free edge of each valve there is a small fibrocartilaginous **nodule**; radiating from this toward the entire fundus, and along the extreme free edge of the valve, are fibrous thickenings. On either side of the nodule, between the thicker margin and fundus, the valve is thin over a crescentic area called the **lunula**.

The aortic valves are called the right, left, and posterior; the pulmonary valves, the right, left, and anterior.* The aortic semilunar valves are stronger than the pulmonary; opposite them there are three dilations in the aortic wall, the aortic sinuses [**sinus aortæ**] or sinuses of Valsalva. From the right and left sinuses the right and left coronary arteries, respectively, arise.

FIG. 474.—INTERIOR VIEW OF THE AORTIC SEMILUNAR VALVES.



After ventricular systole the increased pressure in the great vessels distends the valves with blood. The noduli meet in the center and the lunulæ, coming into mutual contact, produce a triradiate line of contact between the valves.

ARCHITECTURE OF THE MYOCARDIUM

In the adult heart the myocardium of the atria is separate from that of the ventricles. There is, between the atria and ventricles, a fibrous partition, the upper and lower surfaces of which give attachment to the muscle fibers of these cavities, respectively.

The fibrous partition (fig. 475) is thickest in the interval between the right and left atrioventricular ostia immediately behind the right end of the posterior circumference of the aorta; this part of it is called the right *trigonum fibrosum*. The *left trigonum fibrosum* is smaller than the right, and occupies the angular interval between the left side of the root of the aorta and the left atrioventricular ostium. Spreading out from the trigona are the *annuli fibrosi* which surround the root of the aorta and the two atrioventricular ostia. A particularly dense and strong portion of the fibrous partition of the heart extends forward from the right trigonum fibrosum; it forms the *septum membranaceum ventriculorum* and blends with the right circumference of the aortic annulus. From the anterior aspect of the aorta it passes forward upon the posterior aspect of the conus arteriosus, where it is known as the *tendon of the conus*, and ends by uniting with the annulus fibrosus of the pulmonary ostium. The tendon of the conus, the septum membranaceum and the greater part of the right trigonum fibrosum are derived from the embryonic aortic septum.

The atrial musculature is attached to the trigona and atrioventricular rings. The superficial fibers are attached to both rings and either encircle both atria in one loop, or enter the septum and form a figure 8. The deeper fibers are attached to one ring and encircle one atrium only; some fibers encircle only the auricle.

The ventricular musculature is very complex and consists of numerous superimposed layers distinguished from one another by the direction taken by the muscle fibers. In a general way,

*The BNA names of the aortic and pulmonary valves are not based upon their relative positions in the body. From transverse sections through the thorax (see any good atlas) it may be seen that one aortic valve is anterior, one pulmonary valve posterior, and the other aortic and pulmonary valves are right and left. If the removed heart is held so that the ventricles are on the right and left of the septum, respectively, the valves take the positions indicated by the BNA. The names given by the BNA to the valves, although conventional (like many other terms of orientation applied to parts of the heart), are convenient, particularly from a developmental standpoint.

the fibers of the deepest layer have a direction crossing those upon the surface of the same area at a right angle. The intervening layers of fibers pass through all stages of obliquity.

Recent work upon the origin and distribution of the ventricular fibers has resulted in the recognition of a certain uniformity of behavior, thus:—

1. All fibers arise from, and are inserted into, the fibrous partition at the base. The fibers are either attached directly to the trigona or annuli, or indirectly to them by means of the chordæ tendineæ and atrioventricular valves.

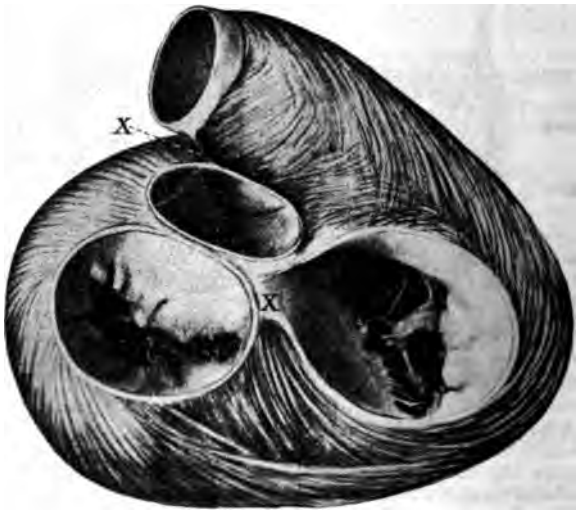
2. The more superficial fibers (fig. 476) tend to encircle the entire heart, passing over the longitudinal sulci. If they enter the septum they do so by passing into the vortex or whirl at the apex of the left ventricle. These fibers have always a definite direction upon the surface, i.e., from right to left upon the sternocostal surface and from left to right on the diaphragmatic (fig. 475).

3. The deeper fibers all enter the septum, and pass across it in a direction oblique or perpendicular to its longitudinal axis. They completely encircle one or both ventricles forming, in the latter case, a double loop (fig. 477).

During systole, as a result of this arrangement:—(1) The papillary muscles and the longitudinal and anteroposterior axes of the ventricles are simultaneously shortened. (2) There is a movement of torsion or 'wringing' which reduces the ventricular cavities to their minimum dimensions.

FIG. 475.—BASE OF A WELL DEVELOPED HEART SHOWING THE COURSE OF THE SUPERFICIAL MUSCLE FIBERS.

From X to X′ around the front of the aorta indicates the course of the aortic septum. (Mall, $\times \frac{3}{4}$.)



Conducting system.—Although the ordinary myocardium of the atria is distinct from that of the ventricles there is, at one place, a connection between them. This connection is effected by means of a small band of muscle which differs histologically from ordinary heart muscle. It is known as the **atrioventricular bundle**, and serves to transmit the atrial rhythm of contraction to the ventricles.

The atrioventricular bundle begins in the septal wall of the atrium a short distance in front of the coronary orifices (fig. 472). It has an expanded free end, the **atrioventricular node**, from which branches pass to be quickly lost in the atrial myocardium. The bundle passes forward covered by endocardium and by one or two millimeters of myocardium, and passes beneath the medial cusp of the tricuspid valve. In passing from the atrium to the ventricle, the bundle skirts the lower margin of the septum membranaceum. Immediately in front of the septum membranaceum it divides into a left and right limb, of which the former pierces the muscular interventricular septum. The right limb now passes beneath the crista supraventricularis and above the papillary muscle of the conus, giving off branches to the latter and to other small papillaries on the septum (fig. 472). Bending somewhat toward the apex, it enters the moderator band which conducts it to the large anterior papillary muscle. From here it passes along one of the trabeculæ connected with the sternocostal wall of the ventricle, or in the wall itself, to reach the posterior papillary muscle or muscles. The right limb is compact and rounded and in the intact heart is usually invisible from the endocardial side except near the root of the moderator band or in the band itself.

The left limb of the bundle appears in the left ventricle a little below the septum membranaceum. It forms a flat, wide band immediately beneath the endocardium, which usually cannot be stripped off without injuring the bundle (fig. 471). It passes along the septal wall toward the apex and divides into two parts, which again subdivide to be distributed to the anterior and the posterior papillary muscles. The branches for the papillary muscles may reach them by traversing the trabeculæ carneæ in the neighborhood, or they may form thin strands

overed by endocardium only, bridge the gap between the septum and the papillary

ddition to the comparatively distinct branches to the papillary muscles of both ven- he bundle gives off finer fibers which form a subendocardial plexus. This plexus, visible aked eye (p. 558) is made up of fibers having a structure similar to those of the ventri- rtion of the bundle. The fibers were described by Purkinje as long ago as 1845 (Arch. ., Physiol. u. wiss. Med.) but it was not until 1906, thirteen years after the discovery of idle by W. His, Jr., that Tawara (Das Reitungssystem des Saügertierherzens, Fischer, ecognised their significance.

re is another node of muscle having characters similar to that of the conducting system, h not connected with it except by myocardium of the ordinary character. This is the ode which is situated at the upper end of the crista terminalis of the right atrium. Una- is still lacking with regard to the physiological significance of this structure.

Vessels and Nerves of the Heart

arteries.—There are two coronary arteries, the right and left; the former takes origin e right sinus of the aorta and the latter from the left.

right coronary artery [a. coronaria dextra] passes forward between the pulmonary and the right atrium, and then follows the right coronary sulcus to the diaphragmatic of the heart (fig. 479), to anastomose with the left coronary artery. The **posterior**

. 476.—Diagram of one Anterior ne Posterior Superficial Bundle rdiac Muscle Fibers seen from). (After MacCallum.)

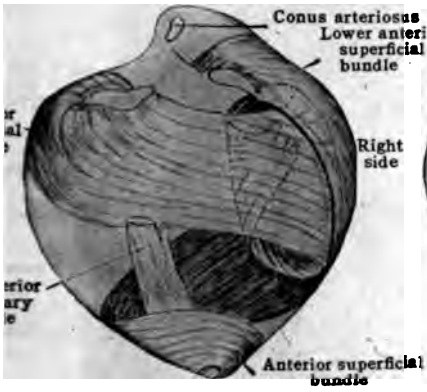


Fig. 477.—Diagram of a Deeper Bundle of Muscle Fibers. (After MacCallum.)

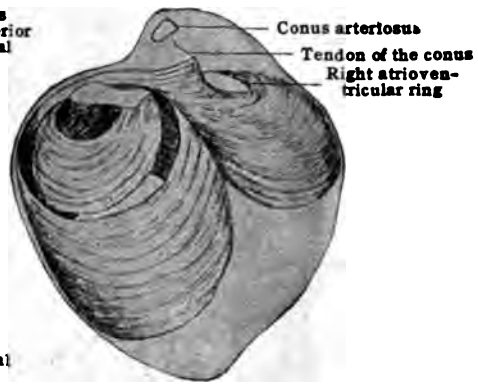


ding branch [ramus descendens posterior] arises at the posterior longitudinal sulcus. It in the furrow between the ventricles toward the apex, near which it anastomoses with es derived from the left coronary artery. The right coronary artery supplies branches right atrium and to the root of the pulmonary artery and aorta; also a branch that ls near the margo acutus (**right marginal**), and a second (**preventricular**) that runs to the r wall of the right ventricle. It supplies both ventricles and the septum.

left coronary artery [a. coronaria sinistra] passes for a short distance forward, between monary artery and the left auricle, and then divides into two principal branches, one of the **anterior descending branch**, runs in the anterior longitudinal sulcus to the apex of the around which it sends branches to anastomose with the right coronary; whilst the other, **:umflex** [ramus circumflexus], winds to the diaphragmatic surface in the coronary groove, stomose with the corresponding twigs of the right artery. In this course it gives off a which follows the margo obtusus (**left marginal**) as well as smaller branches to the left , both ventricles, and the commencement of the aorta and some pulmonary vessels.

cardiac or **coronary veins** accompany the coronary arteries and return the blood from lls of the heart.

great cardiac vein [v. cordis magna], (fig. 478) runs in the anterior longitudinal sulcus, round the left side of the heart in the coronary sulcus to terminate in the commence- f the coronary sinus. Its mouth is usually guarded by two valves. It receives in its the posterior vein of the left ventricle, and other smaller veins from the left atrium and le, all of which are guarded by valves.

middle cardiac vein [v. cordis media], sometimes the larger of the two chief veins, com- ites with the foregoing at its commencement above the heart apex. It ascends in the or longitudinal groove, receiving blood from the ventricular walls, and joins the coronary hrough an orifice guarded by a single valve, close to its termination.

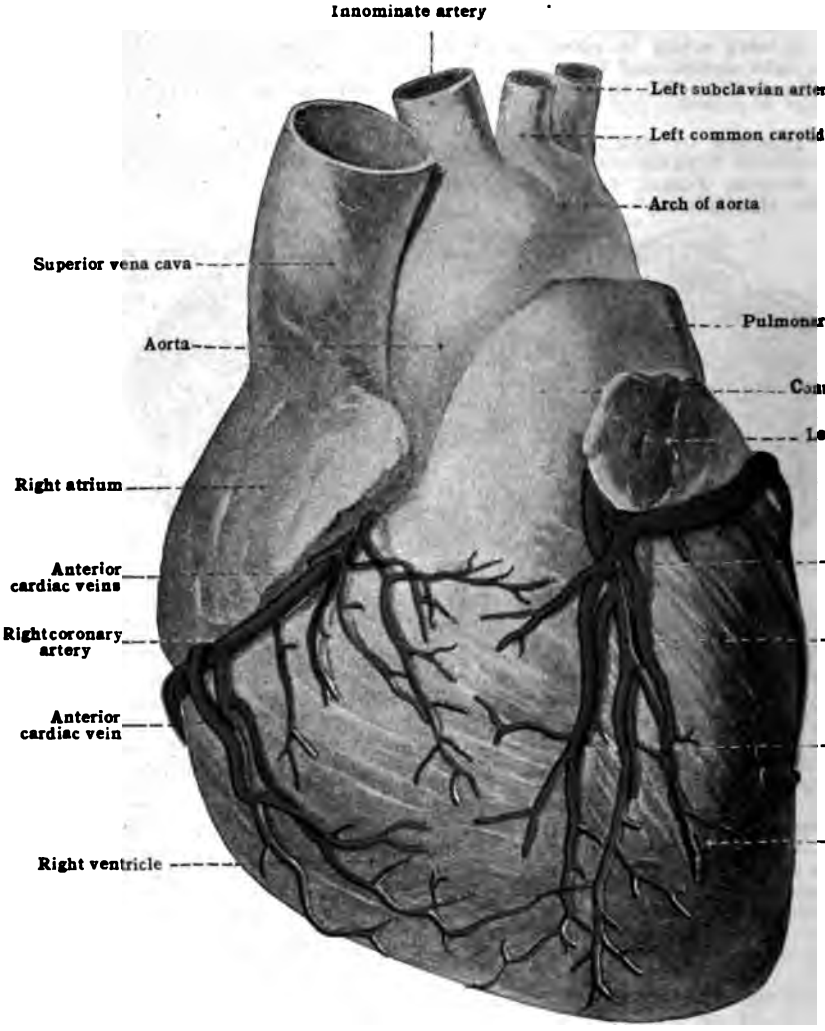
posterior vein of the left ventricle [v. post. ventriculi sinistri], lies upon the posterior of the ventricle and, receiving branches from it, passes upward to terminate directly coronary sinus.

anterior cardiac veins [vv. cordis anteriores] consist of several small branches from the f the right ventricle, which vary in number; they either open separately into the right or join the lesser cardiac vein (fig. 478).

The **small cardiac** vein [v. cordis parva] is a small vessel which receives branches from b the right atrium and ventricle, and winds around the right side of the heart, in the coron sulcus, to terminate in the coronary sinus.

The **coronary sinus** [sinus coronarius] (fig. 479) may be regarded as a much dilated term portion of the great cardiac vein. It is about 2.5 cm. (1 in.) in length, is covered by musc fibers from the atrium, and lies in the coronary sulcus below the base of the heart. Its cardi orifice, with the coronary (Thebesian) valve, has already been described. Besides the tributa veins already named, a small **oblique vein** [v. obliqua atrii sinistri] of the left atrium may some times be traced, upon the back of the left atrium; it passes from the ligament of the left vena cava (Marshall) to the coronary sinus. This little vein, which is not always pervious or easy of demonstration, never possesses a valve at its orifice. Like the coronary sinus it is a remnant of the left superior vena cava of early fetal life.

FIG. 478.—STERNOCOSTAL SURFACE OF THE HEART, SHOWING ITS ARTERIES AND VEINS. (After Spalteholz.)



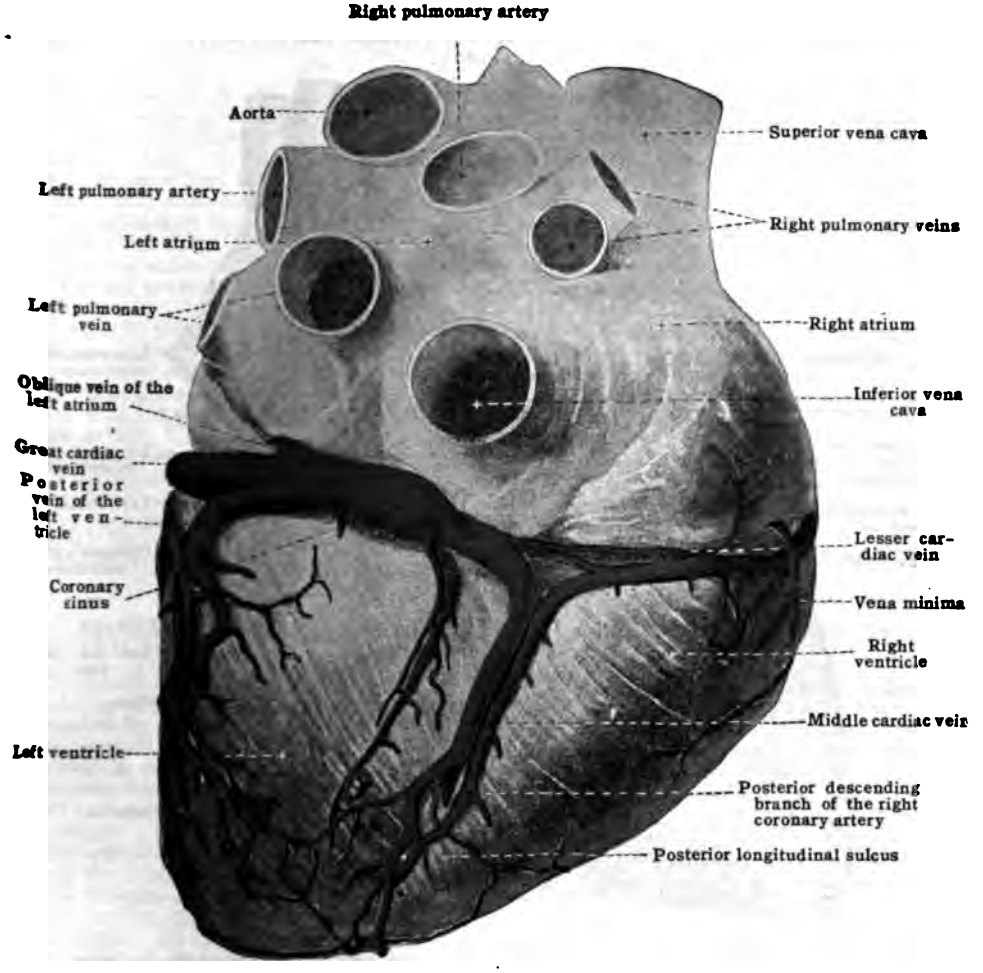
The **smallest cardiac** veins [vv. cordis minimæ] drain blood from the septum and lateral walls of the atria, particularly the right; also from the conus arteriosus. They open directly into the right atrium.

Although *anastomoses* occur between the two coronary arteries, these are by no means extensive, and are not sufficiently free to allow of the establishment of a satisfactory collateral circulation in the case of the blocking of one coronary artery. Interference with the cardiac circulation is apt to produce rapid pathological changes in the heart musculature, provided it is sudden in occurrence. If obliteration of the artery take place gradually, however, some relief may be afforded by the establishment of a collateral circulation through the venæ minimæ, which open out from both the atrial and ventricular cavities and communicate with the finer branches of the cardiac veins, and also with the general capillary network in the cardiac walls.

The lymphatic vessels of the heart pass chiefly through the anterior mediastinal lymph-[illegible] into the bronchomediastinal trunk. (See Section VII.)

The cardiac nerves, derived from the vagus and the cervical sympathetic, descend into the [illegible]erior mediastinum, passing in front of and behind the arch of the aorta; they unite to form superficial and deep cardiac plexuses. The superficial plexus lies above the right pul-[illegible]ary artery as the latter passes beneath the aortic arch. The deep plexus lies between [illegible] trachea and the arch of the aorta, above the bifurcation of the pulmonary trunk. For [illegible] connections of the plexuses see section on NERVOUS SYSTEM.

FIG. 479.—BASE AND DIAPHRAGMATIC SURFACE OF THE HEART, SHOWING ITS ARTERIES AND VEINS. (After Spalteholz.)



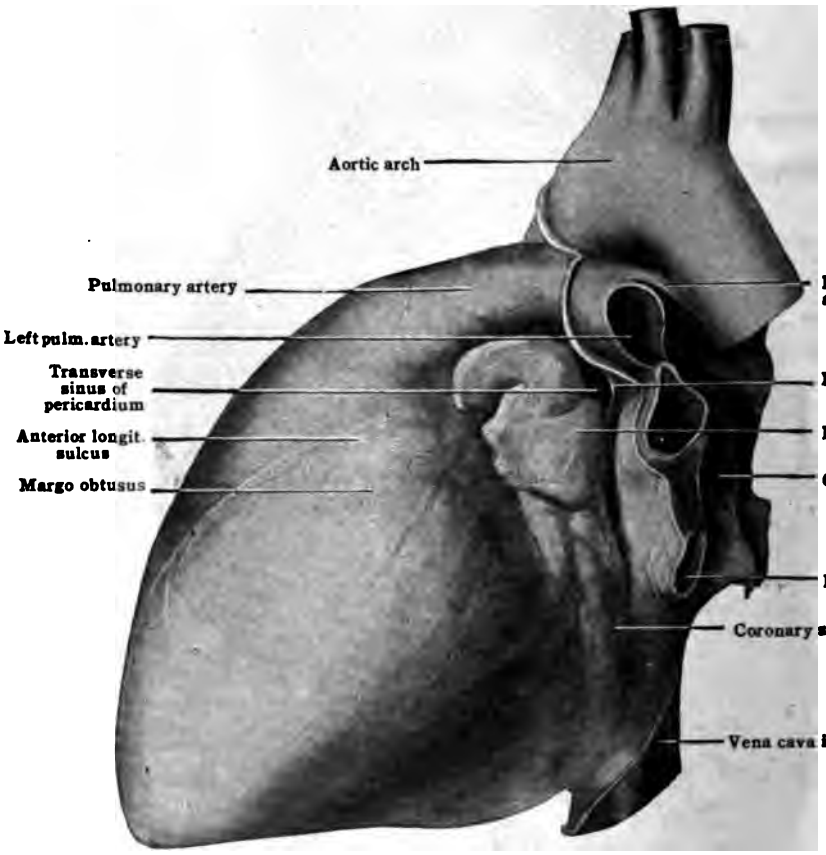
2. THE PERICARDIUM

The **pericardium** is a cone-shaped, fibroserous sac which surrounds the heart and contains a small amount of fluid [liquor pericardii]. Its apex is above at the root of the great vessels, and its base below, adherent to the diaphragm. It consists of an outer *fibrous* layer and an inner *serous* layer. The virtual space between the serous pericardium and the epicardium is commonly called the *pericardial cavity.*

The fibrous layer is strong and inelastic, made of interlacing fibers. Its connection with the central tendon of the diaphragm is intimate, particularly in the region of the caval opening, but elsewhere it is attached loosely by means of areolar tissue. Above, it is lost on the sheaths of the great vessels, all of which receive distinct investments, with the single exception of the vena cava inferior, which pierces it from below. The aorta, vena cava superior, the pulmonary artery, and the four pulmonary veins, are all ensheathed in this manner. The pericardium is connected above with the deep cervical fascia. Two variable bands of fibrous tissue, the **sternopericardial ligaments** connect the front of the pericardium above and below, with the posterior surface of the sternum.

The serous layer is smooth and glistening and consists of connective tissue, rich in elastic fibers, covered by endothelium. It lines the interior of the fibrous layer and is continuous with the epicardium or serous covering of the heart. The reflection of the serous layer from the heart to the fibrous layer of the pericardium occurs both at the arterial and at the venous attachments of the heart. At the arterial attachment a simple tube of epicardium is reflected along the pulmonary artery and aorta. At the venous attachment the serous layer is reflected from the front of the pulmonary veins on the left, and from the front of these and from the roots of the vena cava on the right. This reflection is separated above from that around the aorta and pulmonary artery (figs. 468, 480). Around the lower margin of the left lower pulmonary vein (fig. 480) and the root of the vena cava inferior, this reflection is continuous with an arched reflection from the back of the atria (figs. 468, 480). The latter reflection forms a pocket which extends upward upon the posterior aspect of the atria which is called the *oblique sinus* of the pericardium.

FIG. 480.—LEFT POSTERIOR VIEW OF THE HEART TO SHOW THE REFLECTIONS OF THE PERICARDIUM.



Between the reflections of the epicardium at the arterial and venous attachments of the heart there is a dorsal communication between the right and left sides of the pericardial cavity This is the **transverse sinus** of the pericardium [s. transversus pericardii]; it passes behind the aorta and pulmonary artery and in front of the superior cava and left atrium.

During early embryonic life the sinus transversus is closed by the dorsal mesocardium (see p. 569). The ventral part of the embryonic mesocardium, which divides the right and left sides of the pericardial cavity, is lost even earlier than the dorsal.

The **ligament of the left superior cava** [lig. venæ cavæ sinistræ] (figs. 467, 480) is a doubling of the serous layer which passes between the left pulmonary artery above and the left superior pulmonary vein below. It contains, besides some fatty and areolar tissue, the shrunken remains of the left vena cava superior. It is usually connected above with the left superior intercostal vein by means of a small tributary of the latter. Passing from its lower end to the left end of the coronary sinus is the small **vena obliqua atrii sinistri** (oblique vein of Marshall). The root of the left superior intercostal (and the adjacent part of the left innominate) vein; the vein passing from the superior intercostal to the lig. venæ cavæ sinistræ; the oblique vein of the left atrium, and the coronary sinus all represent parts of the embryonic left vena cava superior.

Relations.—In front of the pericardium are found the thymus gland or its remains, areolar ue, the sternopericardial ligaments, the left transversus thoracis muscle, the internal mam- ry vessels, the anterior margins of the pleural sac and lungs, and the sternum. Later- , it is overlapped by the lungs with their pleural sacs, and it is in contact with the phrenic ves and their accompanying vessels. Posteriorly, it is in relation with the esophagus and us nerves, the descending aorta, the thoracic duct and vena azygos, and the roots of the lungs. ow it is separated by the diaphragm from the stomach and the left lobe of the liver.
Vessels.—The arteries of the pericardium are derived from the pericardiac, esophageal, bronchial branches of the thoracic aorta and from the internal mammary and phrenic ries.

RELATIONS OF THE HEART AND PERICARDIUM TO THE THORACIC WALL

Heart (fig. 481 A and B).—The **base** of the heart is opposite the fifth to the ninth acic vertebra *posteriorly*. *Anteriorly* the **apex** is in the fifth intercostal space, 7.5 to 8 (3 to 3¼ in.) from the median line. The **base** (above) corresponds to a line (A) drawn a point 1 cm. (⅜ in.) below the second left chondrosternal articulation, and 3 cm. (1⅛ in. the median line, to another point (the same distance from the median line) 1 cm. above right third chondrosternal articulation. The **margo acutus**, or lower border corresponds line (B) drawn from the apex through the xiphisternal articulation, to a point on the sixth al cartilage 2 cm. to the right of the median line. The **right border** of the heart may be cated approximately by a line (slightly convex to the right) joining the right ends of A and The **left border** corresponds to a line (slightly convex to the left) joining the left end of the **apex**.
If a line be drawn from the upper margin of the left third chondrosternal articulation to the t edge of the sternum in the fifth intercostal space, its upper end will lie over the center of **pulmonary ostium**, and its lower two-thirds (approximately) will overlie the main axis of he **tricuspid ostium**. The **aortic ostium** is immediately to the left of the line mentioned re, with its center at the left edge of the sternum opposite the third space. The **mitral** um is very largely behind the third left interspace; its upper end is behind the third ilage, its lower behind the left margin of the sternum opposite the fourth cartilage and space. Of the **ostia of the heart**, the pulmonary is nearest the anterior thoracic wall, the aortic is itly in advance of the tricuspid, and the mitral is the deepest of all.
The **pericardium** follows the heart closely. The upper end (apex) in the subject used in aring fig. 481 extended up, behind the sternum, to the lower margin of the first costal lage on the right and the upper margin of the second on the left.

MORPHOGENESIS OF THE HEART AND PERICARDIUM

The heart is formed by the blending in the median line of two longitudinal endothelial s lying upon the ventral aspect of the foregut of the early embryo. Each tube is partially ounded by the splanchnic mesoderm which forms a septum between the right and left sides ie celomic cavity. The blended endothelial tubes form the **endocardium**; the splanchnic derm in relation with them becomes the **myoepicardium**. The double layer of splanchnic derm which unites the myoepicardium with the somatic mesoderm forms the (temporary) al and ventral mesocardia. The somatic mesoderm of the heart region becomes the **ardium**. (See also Section I, fig. 34.)
The originally straight heart-tube grows rapidly and becomes tortuous, since its length soon eds the limit assigned by its fixed arterial and venous ends. Its arterial end is continued the truncus arteriosus, which is later divided into the pulmonary artery and the ascending a. Its venous end receives the right and left ducts of Cuvier, with the vitelline and um- al veins. By the formation of a series of alternate bulgings and constrictions the heart mes differentiated into the sinus venosus, atrium, ventricle and conus arteriosus, counting the venous to the arterial end. These parts by a process of progressive differentiation and ing (fig. 482) soon occupy relative positions somewhat approaching those of the adult.
The sinus venosus lies on the dorsal wall of the atrium, and is composed of right and left s united by a median portion. The sinus is separated from the atrium by a sagitally ted slit-like opening, guarded by right and left lateral valves which project into the atrium. atrium is wide, being prolonged into a ventrally projecting pouch on either side, the future and left auricle. The ventricle is situated caudally and somewhat ventrally to the atrium. right limb of the common ventricle, which leads into the conus arteriosus, is the future ventricle; the left limb, connected with the atrium, is the future left ventricle. The nunication between the atrium and the ventricle, known as the atrial canal (fig. 483), licated on the exterior by a constriction; its interior consists of a transversely placed slit. conus arteriosus is continued from the ventricle without obvious constriction and passes into the truncus arteriosus.
The **sinus venosus** early loses its bilateral symmetry owing to the rapid enlargement of the sinus-horn. This horn soon receives, through the proximal portion of the right vitelline (*vena cava inferior*), all the blood from the left vitelline and both umbilical veins. The common cardinal (duct of Cuvier) eventually gains ascendency over the left and becomes *ena cava superior*. The left horn of the sinus venosus, which now drains the dwindling left non cardinal (duct of Cuvier) (*left superior cava*) and the coronary veins, become the *ary sinus*. The right horn gradually becomes absorbed into the right end of the atrial

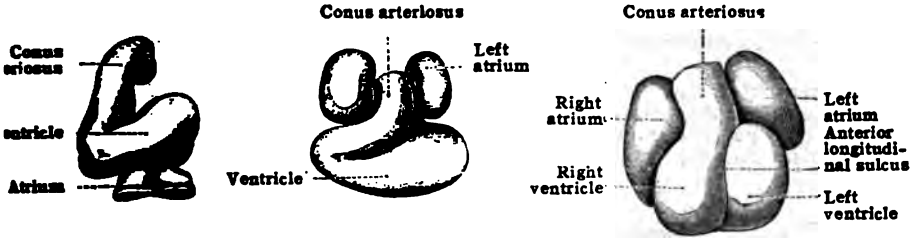
r and the superior and inferior cava and the coronary sinus acquire separate openings in chamber.

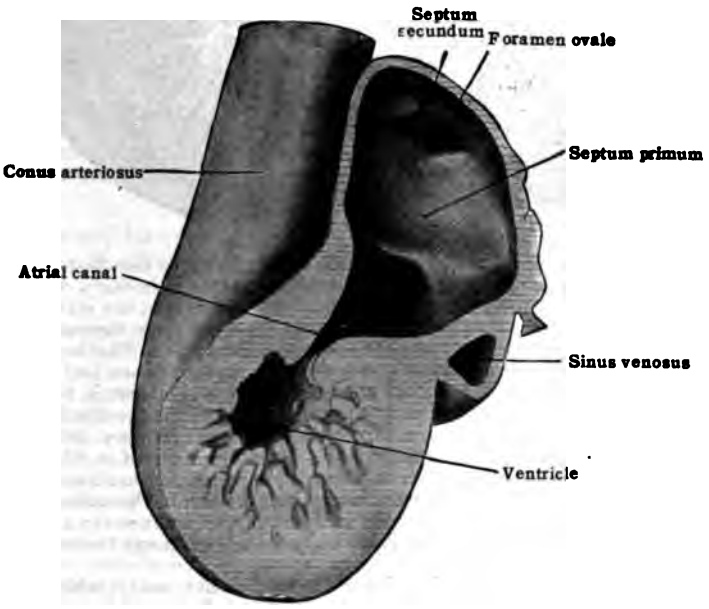
the atrium a septum begins early to grow from the ventrocephalic wall of the atrium, rd the atrial canal. As the interatrial communication (ostium primum) around the edge of rowing septum is becoming narrow a perforation occurs near the attached margin of the im (ostium secundum); the *septum primum* thus remains incomplete (fig. 483). To the of the septum primum another septum (s. secundum) is formed later; this never stretches letely across the atrium and is rather a crescentic ridge than a true septum. Until the edges of the two septa overlap one another there is a direct passage leading from one side

482.—MODELS SHOWING THE DEVELOPMENT OF THE HEART. VENTRAL VIEW. (After His.)



he atrium to the other; when overlapping finally occurs, the interatrial communication amen ovale) becomes oblique but persists until birth. (For fetal relations, see p. 34; for lt, see p. 553.) The cavities resulting from the division of the common atrium are the t *and left atria* of the adult. The foramen ovale is bounded on the right side by the septum undum the free edge of which forms the *limbus fossæ ovalis*. The channel is bounded on the by the septum primum which slants into the left atrium. The free edge of the septum mum becomes the *valvula foraminis ovalis*, while the remainder becomes the membranous ial septum of the adult.

g. 483.—SAGITTAL SECTION THROUGH A RECONSTRUCTION OF THE HEART OF A 9 MM. HUMAN EMBRYO SEEN FROM THE LEFT SIDE. (Tandler, × 75.)



The portion of the dorsal wall of the right atrium immediately adjoining the septa is derived the sinus venosus. This part of the atrium (the *sinus venarum*) receives the venæ cavæ the coronary sinus. The left sinus-valve is attached to both of the embryonic atrial septa assists the septum secundum in the formation of the *limbus foraminis ovalis*. The cephalic of the right sinus-valve disappears along the line of the (adult) *crista terminalis*, which efore forms the right margin of the portion of the right atrium derived from the sinus sus. The caudal part of this valve persists as the *inferior caval and coronary valves*.

The left atrium receives, through the dorsal mesocardium, the originally single pulmonary . This common stem is absorbed into the atrial wall; later, the primitive right and left taries are absorbed in a similar way, leaving the four pulmonary veins of the adult open- separately into the left atrium. The part of the left atrium between the pulmonary veins nerefore, not part of the original atrial wall.

The ventricles are divided by a septum (*s. musculare ventriculorum*) (fig. 484, *SV*) wh grows from the caudal wall of the common ventricular cavity toward the atrial canal. T canal moves to the right, and the dorsal part of the septum blends with its dorsal lip. The ventral edge of the interventricular septum helps to bound the foramen through which bl from the left ventricle must enter the right on its way to the conus arteriosus. The fora persists until its free margin, having been joined by the aortic septum, becomes the circum ence of the *aortic ostium*.

The aortic septum is a composite structure formed partly by a septum growing betwee fourth and sixth pairs of aortic arches, and partly by endocardial swellings which appe the interior of the conus and truncus arteriosus. When fully formed it extends spirally along truncus and conus, and enters the right half of the common ventricular cavity, where it join right side of the free edge of the interventricular septum. The septum is spirally curved in s a way that the blood from the left ventricle passes no longer through the right ventricle

FIG. 484.—RECONSTRUCTION OF THE HEART OF AN 11 MM. HUMAN EMBRYO. CAUDAL VI (Mall, ×50.)

The lower part of the ventricular portion has been cut off. Connective tissue septa colo yellow. *Ao*, aorta; *Ap*, anterior papillary muscle; *La*, left atrium; *Lo*, left venous ostium; large (anterior) papillary muscle of right ventricle; *Mpm*, medial papillary muscle; *PP*, terior papillary muscle; *P*, pulmonary artery; *RA*, right atrium; *SV*, septum ventriculo

traverses a channel (*the aorta*) through the conus and truncus to the first four pairs of a arches. The blood from the right ventricle passes through *the pulmonary* division of the and truncus arteriosus, anteriorly and to the left of the aorta, into the sixth arches. Fu differentiation brings about the external separation of the aorta from the pulmonary arter their common covering of epicardium persists as such in the adult. The lower end of the septum persists in the adult as the *septum membranaceum ventriculorum* and the *crista sup tricularis*, the relations of which to the septum musculare are well shown in fig. 472. Duri formation of the aortic septum four endocardial swellings appear at the distal part of the in of the conus. These are arranged as smaller and larger opposite pairs; the smaller and swellings, therefore, alternating around the lumen. The larger pair of swellings assists (b tial blending) in the formation of the aortic septum. When the septum is complete, half o of the larger swellings is contained in the aorta and half of each in the pulmonary artery. of the smaller swellings remains in the aorta and one in the pulmonary artery, so that are now three swellings in each vessel. Each of these six swellings becomes undermi form a *semilunar valve* of the adult.

The atrioventricular valves.—The interior of the ventricular cavity, which is at first sm becomes undermined in an irregular way, to form a system of myocardial trabeculæ. Th of the transversely directed atrial canal become thickened into prominent anterior and po endocardial cushions; these project into the ventricular cavity and become involved in its cardial trabecular system. The atrial canal, which has now moved to the right, be divided sagittally, into a right and a left *venous ostium venosum*, by the septum primum. interventricular septum joins the ventricular side of the posterior endocardial cushion. anterior and posterior endocardial cushions blend with one another and with the s primum to form an atrioventricular valve-cusp on either side of the interventricular se viz., the anterior cusp of the mitral in the left ostium, and the medial cusp of the tricuspid right. The posterior cusp of the mitral and the anterior and posterior cusps of the tricus formed later, partly from endocardial tubercles developing in either ostium, and partly process of undermining of the ostia from the ventricular side. The atrial musculature e into the atrioventricular valves and remains for a while continuous with the trabecular s

the ventricles. This connection between atrial and ventricular musculature eventually becomes non-muscular. Muscle is found at the basal region of the valve-cusps in the adult, and occasionally persists in the chordæ tendineæ.

The connection between the atrial and ventricular musculature is not confined to that of the valvular and trabecular system. The connection between the atrial and ventricular portions of the myocardium remains complete until the embryo has reached the length of about 4 mm. From that time on the myocardium of the atrioventricular junction begins to be replaced by the developing fibrous annuli of the venous ostia. The original connection between the atrial and ventricular musculature persists at one place only, i. e., the site of the *interventricular bundle*.

The pericardial cavity is the original cephalic end of the intraembryonic celom (see p. 565). The somatic mesoderm of the pericardial region forms the adult *pericardium*. The splanchnic mesoderm persists only in the part which furnishes the *myoepicardium*. The ventral and dorsal mesocardia, both of which are formed by the splanchnic mesoderm, are, in the main, transitory. The early disappearance of the ventral mesocardium unites the right and left sides of the pericardial celom upon the ventral side of the heart. The dorsal mesocardium persists at the arterial and venous ends of the heart only. The loss of the dorsal mesocardium between the latter points gives rise to the *sinus transversus pericardii* of the adult.

During development, the heart and pericardium migrate from a point opposite the cephalic end of the pharynx to the region of the caudal end of the esophagus. This migration is evidenced in the adult by the course of the recurrent and of the cardiac nerves.

B. THE ARTERIES AND VEINS

The **arteries** [arteriæ], proportionately to their size, have much thicker walls than the veins. After death they retain their natural form, but are contracted and usually contain a small amount of pale clot. In a very general way the thickness of wall is proportional to caliber.

The larger arteries usually take a direct course and branch dichotomously. In descriptive anatomy if dichotomous branches are of nearly equal size it is common for each to take another name; if one branch preponderates in size, it usually retains the name of the parent trunk, while the smaller is regarded as a collateral branch [vas collaterale]. There are numerous exceptions to dichotomous branching; branches may run perpendicularly or recurrently to the vessel from which they arise; or several branches may arise simultaneously.

Anastomosis between large or medium sized arteries occurs less frequently than in veins of corresponding magnitude. Anastomoses do occur, however, particularly in the form of arches, such as the palpebral, plantar and volar arches, or the arches between the intestinal arteries. This form of anastomosis is sometimes called inosculation. Between smaller arteries anastomosis is usually free as in the case, for instance, of the articular retia. In some organs anastomosis (excepting capillary) between neighboring arteries can scarcely be said to exist at all; the a. centralis retinæ affords a good example, as do the arteries of the brain, spleen, and kidney; such arteries are called terminal.

The larger arteries are supplied by *vasa vasorum*, frequently arising from their own recurrent branches.

The **veins** [venæ] have thin walls, and after death are either collapsed or filled with clot or discolored serum. They are characterized by the presence of valves.

Frequent anastomoses occur between veins of all sizes; plexuses are of frequent occurrence. *Venæ comitantes* are veins which, usually in pairs, accompany many of the larger arteries; they communicate with one another, around the artery, very freely. Veins do not primitively accompany arteries. In the case of the extremities the primitive veins ramify upon the surface of the limb. The deep veins of the limbs are of later formation and to them the superficial veins subsequently become tributary.

The veins from the stomach, spleen, pancreas and intestine are collected into a large trunk, the **portal vein**. This does not open into the vena cava inferior directly, but breaks up into numerous capillaries (sinusoids) in the liver. From these the blood is returned, through the hepatic veins, to the inferior cava.

Many veins are provided with **valves**, the free borders of which are directed toward the heart. In the small veins the valves are single; in the larger veins they are usually double, rarely treble. Valves are much more numerous in the veins of infants than those of the adult; their number diminishes progressively with advancing age. Valves are most numerous in the superficial veins, and in the deep veins of the extremities; in many veins of the head and neck valves occur only at the point of termination in a larger trunk.

The cranial *venous sinuses* are modified veins, consisting of intima only which lines channels in the fibrous dura mater. The venous spaces in cavernous tissue, such as occurs in the corpora cavernosa, may be looked upon as specially modified veins.

The larger veins, like the arteries, have *vasa vasorum*.

The section dealing with arteries and veins is divided as follows: 1, pulmonary artery and veins; 2, the systemic arteries; and, 3, the systemic veins. At the heads of the second and third divisions are brief accounts of morphogenesis and variations.

1. THE PULMONARY ARTERY AND VEINS

The **pulmonary artery** [a. pulmonalis] (fig. 485) passes from the right ventricle to the lungs. It differs from all other arteries in the body in that it contains venous blood. It arises as a short, thick trunk from the **conus arteriosus** of the right ventricle, and, after a course of about 5 cm. (2 in.) within the pericardium, divides into a right and a left branch. These branches pass to the right and the left lung respectively.

The **trunk of the pulmonary artery** at its origin is somewhat anterior to the ascending aorta, and slightly overlaps that vessel. It passes upward, backward, and to the left, forming a slight curve around the front and left side of the ascending aorta; having reached the concavity of the aortic arch, on a plane posterior to the ascending aorta, it divides into its right and left branches, which diverge from each other at an angle of about 130°. The division of the pulmonary artery occurs immediately to the left of the second left chondrosternal articulation.

In the fetus, the pulmonary artery continues its course upward, backward, and to the left under the name of the **ductus arteriosus (Botal'li)**, and opens into the descending aorta just below the origin of the left subclavian artery. After birth, the lumen of the ductus arteriosus becomes obliterated, and its wall is represented in postnatal life by a fibrous cord, the **ligamentum arteriosum** (fig. 480).

Relations.—In front, the trunk of the pulmonary artery is covered by the remains of the thymus gland, and the pericardium. The artery lies, at its commencement, behind the upper margin of the third left chondrosternal articulation. The right margin of the artery is behind the second piece of sternum but the greater part of the vessel is behind the medial end of the second intercostal space.

Behind, it lies successively upon the ascending aorta and the left atrium.

To the **right** are the ascending aorta, the right atrium, the right coronary artery, and the cardiac nerves.

To the **left** are the pericardium, the left pleura and lung, the left auricle, the left coronary artery, and the cardiac nerves.

The **right pulmonary artery** [ramus dexter] longer than the left, passes almost horizontally under the arch of the aorta to the root of the right lung, where it divides, either directly or indirectly, into three branches, one for each lobe. These branches follow the course of the bronchi, dividing and subdividing for the supply of the lobules of the lung. The terminal branches do not anastomose with each other.

Relations.—In its course to the lung it has **in front** of it the ascending aorta, the superior vena cava, the phrenic nerve, the anterior pulmonary plexus, and the reflection of the pleura. **Behind** are the right bronchus and the termination of the azygos vein. **Above** is the arch of the aorta, and **below** are the left atrium and the upper right pulmonary vein.

At the root of the lung it has the right bronchus **above** and **behind it;** the pulmonary veins **below** and in **front.** Crossing in front of it and the other structures forming the root of the lung are the phrenic nerve and the anterior pulmonary plexus; behind are the azygos vein, the vagus nerve, and the posterior pulmonary plexus.

The **left pulmonary artery** [ramus sinister], shorter and slightly smaller than the right, passes in front of the descending aorta to the root of the left lung, where it divides into two branches for the supply of the upper and lower lobes respectively. These divide and subdivide as on the right side.

Relations.—At the root of the lung it has the left bronchus **behind and also below** it, in consequence of the more vertical direction taken by the left bronchus than by the right. **Below** and **in front** are the pulmonary veins, while passing from the artery and the upper left pulmonary vein is the ligament of the left superior cava. Crossing in front of it and the other structures forming the root of the lung are the phrenic nerve, the anterior pulmonary plexus, and the reflection of the left pleura; crossing behind it are the descending aorta, the left vagus nerve, and the posterior pulmonary plexus.

The **pulmonary veins** [vv. pulmonales] (figs. 468, 485) return the aërated blood from the lungs to the heart. They are usually four in number, superior and inferior, of the right and left sides. Occasionally, however, there are three pulmonary veins on the right side, the result of the vein from the middle lobe of the right lung opening separately into the left atrium instead of joining as usual the upper of the two right pulmonary veins. The relations of the pulmonary veins to the pulmonary arteries and bronchi in the lungs are given with the anatomy of the lungs (Section X).

The pulmonary veins are about 15 mm. in length. In the pericardium the [illegible] pulmonary veins [vv. pulmonales dextræ] both pass behind the superior [illegible] cava. The superior vein receives the vein from the right middle lobe and [illegible] below and in front of the right pulmonary artery.

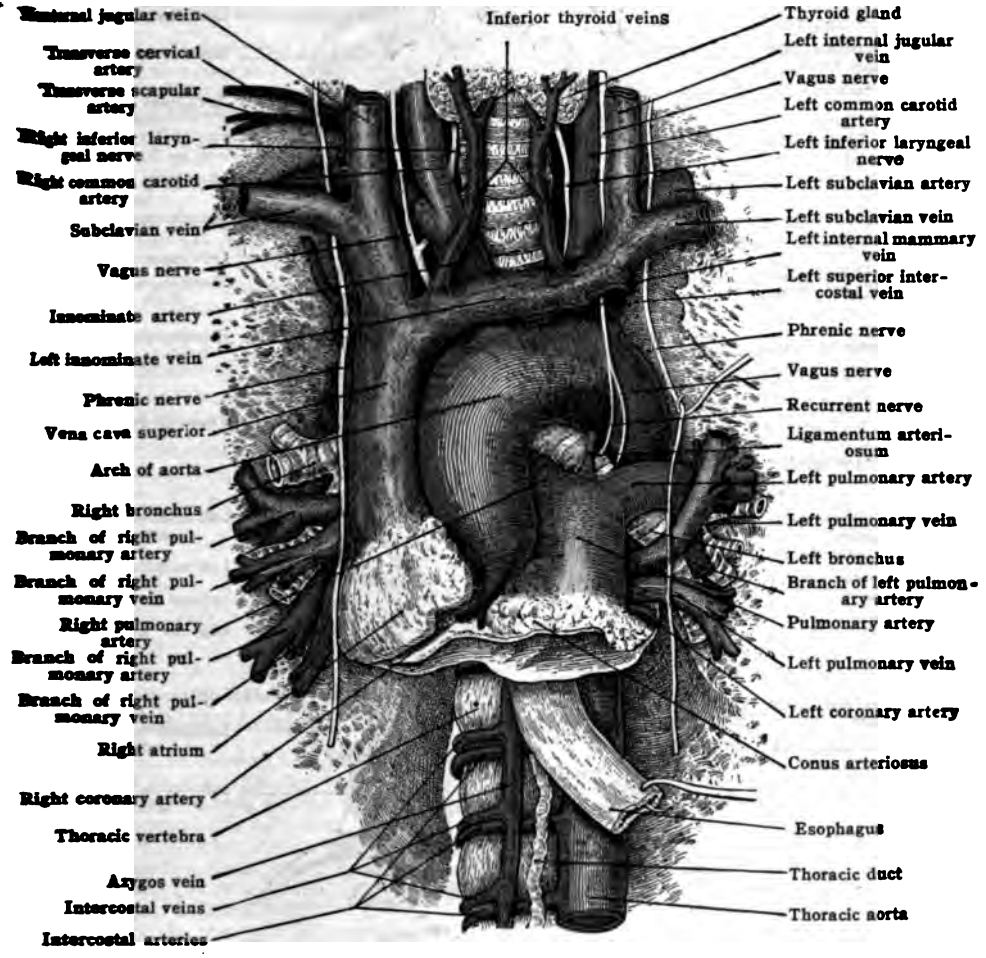
The left pulmonary veins [vv. pulmonales sinistræ] enter the left atrium about [illegible]m. in front of the veins of the right side. The superior vein is below the left [illegible]monary artery.

2. THE SYSTEMIC ARTERIES

THE AORTA

The aorta (fig. 486) is the main systemic arterial trunk, and from it all the [illegible]stemic arteries are derived. It begins at the left ventricle of the heart, and [illegible]cends near the anterior thoracic wall as high as the second right chondrosternal

FIG. 485.—THE GREAT VESSELS OF THE THORAX.
(Modified from a dissection in St. Bartholomew's Hospital Museum.)

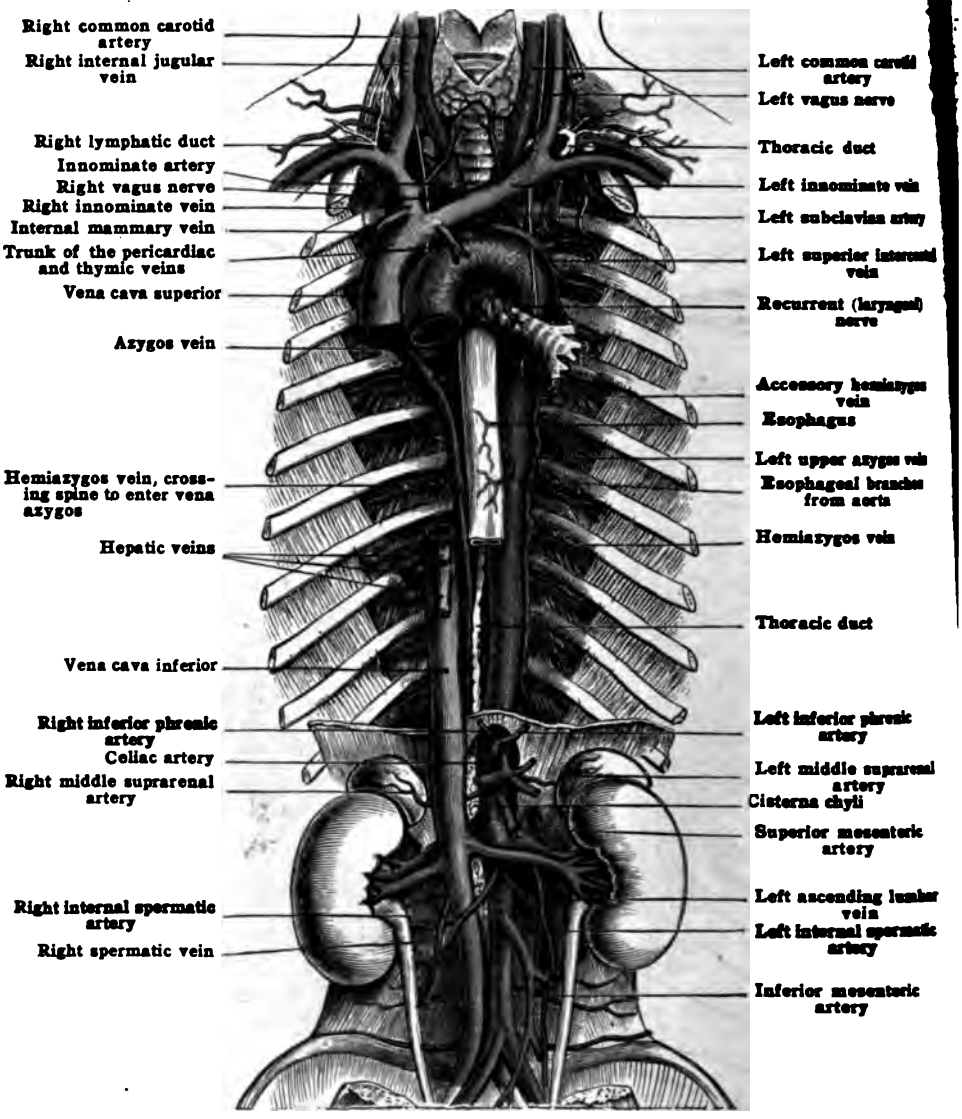


articulation [aorta ascendens]. It then turns backward and to the left forming **an arch [arcus aortæ] which** reaches the posterior thoracic wall at the left side of **the fourth thoracic vertebra.** From here it runs downward along the vertebral **column [aorta descendens] through** the thorax and abdomen and ends by dividing, **opposite the fourth lumbar** vertebra, into the right and left common iliac arteries. **From the point of bifurcation a** small vessel, the middle sacral, is continued down **the middle line in front of the** sacrum and coccyx. The middle sacral represents **the sacrococcygeal aorta.**

The Ascending Aorta

The **ascending aorta** [aorta ascendens] (fig. 486) begins at the upper part of the left ventricle, on a level with the third intercostal space, and ascends behind the sternum to the upper border of the right second chondrosternal articulation. It measures about 5 to 5.5 cm. (2 to 2¼ in.), forming, as it ascends, a gentle curve with its convexity to the right. It is enclosed for the greater part of its length in the pericardium, being invested, together with the pulmonary artery, in a common sheath formed by the serous layer of that membrane. A dilation known

Fig. 846.—The Thoracic and Abdominal Aorta.



as the **bulbus aortæ** occurs immediately above the heart upon which are three localized bulgings, known as the **aortic sinuses** (sinuses Valsalva); they are placed, one to the right, one to the left, and one posteriorly. From the right and left are derived the coronary arties of the heart. (See **Heart.**)

Relations.—In front the ascending aorta is overlapped at its commencement by the right auricle, conus arteriosus and pulmonary artery. Higher up, as the pulmonary artery and auricle diverge, it is separated from the manubrium by the pericardium, the remains of the thymus gland, and by the loose tissue and in the superior mediastium. It is here slightly overlapped also by the right pleura and by the edge of the right lung in full inspiration. The root of the right coronary artery is also in front. Behind are the left atrium of the heart, the right

The pulmonary veins are about 15 mm. in length. In the pericardium the **right pulmonary veins** [vv. pulmonales dextræ] both pass behind the superior **vena cava**. The superior vein receives the vein from the right middle lobe and runs **below** and in front of the right pulmonary artery.

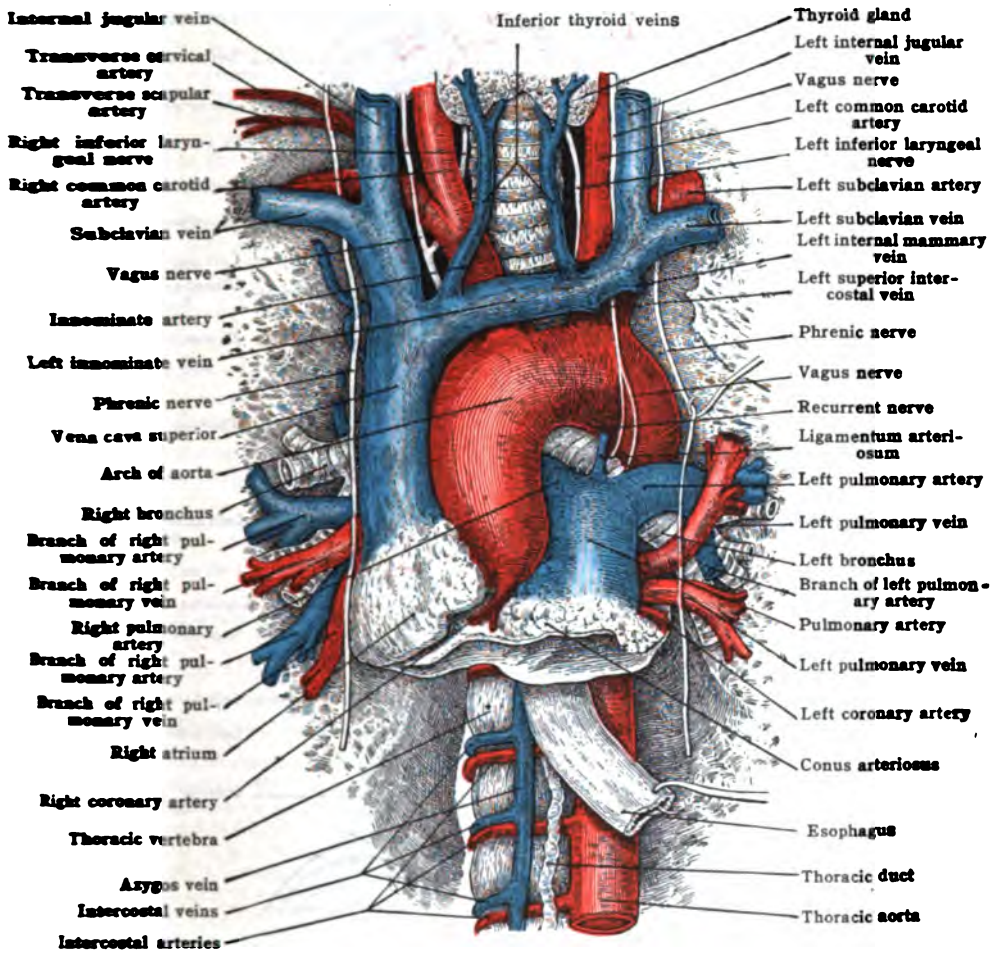
The left pulmonary veins [vv. pulmonales sinistræ] enter the left atrium about 3 cm. **in** front of the veins of the right side. The superior vein is below the left **pulmonary** artery.

2. THE SYSTEMIC ARTERIES

THE AORTA

The aorta (fig. 486) is the main systemic arterial trunk, and from it all the **systemic arteries** are derived. It begins at the left ventricle of the heart, and **ascends** near the anterior thoracic wall as high as the second right chondrosternal

FIG. 485.—THE GREAT VESSELS OF THE THORAX.
(Modified from a dissection in St. Bartholomew's Hospital Museum.)

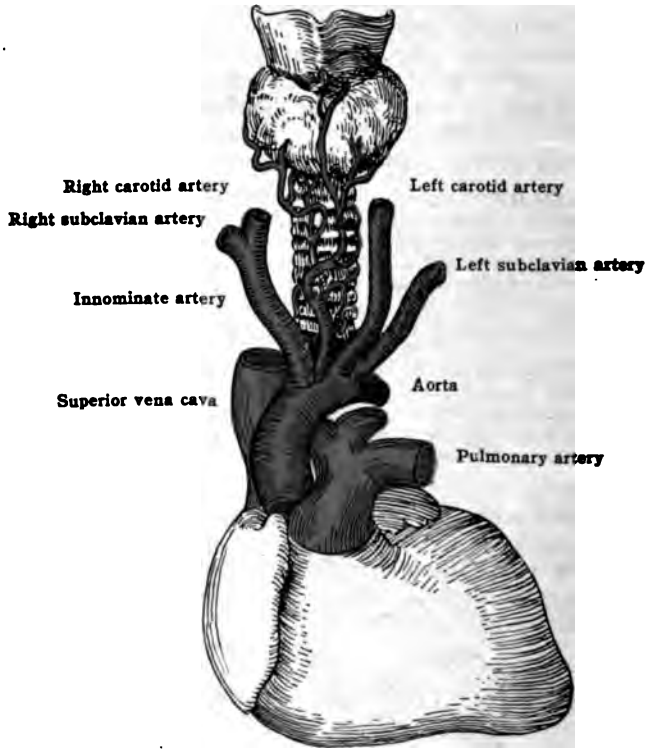


articulation [**aorta ascendens**]. It then turns backward and to the left forming an arch [**arcus aortæ**] which reaches the posterior thoracic wall at the left side of the fourth thoracic vertebra. From here it runs downward along the vertebral column [**aorta descendens**] through the thorax and abdomen and ends by dividing, opposite the fourth lumbar vertebra, into the right and left common iliac arteries. From the point of bifurcation a small vessel, the middle sacral, is continued down the middle line in front of the sacrum and coccyx. The middle sacral represents the sacrococcygeal aorta.

THE COMMON CAROTID ARTERIES

The **common carotid** arteries [aa. carotides communes] pass up deeply the thorax on either side of the neck to about the level of the upper border thyroid cartilage, where they divide into the external and internal ca arteries. The **external carotid** supplies the structures at the upper part c neck, the larynx, pharynx, tongue, face, the structures in the pterygoid re the scalp, and the membranes of the brain. The **internal carotid** gives c branch in the neck, but enters the cranium and supplies the greater part c brain, the structures contained in the orbit, and portions of the membra the brain.

FIG. 487.—THE THYROIDEA IMA. (After Henle.)



The common carotid artery on the right side arises from the bifurcation o innominate at the upper limit of the sternoclavicular joint; on the left side the arch of the aorta a little to the left of the innominate artery, and on a somewhat posterior to that vessel (fig. 485). The portion of the left com carotid artery which extends from the arch of the aorta to the upper limit sternoclavicular articulation lies deeply in the chest, and requires a sep description; but above the level of the sternoclavicular joint the relations right and left carotids are practically the same.

THORACIC PORTION OF THE LEFT COMMON CAROTID ART

Within the thorax the left common carotid is deeply placed behin manubrium of the sternum, and is overlapped by the left lung and pleur arises from the middle of the aortic arch, close to the left side of the innon artery, and a little posterior to the vessel, and ascends obliquely in front trachea to the left sternoclavicular articulation, above which its relatio similar to those of the right common carotid (fig. 486).

Relations.—In front, but at some little distance, are the manubrium and the origins left sternohyoid and sternothyroid muscles, whilst in contact with it are the remains thymus gland, and the loose connective tissue and fat of the superior mediastinum. C

s the left innominate vein. Behind, it lies successively upon the trachea, the left ; (inferior laryngeal) nerve, the esophagus (which here inclines a little to the left) and ıcic duct. To its **right side** is the root of the innominate artery, and higher up are the ınd the inferior thyroid veins. To its **left side,** but on a posterior plane, are the left ın artery and the left vagus nerve; and, slightly overlapping it, the edge of the ra and lung.

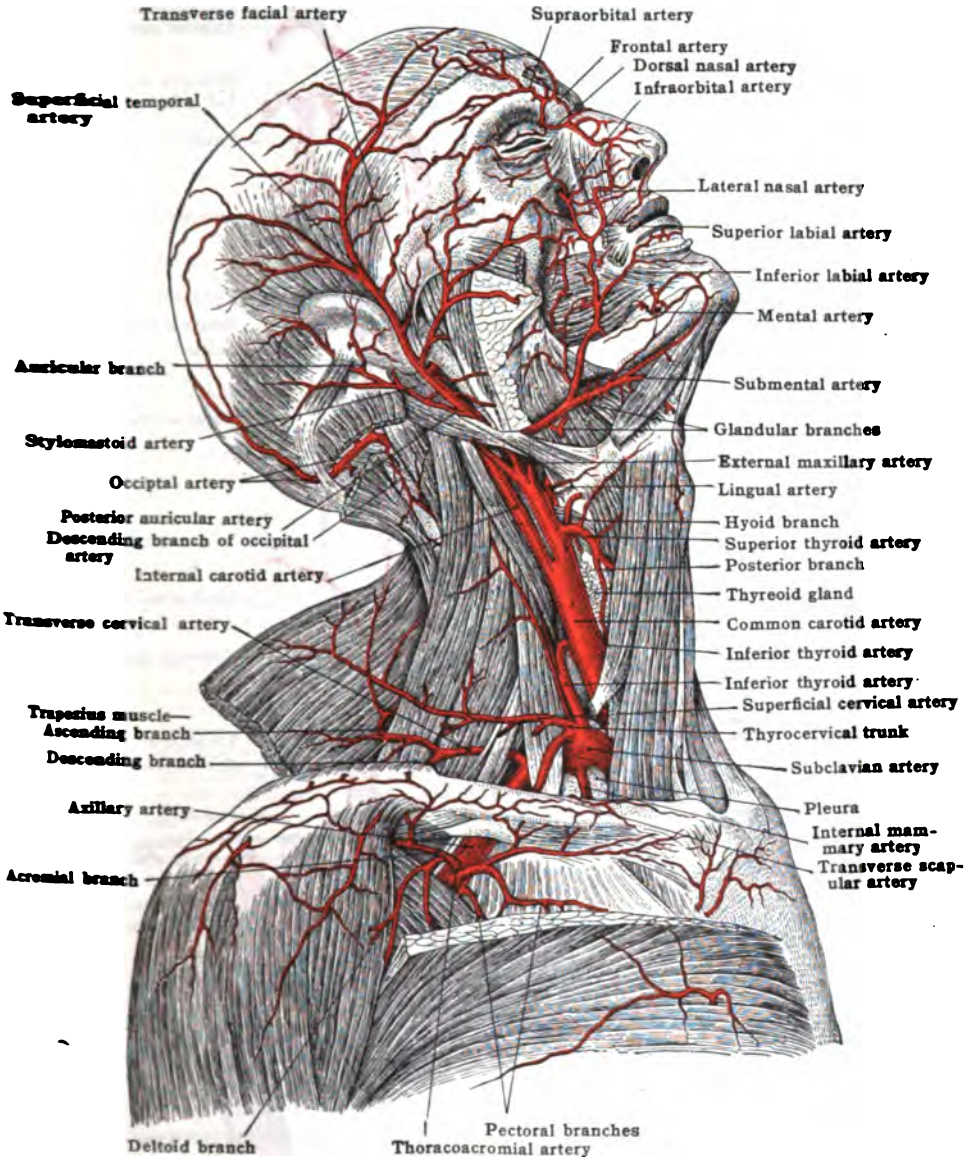
its root is the left innominate vein. **Behind,** it lies successively upon the trachea, the left recurrent (inferior laryngeal) nerve, the esophagus (which here inclines a little to the left) and the thoracic duct. To its **right side** is the root of the innominate artery, and higher up are the trachea and the inferior thyroid veins. To its **left side,** but on a posterior plane, are the left subclavian artery and the left vagus nerve; and, slightly overlapping it, the edge of the left pleura and lung.

FIG. 488.—ARTERIES OF THE HEAD AND NECK. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)

In this case the external maxillary artery ends by inosculating with the infraorbital. The dorsal nasal branch of the ophthalmic is larger than usual (Cf. fig. 493.)



THE COMMON CAROTID ARTERY IN THE NECK

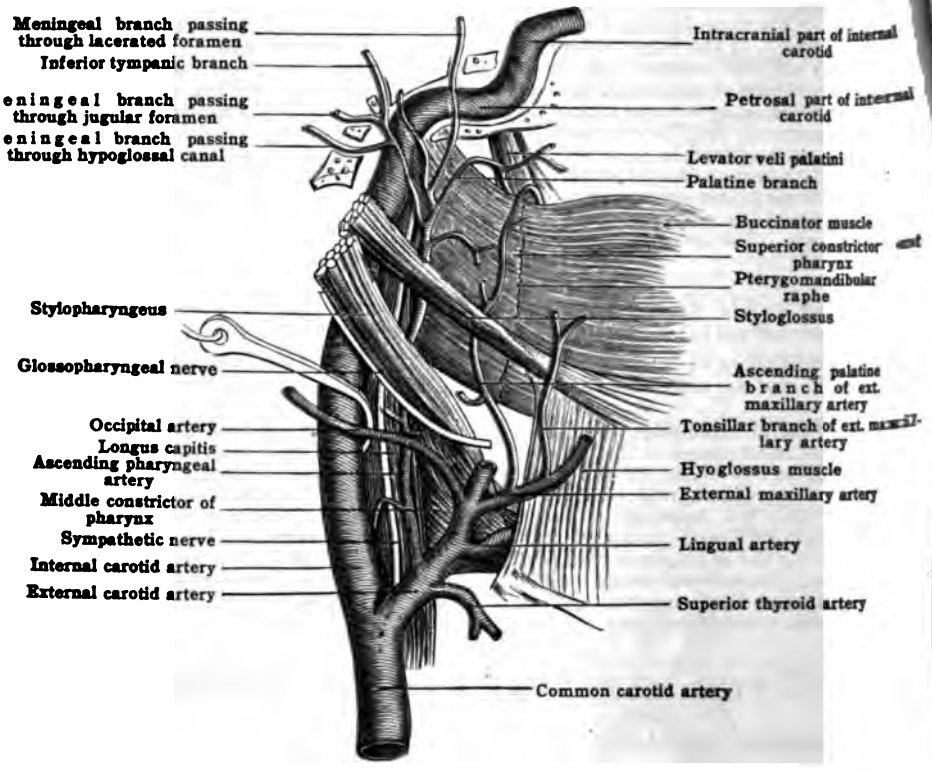
The **common carotid artery in the neck** extends from the sternoclavicular articulation to the upper border of the thyroid cartilage on a level with the fourth cervical vertebra, where it divides into the external and internal carotid arteries. A line drawn from the sternoclavicular joint to a point just behind the neck of the mandible would indicate its course. The artery is at first deeply placed beneath the sternomastoid, sternohyoid, and sternothyroid muscles, and at the level of the top of the sternum is only 2 cm. (¾ in.) distant from its fellow

yngeal branch of the vagus nerve, a portion of the parotid gland, and the stylohyoid ligament. It measures about 6.5 cm. (2⅗ in.) in length.

Relations.—**In front,** in addition to the skin, superficial fascia, platysma, and deep fascia, it has the hypoglossal nerve, the lingual, common facial and posterior facial veins, the posterior belly of the digastric and stylohyoid muscles, the superior cervical lymphatic glands, branches of the facial nerve, and the parotid gland. The sternomastoid also overlaps it in the natural state of the parts. **Behind,** it is in relation with the internal carotid, from which it is separated by the styloglossus and stylopharyngeus muscles, the glossopharyngeal nerve, the pharyngeal branch of the vagus nerve, the stylohyoid ligament, and the parotid gland. The superior laryngeal nerve crosses behind both the external and internal carotid arteries. **Medially,** it is in relation with the hyoid bone, the pharyngeal wall, the ramus of the mandible, the stylomandibular ligament which separates it from the submaxillary gland, and the parotid gland. **Laterally,** in the first part of its course, it is in contact with the internal carotid artery.

The **branches of the external carotid** are usually given off in the following order, from below upward:—(1) Ascending pharyngeal; (2) superior thyroid; (3) lingual; (4) external maxillary (facial); (5) sternocleidomastoid; (6) occipital; (7) posterior auricular; (8) superficial temporal; (9) internal maxillary.

FIG. 490.—RIGHT ASCENDING PHARYNGEAL ARTERY. (Walsham.)
The internal carotid artery is hooked aside.



1. THE ASCENDING PHARYNGEAL ARTERY

The **ascending pharyngeal** artery [a. pharyngea **ascendens**] (**fig. 490**) is usually the first or second branch of the external carotid. **Occasionally it** comes off at the bifurcation of the common carotid from the **common carotid itself.** It is a long slender vessel which runs deeply seated up the neck **to the base** of the skull, having the walls of the pharynx and the tonsil **medially, the internal** carotid artery **laterally,** and the vertebral column, the **longus capitis** (**rectus** capitis anterior major), and the sympathetic nerve **posteriorly. In front it is** crossed by the styloglossus (fig. 490) and the stylopharyngeus **muscles and** the glossopharyngeal nerve.

BRANCHES OF THE ASCENDING PHARYNGEAL ARTERY

The branches of the ascending pharyngeal **artery are small** and variable. They supply the longus and rectus capitis muscles, the **upper cervical** sympathetic

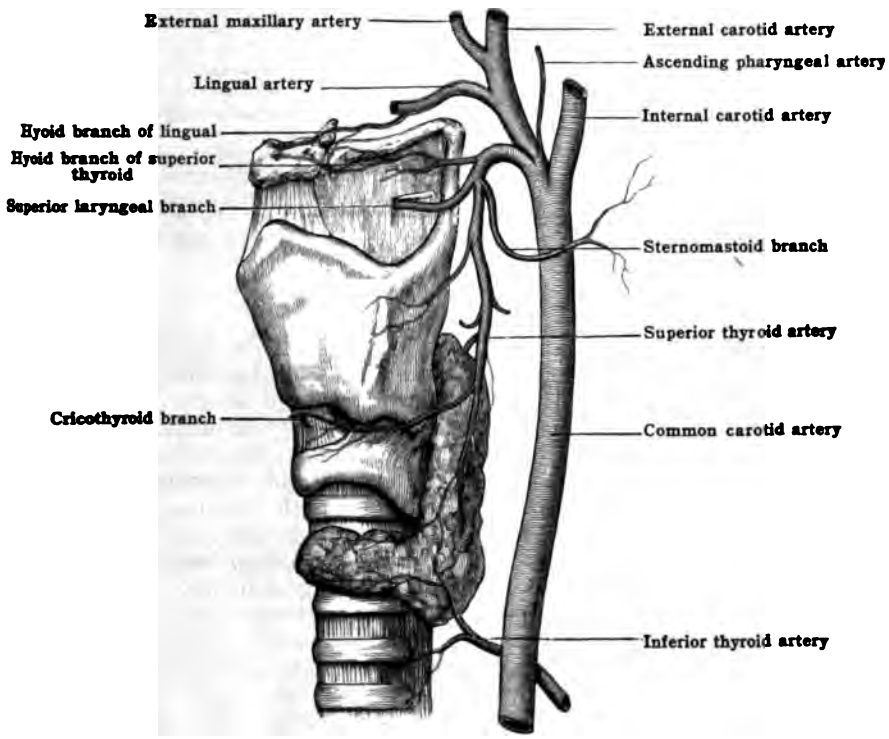
ganglion and adjacent lymph-nodes, as well as the pharynx, soft palate, ear, cranial nerves, and meninges.

The **pharyngeal** branches [rami pharyngei] supply the superior and middle constrictor muscles and the mucous membrane lining them. These vessels anastomose with branches of the superior thyroid. One branch (the **palatine**) passes over the upper edge of the superior constrictor to the soft palate and its muscles. This branch follows a course similar to that taken by the ascending palatine artery, and when the latter is small may take its place. It generally gives off small twigs to the auditory (Eustachian) tube and tonsil. The **inferior tympanic** artery [a. tympanica inferior] accompanies the tympanic branch of the glossopharyngeal nerve through the tympanic canaliculus into the tympanum, and anastomoses with the other tympanic arteries. The **posterior meningeal** artery [a. meningea posterior] is distributed to the membranes of the brain. Some twigs pass with the jugular vein through the jugular foramen into the cranium, and supply the dura mater in the posterior fossa of the skull. Others occasionally reach the same fossa through the hypoglossal (anterior condyloid) canal in company with the hypoglossal nerve; while others pass through the cartilage of the lacerated foramen and supply the middle fossa of the skull.

2. THE SUPERIOR THYROID ARTERY

The **superior thyroid** artery [a. thyreoidea superior] (figs. 488, 491) arises from the front of the external carotid a little above the origin of that vessel, and, coursing forward, medially, and then downward, in a tortuous manner, supplies

FIG. 491.—SCHEME OF LEFT SUPERIOR THYROID ARTERY. (Walsham.)



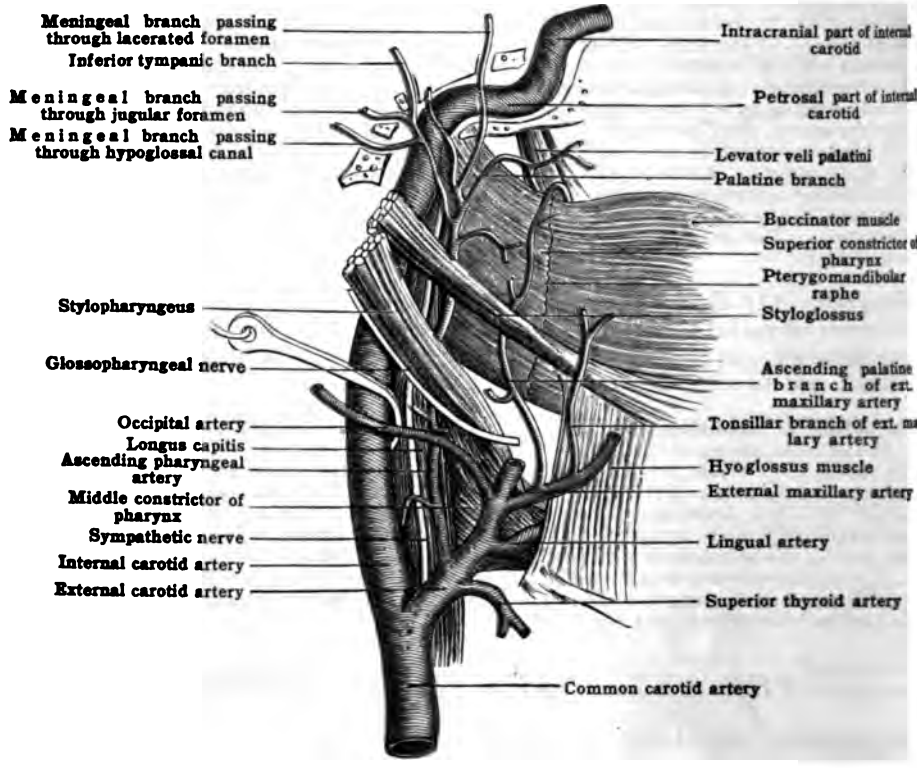
the depressor muscles of the hyoid bone, the larynx, the thyroid gland, and the lower part of the pharynx. The artery at first runs forward and a little upward, just beneath the greater cornu of the hyoid bone. In this part of its course it lies in the superior carotid triangle, and is quite superficial, being covered only with the integument, fascia, and platysma. It next turns downward, and passes beneath the omohyoid, sternohyoid, and sternothyroid muscles, and ends at the upper part of the thyroid gland in the terminal glandular branches. The superior thyroid vein passes beneath the artery on its way to the internal jugular vein. The superior thyroid is the artery most commonly divided in cases of suicidal wounds of the throat.

yngeal branch of the vagus nerve, a portion of the parotid gland, and the stylohyoid ligament. It measures about 6.5 cm. ($2\frac{3}{5}$ in.) in length.

Relations.—**In front,** in addition to the skin, superficial fascia, platysma, and deep fascia, it has the hypoglossal nerve, the lingual, common facial and posterior facial veins, the posterior belly of the digastric and stylohyoid muscles, the superior cervical lymphatic glands, branches of the facial nerve, and the parotid gland. The sternomastoid also overlaps it in the natural state of the parts. **Behind,** it is in relation with the internal carotid, from which it is separated by the styloglossus and stylopharyngeus muscles, the glossopharyngeal nerve, the pharyngeal branch of the vagus nerve, the stylohyoid ligament, and the parotid gland. The superior laryngeal nerve crosses behind both the external and internal carotid arteries. **Medially,** it is in relation with the hyoid bone, the pharyngeal wall, the ramus of the mandible, the stylomandibular ligament which separates it from the submaxillary gland, and the parotid gland. **Laterally,** in the first part of its course, it is in contact with the internal carotid artery.

The branches of the external carotid are usually given off in the following order, from below upward:—(1) Ascending pharyngeal; (2) superior thyroid; (3) lingual; (4) external maxillary (facial); (5) sternocleidomastoid; (6) occipital; (7) posterior auricular; (8) superficial temporal; (9) internal maxillary.

FIG. 490.—RIGHT ASCENDING PHARYNGEAL ARTERY. (Walsham.)
The internal carotid artery is hooked aside.



1. THE ASCENDING PHARYNGEAL ARTERY

The **ascending pharyngeal** artery [a. pharyngea ascendens] (**fig.** 490) is usually the first or second branch of the external carotid. **Occasionally** it comes off at the bifurcation of the common carotid from the **common carotid** itself. It is a long slender vessel which runs deeply seated up the neck **to the base** of the skull, having the walls of the pharynx and the tonsil **medially, the** internal carotid artery **laterally,** and the vertebral column, the **longus capitis** (rectus capitis anterior major), and the sympathetic nerve **posteriorly. In front** it is crossed by the styloglossus (fig. 490) and the stylopharyngeus **muscles and** the glossopharyngeal nerve.

BRANCHES OF THE ASCENDING PHARYNGEAL ARTERY

The branches of the ascending pharyngeal **artery are small** and variable. They supply the longus and rectus capitis muscles, the **upper cervical** sympathetic

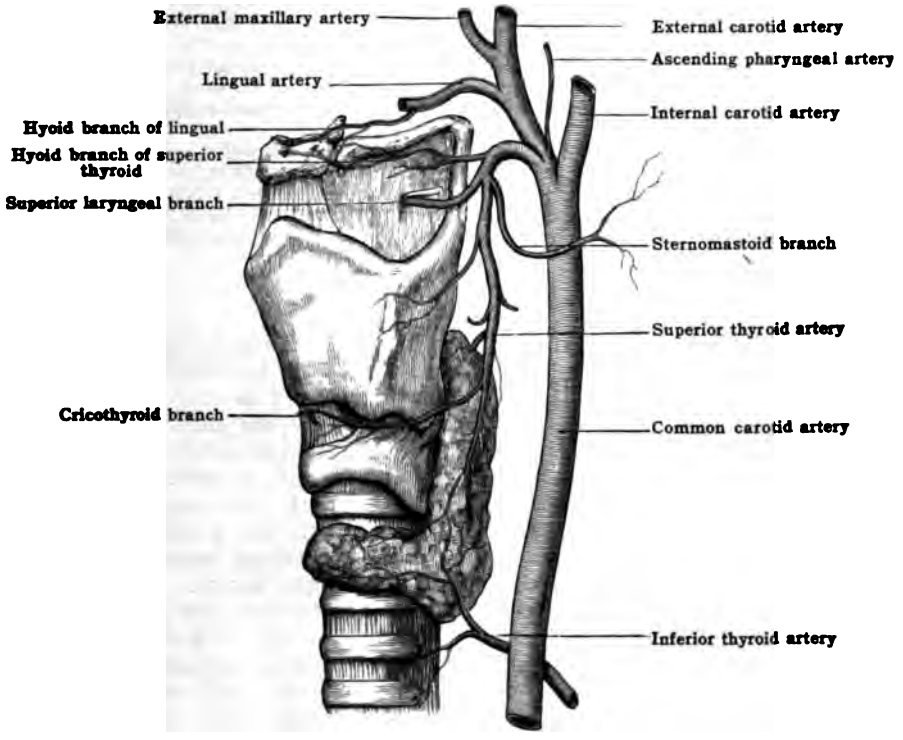
nglion and adjacent lymph-nodes, as well as the pharynx, soft palate, ear, ranial nerves, and meninges.

The **pharyngeal** branches [rami pharyngei] supply the superior and middle constrictor uscles and the mucous membrane lining them. These vessels anastomose with branches f the superior thyroid. One branch (the **palatine**) passes over the upper edge of the superior nstrictor to the soft palate and its muscles. This branch follows a course similar to that taken y the ascending palatine artery, and when the latter is small may take its place. It generally ves off small twigs to the auditory (Eustachian) tube and tonsil. The **inferior tympanic** tery [a. tympanica inferior] accompanies the tympanic branch of the glossopharyngeal nerve hrough the tympanic canaliculus into the tympanum, and anastomoses with the other tympanic arteries. The **posterior meningeal** artery [a. meningea posterior] is distributed to the membranes of the brain. Some twigs pass with the jugular vein through the jugular foramen into the cranium, and supply the dura mater in the posterior fossa of the skull. Others occasionally reach the same fossa through the hypoglossal (anterior condyloid) canal in company with the hypoglossal nerve; while others pass through the cartilage of the lacerated foramen and supply the middle fossa of the skull.

2. THE SUPERIOR THYROID ARTERY

The **superior thyroid** artery [a. thyreoidea superior] (figs. 488, 491) arises from the front of the external carotid a little above the origin of that vessel, and, coursing forward, medially, and then downward, in a tortuous manner, supplies

FIG. 491.—SCHEME OF LEFT SUPERIOR THYROID ARTERY. (Walsham.)



the depressor muscles of the hyoid bone, the larynx, the thyroid gland, and the lower part of the pharynx. The artery at first runs forward and a little upward, just beneath the greater cornu of the hyoid bone. In this part of its course it lies in the superior carotid triangle, and is quite superficial, being covered only with the integument, fascia, and platysma. It next turns downward, and passes beneath the omohyoid, sternohyoid, and sternothyroid muscles, and ends at the upper part of the thyroid gland in the terminal glandular branches. The superior thyroid vein passes beneath the artery on its way to the internal jugular vein. The superior thyroid is the artery most commonly divided in cases of suicidal wounds of the throat.

Branches of the Superior Thyroid Artery

The named **branches of the superior thyroid artery** are:—(1) The hyoid; (2) the sternomastoid; (3) the superior laryngeal; (4) the cricothyroid; (5) anterior; (6) posterior; and (7) glandular.

(1) The **hyoid** branch [ramus hyoideus] is usually a small twig which passes along the lower border of the hyoid bone, lying on the thyrohyoid membrane under cover of the thyrohyoid and sternohyoid muscles. It supplies the infrahyoid bursa and the thyrohyoid muscle, and anastomoses with its fellow of the opposite side, and with the hyoid branch of the lingual. When the latter artery is small, the hyoid branch of the superior thyroid is usually comparatively large, and *vice versa*.

(2) The **sternomastoid** branch [ramus sternocleidomastoideus] (fig. 491) courses downward and backward across the carotid sheath, and entering the sternomastoid supplies the middle portion of that muscle. It gives off slender twigs to the thyrohyoid, sternohyoid, and omohyoid muscles, and the platysma and integuments covering it. At times the vessel arises directly from the external carotid. It lies usually somewhere in the upper part of the incision for tying the common carotid above the omohyoid muscle.

(3) The **superior laryngeal** artery [a. laryngea superior] (fig. 491) passes medially beneath the thyrohyoid muscle, and, perforating the thyrohyoid membrane along with the internal branch of the superior laryngeal nerve, supplies the intrinsic muscles and mucous lining of the larynx. Its further distribution within the larynx is given with the description of that organ. This branch sometimes arises from the external caroid direct. It may enter the larynx by passing through a foramen in the thyroid cartilage.

(4) The **cricothyroid** [ramus cricothyreoideus] passes across the cricothyroid membrane immediately beneath the lower border of the thyroid cartilage. It anastomoses with its fellow of the opposite side, and usually sends a small branch through the membrane into the interior of the larynx. Occasionally a considerable twig descends over the cricoid cartilage to enter the isthmus of the thyroid gland. The cricothyroid has, however, frequently been seen of comparatively large size—once as large as the radial, and crossing the membrane obliquely. In order to avoid injuring the cricothyroid artery in the operation of laryngotomy, it is usual, if the operation has to be done in a hurry to make the incision through the cricothyroid membrane in a transverse direction, and as near to the cricoid cartilage as possible.

(5) The **anterior** branch [ramus anterior] is the terminal branch supplying the isthmus and the neighboring part of the lateral lobe of the thyroid gland.

(6) The **posterior** branch [ramus posterior], also terminal, supplies the posterior part of the lateral lobe, and sends branches to the inferior constrictor of the pharynx and to the esophagus. It anastomoses with the ascending branches of the inferior thyroid artery.

(7) The **glandular** branches [rami glandulares] are the ultimate twigs, arising from the anterior and posterior terminal branches, for the supply of the thyroid gland.

3. THE LINGUAL ARTERY

The **lingual** artery [a. lingualis] (fig. 492) arises from the front of the external carotid, between the superior thyroid and external maxillary (facial) arteries, often as a common trunk with the latter vessel, and nearly opposite or a little below the greater cornu of the hyoid bone. It may, for purposes of description, be divided into three portions: the **first,** or **oblique,** extends from its origin to the posterior edge of the hyoglossus muscle; the **second,** or **horizontal,** lies beneath the hyoglossus; the **third,** or **ascending,** beneath the tongue. The **first** or **oblique portion** is situated in the superior carotid triangle, and is superficial, being covered merely by the integument, platysma, and deep fascia. Here it lies on the middle constrictor muscle and superior laryngeal nerve. After ascending a short distance, it curves downward and forward beneath the hypoglossal nerve, and, in the **second part of its course,** runs horizontally along the upper border of the hyoid bone, beneath the hyoglossus, by which it is separated from the hypoglossal nerve and its vena comitans, and the posterior belly of the digastric and the stylohyoid muscles. In this part of its course it lies successively on the middle constrictor of the pharynx and the genioglossus, covered by the hyoglossus muscle. In the **third part of its course** it ascends tortuously, usually beneath the anterior margin of the hyoglossus, to the lower surface of the tongue, and is thence continued to the tip of that structure lying between the lingualis and the genioglossus muscles. From the anterior edge of the hyoglossus to its termination it is covered only by the mucous membrane of the lower surface of the tongue. The lingual artery is accompanied by small venæ comitantes.

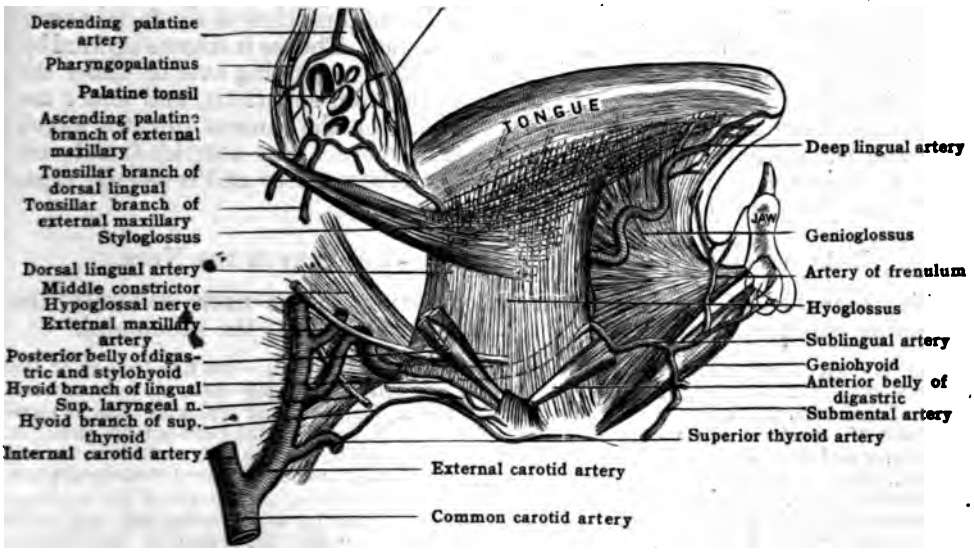
Branches of the Lingual Artery

The named **branches of the lingual artery** are:—(1) The hyoid; (2) the dorsal lingual; (3) the sublingual; and (4) the deep lingual (ranine).

(1) **The hyoid branch** [ramus hyoideus] (fig. 492) is a small vessel which arises from the first part of the lingual, and courses along the upper border of the hyoid bone, superficial to the hyoglossus, but beneath the insertion of the posterior belly of the digastric and the stylohyoid. It anastomoses with its fellow of the opposite side, and with the hyoid branch of the superior thyroid artery, and supplies the contiguous muscles.

(2) **The dorsalis linguæ** (fig. 492) arises from the second portion of the lingual artery, usually under cover of the posterior edge of the hyoglossus muscle. It ascends to the back of the dorsum of the tongue, and, dividing into branches, supplies the mucous membrane on each side of the V formed by the vallate papillæ. It also supplies the palatine arches (pillars) and the tonsil, where it anastomoses with the other faucial and tonsillar arteries. Instead of a single artery, as above described, there may be several small vessels running directly to the parts mentioned. The artery anastomoses in the mucous membrane by very small branches with the vessel of the opposite side; but the anastomosis is so minute that when one lingual artery is injected the injection merely passes across to the opposite side at the tip of the tongue; and when the tongue is divided accurately in the middle line, as in the removal of one-half of that organ, practically no hemorrhage occurs.

FIG. 492.—SCHEME OF THE RIGHT LINGUAL ARTERY. (Walsham.)



(3) **The sublingual artery** [a. sublingualis] (fig. 492) usually comes off from the lingual at the anterior margin of the hyoglossus. It passes beneath the mylohyoid to the sublingual gland, which it supplies, and finally it usually anastomoses with the submental artery, a branch of the external maxillary (facial). It also supplies branches to the side of the tongue, and gives off a terminal twig, which anastomoses beneath the mucous membrane of the floor of the mouth (to which it also gives twigs) with the artery of the opposite side. The artery of the frenulum is usually derived from this vessel (fig. 492).

(4) **The deep lingual** [a. profunda linguæ] or ranine artery, the termination of the lingual, courses forward beneath the mucous membrane, on the lower surface of the tongue, to the tip. It lies upon the lateral side of the genioglossus, between that muscle and the inferior lingualis, and is accompanied by the lingual vein and terminal branch of the lingual nerve. It follows a very tortuous course, so that it is not stretched when the tongue is protruded. Branches are given off from it to the contiguous muscles and mucous membrane. Near the tip of the tongue it communicates with its fellow of the opposite side.

4. THE EXTERNAL MAXILLARY (FACIAL) ARTERY

The external maxillary or facial artery [a. maxillaris externa] (figs. 488, 493) arises immediately above the lingual from the fore part of the external carotid, at times as a common trunk with the lingual. It courses forward and upward in a tortuous manner to the mandible, and, passing over the body of that bone at the anterior edge of the masseter muscle, winds obliquely upward and forward over the face to the medial angle of the eye, where it anastomoses, under the name of the **angular artery,** with the dorsal nasal branch of the ophthalmic. It is usually described as having two portions—the cervical and the facial.

The cervical portion (fig. 493) ascends tortuously from its origin from the external carotid upward and forward beneath the posterior belly of the digas-

tric and beneath the stylohyoid muscle and the hypoglossal nerve. Then, making a turn, it runs horizontally forward for a short way beneath the jaw, either imbedded in, or lying under the submaxillary gland with the mylohyoid and styloglossus beneath it. On leaving the cover of the gland it forms a loop passing first downward and then upward over the lower border of the jaw immediately in front of the masseter muscle, where it is superficial, being merely covered by the integument and platysma.

Here it can be felt beating, and can be readily compressed. In the above course it lies in the posterior part of the submaxillary triangle, and, in addition to the structures already mentioned as crossing it, is covered by the skin, superficial fascia, and platysma, and by one or two submaxillary lymphatic nodes. The vein is separated from the artery by the submaxillary gland, the posterior belly of the digastric muscle, the stylohyoid muscle, and the hypoglossal nerve.

The **facial portion** (fig. 493) of the external maxillary artery ascends tortuously forward toward the angle of the mouth, passing under the platysma (risorius), the zygomatic muscle, the zygomatic head of the quadratus labii superioris (zygomaticus minor), and the zygomatic and buccal branches of the facial nerve. It here lies upon the jaw and the buccinator muscle. Thence it courses upward by the side of the nose toward the medial angle of the eye, passing over or under the infraorbital and angular heads of the quadratus labii superioris, and under the infraorbital branches of the facial nerve. It lies on the caninus (levator anguli oris) and the infraorbital branches of the fifth nerve. The anterior facial vein takes a straighter course than the external maxillary artery and is usually separated from the latter by the zygomatic muscle.

Branches of the External Maxillary Artery in the Neck

The **branches of the external maxillary artery in the neck** are:—(1) The ascending palatine; (2) the tonsillar; (3) the glandular; (4) the submental.

(1) **The ascending palatine** [a. palatina ascendens] (figs. 492, 493).—**the first branch of the** external maxillary, but often a distinct branch of the external carotid—**ascends between the** internal and external carotids, and then between the styloglossus **and stylopharyngeus muscles**, and on reaching the wall of the pharynx is continued upward **between the superior** constrictor and internal pterygoid muscles toward the base of the skull **as high as the levator veli** palatini, where it divides into two branches, a palatine and a tonsillar. **One of these branches, the palatine,** passes with the levator veli palatini over the curved upper **margin of the superior** constrictor to the soft palate. It anastomoses with its fellow of the **opposite side and with** the descending palatine branch of the internal maxillary, also with **the ascending pharyngeal,** which often to a great extent supplies the place of this artery. The other **branch, the tonsillar,** supplies the tonsil and the auditory (Eustachian) tube, anastomosing **with the tonsillar branch** of the external maxillary (facial) and ascending pharyngeal arteries. **The ascending palatine** artery supplies the muscles between which it runs on its way to the **palate.**

(2) The **tonsillar** branch [ramus tonsillaris] (fig. 493) ascends **between the styloglossus and** internal pterygoid muscles to the level of the tonsil, where it perfo**rates the superior constrictor** muscle of the pharynx, and ends in the tonsil, anastomosing with **the tonsillar branch of the** ascending palatine and with the other tonsillar arteries (fig. 492). **It gives branches also to the** root of the tongue.

(3) The **glandular** branches [rami glandulares] are distributed **to the submaxillary gland** as the artery is passing through or beneath that structure. **A small twig from one of these** branches usually supplies the submaxillary (Wharton's) duct.

(4) The **submental** artery [a. submentalis] (fig. 493) comes **off from the external maxillary** as the latter vessel lies under cover of the submaxillary gland, **and, passing forward on the** mylohyoid muscle between the base of the jaw and the anterior belly of **the digastricus, supplies** these structures and the overlying platysma and integuments. **It anastomoses with the sub**lingual artery.

Branches of the External Maxillary Artery on the Face

From the **lateral** or **concave** side of the artery **are given off branches which** supply the masseter muscle and anastomose with the **masseteric and buccinator** branches of the internal maxillary artery, the transverse **facial artery, and the** infraorbital arteries.

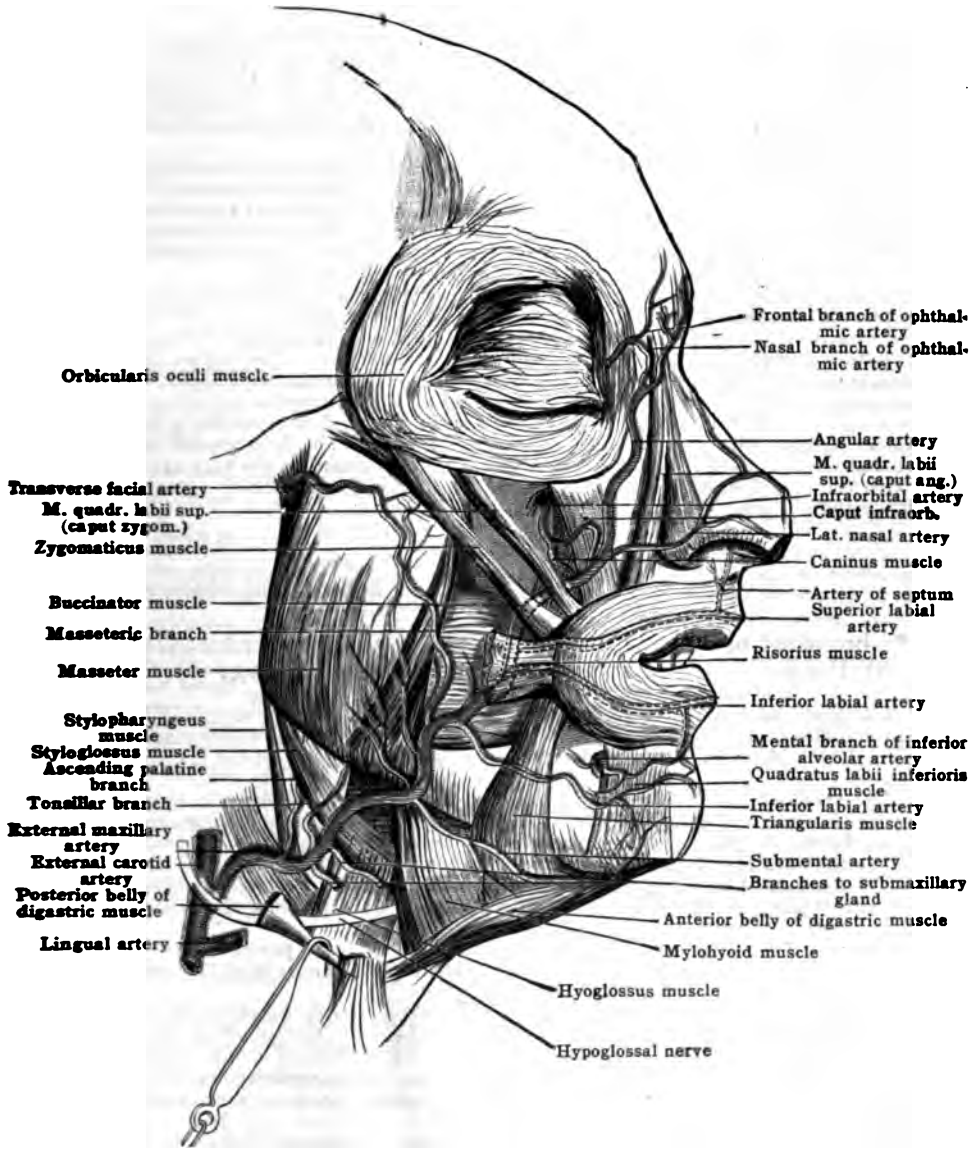
From the **medial** or **convex** side the following larger **and named vessels are** given off:—(1) The inferior labial; (2) the superior labial; **and (3) the angular.**

(1) The **inferior labial** artery [a. labialis inferior] arises at the **angle of the mouth (fig. 493)** and runs in the lower lip within the substance of the orbicularis oris, **close to the mucous mem**brane. It anastomoses with the artery of the other side. **Frequently an additional branch** passes from the external maxillary to the lower lip.

(2) The **superior labial** artery [a. labialis superior] arising from the external maxillary higher [illegible] the inferior (fig. 493), passes forward beneath the zygomaticus, and then, like the inferior [illegible], courses tortuously along the lower margin of the upper lip between the orbicularis oris and [illegible] mucous membrane, about 1.2 cm. (½ in.) from the junction of the mucous membrane and [illegible] skin. It is usually larger than the inferior labial. It anastomoses with its fellow of the [illegible]osite side, and gives off a small artery to the septum—**arteria septi nasi.** Compression of [illegible] vessel will sometimes control hemorrhage from the nose.

(3) The **angular** artery [a. angularis] (fig. 493) is the terminal branch of the external max[illegible]ry. It supplies the nose and anastomoses at the medial angle of the eye with the dorsal nasal [illegible]nch of the ophthalmic. It lies to the medial side of the lacrimal sac and supplies that [illegible]ecture and the lower part of the orbicularis oculi, beneath which a branch anastomoses with [illegible] infraorbital artery.

FIG. 493.—RIGHT EXTERNAL MAXILLARY ARTERY AND BRANCHES. (Walsham.)



5. THE STERNOCLEIDOMASTOID ARTERY

The **sternocleidomastoid** artery [a. sternocleidomastoidea] arises from the posterior side of the external carotid at the point where the carotid is crossed by the digastric muscle. It is distributed to the sternocleidomastoid muscle, and is frequently represented by one *of the muscular* branches of the occipital artery.

6. THE OCCIPITAL ARTERY

The **occipital** artery [a. occipitalis] (fig. 494) is usually a vessel of considerable size. It comes off from the posterior part of the external carotid opposite the external maxillary (facial), or else a little higher than that vessel. It then runs upward and backward to the interval between the mastoid process of the temporal bone and transverse process of the atlas, and, after running horizontally backward in a groove on the mastoid portion of the temporal bone, again turns upward, and ends by ramifying in the scalp over the back of the skull, extending as far forward as the vertex.

The vessel may be divided into three parts—viz., that anterior to the sternomastoid muscle; that beneath the sternomastoid; and that posterior to the sternomastoid.

In the **first part of its course** the occipital artery is covered by the integument and fascia, and is more or less overlapped by the posterior belly of the digastric muscle, the parotid gland, and posterior facial (temporomaxillary) vein. It is crossed by the hypoglossal nerve as the latter winds forward over the carotid vessels to reach the tongue. It successively crosses in front of the internal carotid artery, the hypoglossal nerve, the vagus nerve, the internal jugular vein, and the spinal accessory nerve.

In the **second part of its course** it sinks deeply beneath the digastric muscle into the interval between the mastoid process of the temporal bone and the transverse process of the atlas. It is here covered by the sternomastoid, splenius capitis, and longissimus capitis muscles and by the origin of the digastric; and lies, first on the rectus capitis lateralis, which separates it from the vertebral artery, then in a groove, the occipital groove, on the mastoid portion of the temporal bone, and then on the insertion of the superior oblique muscle.

In the **third part of its course** it enters the triangular interval formed by the diverging borders of the splenius capitis and the superior nuchal line of the occipital bone. Here it lies beneath the integuments and the aponeurosis uniting the occipital attachments of the sternomastoid and trapezius, and rests upon the semispinalis capitis (complexus) just before the insertion of that muscle into the occipital bone. In company with the greater occipital nerve, it perforates the aponeurosis, or less often the posterior belly of the epicranius (occipitofrontalis), and follows roughly, but in a tortuous course, the line of the lambdoid suture, lying between the integument and the cranial aponeurosis. In the scalp it divides into several large branches, which ramify over the back of the skull and reach as far forward as the vertex. They anastomose with the corresponding branches of the opposite side, and with the posterior auricular and the superficial temporal arteries.

Branches of the Occipital Artery (Fig. 494)

The branches of the occipital artery are:—(1) The muscular; (2) the meningeal; (3) the auricular; (4) the mastoid; (5) the descending; (6) the occipital.

(1) The **muscular** branches [rami musculares] (fig. 494) supply the sternocleidomastoid and adjacent muscles. One of these branches may take the place of the sternomastoid branch of the external carotid. The hypoglossal nerve then, as a rule, loops around it instead of around the occipital.

(2) The **meningeal** branches [rami meningei] (fig. 494), one or more in number, are long slender vessels which leave the occipital artery as it crosses the internal jugular vein and, ascending along the vessel, pass with it through the jugular or hypoglossal foramen, and are distributed to the dura mater lining the posterior fossa of the skull.

(3) The **auricular** branch [ramus auricularis] ascends over the mastoid process to the back of the ear, and supplies the auricle. It sometimes takes the place of the posterior auricular artery (fig. 494).

(4) The **mastoid** branch [ramus mastoideus] is a small twig that passes into the skull through the mastoid foramen, supplying the dura mater, the diploë, the walls of the transverse sinus, and the mastoid cells.

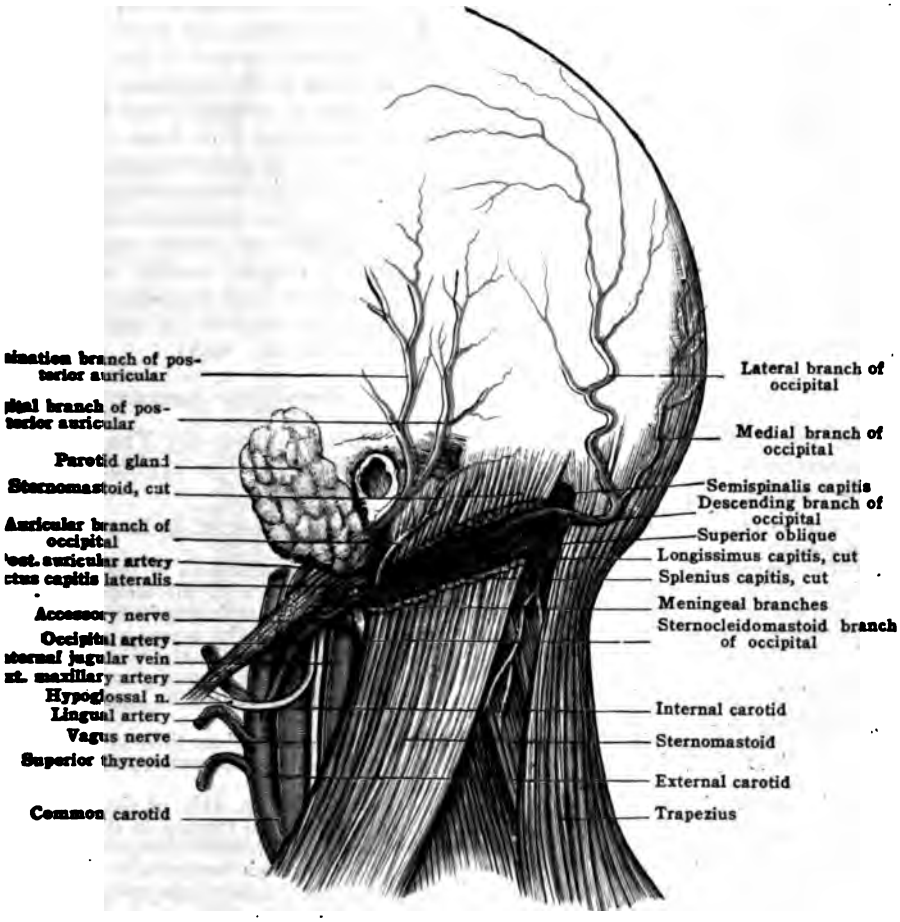
(5) The **descending** or **princeps cervicis** [ramus descendens] (fig. 494), the largest of the branches of the occipital, arises from that artery just before it emerges from beneath the splenius, and, descending for a short distance between the splenius and semispinalis capitis (complexus), divides into a superficial and a deep branch. The **superficial branch** perforates the splenius, supplies branches to the trapezius, and anastomoses with the ascending branch of the transverse cervical artery. The **deep branch** passes downward between the semispinalis capitis (complexus) and colli, and anastomoses with the deep cervical branch of the costocervical trunk and with branches of the vertebral. The anastomoses between the above-mentioned arteries form important collateral channels after ligature of the common carotid and subclavian arteries (fig. 489).

(6) The **occipital** or **terminal** branches [rami occipitales] (fig. 494), usually two in number, named from their position medial and lateral, ramify over the scalp, and have already been described. The medial branch generally gives off a twig which enters the parietal foramen (parietal artery) and is distributed to the dura mater. The occipital artery may also give off the stylomastoid, the posterior auricular, or the ascending pharyngeal arteries.

7. THE POSTERIOR AURICULAR ARTERY

he posterior auricular artery [a. auricularis posterior] (fig. 494) arises from osterior part of the external carotid artery, usually immediately above the rior belly of the digastric, about the level of the tip of the styloid process. sionally it arises under cover of the digastric, quite close to, or as a common k with, or as a branch of, the occipital. It courses upward and backward in arotid gland to the notch between the margin of the external acoustic meatus the mastoid process, where it divides into branches. In this course it rests he styloid process, crosses the accessory nerve, and is crossed by the facial e.

FIG. 494.—LEFT OCCIPITAL AND POSTERIOR AURICULAR ARTERIES. (Walsham.)



BRANCHES OF THE POSTERIOR AURICULAR ARTERY

he branches of the posterior auricular artery are:—(1) the stylomastoid; (2) auricular; (3) the occipital (fig. 494).

he posterior auricular also gives branches to the parotid gland and the adjacent muscles, ly, the posterior belly of the digastric, the stylohyoid, and auricularis posterior (retrahens n).

) **The stylomastoid artery** [a. stylomastoidea] comes off from the posterior auricular r just before it reaches the notch between the margin of the external acoustic meatus he mastoid process, and, following the facial nerve upward, enters the stylomastoid fora- in the temporal bone. In the facial canal (aqueduct of Fallopius) it gives off the following d twigs:—(*a*) **meatal,** to the external acoustic meatus; (*b*) **mastoid** [rami mastoidei], to astoid cells and tympanic antrum; (*c*) **stapedic** [ramus stapedius], which runs forward to tapedius muscle; (*d*) **posterior tympanic** [a. tympanica posterior], which anastomoses with nterior tympanic branch of the internal maxillary, forming with it in the fetus a vascular around the membrana tympani; (*e*) **vestibular,** to the vestibule and semicircular canals; *f*) **terminal,** a *small twig which leaves the facial* canal (by the hiatus) with the great super-

ficial petrosal nerve, and anastomoses with the superior petrosal branch of the middle meningeal artery.

(2) The **auricular** branch [ramus auricularis] passes upward behind the ear and beneath the auricularis posterior (retrahens aurem), supplying the medial surface of the pinna and adjacent skin. It anastomoses with the posterior branch of the superficial temporal artery. The branches to the pinna not only supply the back of that structure, but some perforate the cartilage, and others turn over its free margin to supply the lateral surface; there they anastomose with the anterior auricular branches from the temporal.

(3) The **occipital** branch [ramus occipitalis] passes upward and backward, crossing the aponeurotic insertion of the sternomastoid muscle. It gives a branch to the posterior belly of the epicranius (occipitofrontalis), and anastomoses with the occipital artery.

8. THE SUPERFICIAL TEMPORAL ARTERY

The **superficial temporal** artery [a. temporalis superficialis] (fig. 488), is the smaller of the two terminal divisions of the external carotid, though apparently the direct continuation of that vessel. It arises opposite the neck of the mandible and, under cover of the parotid gland, passes upward in the interval between the condyle and the external acoustic meatus to the zygoma, lying on the capsule of the temporomandibular joint. Thence it ascends over the posterior zygomatic root and the temporal aponeurosis for about 4 or 5 cm. ($1\frac{1}{2}$ or 2 in.), and there divides into frontal and parietal branches. It is surrounded by a dense plexus of sympathetic nerves, and is accompanied by the auriculotemporal nerve, which lies beneath and generally a little behind it. It is crossed by the temporal and zygomatic branches of the facial nerve, and by the auricularis anterior (attrahens aurem) muscle. As it crosses the zygoma it can be readily felt pulsating immediately in front of the auricle, and in this situation can be compressed against the bone. It is here quite superficial, being merely covered by the integuments and a delicate prolongation from the cervical fascia (fig. 488).

Branches of the Superficial Temporal Artery

The **branches of the superficial temporal** artery are:—(1) The parotid; (2) the transverse facial; (3) the anterior auricular; (4) the zygomatico-orbital; (5) the middle temporal; (6) the frontal; (7) the parietal.

(1) The **parotid** branches [rami parotidei] are small twigs given off in the substance of the parotid gland.

(2) The **transverse facial** [a. transversa faciei] is the largest branch of the temporal. It sometimes arises from the external carotid as a common trunk with the temporal. It is at first deeply seated in the substance of the parotid gland, but soon emerging from the upper part of the anterior border of the gland, courses transversely across the masseter muscle about a finger's breadth below the zygoma. The parotid duct runs below it, and the zygomatic (infraorbital) branches of the facial nerve above it. It supplies the parotid gland, the masseter muscle, and the skin of the face, and anastomoses with the infraorbital, the buccal, and the external maxillary (facial) arteries.

(3) The **anterior auricular** branches [rami auriculares anteriores] are three or four in number and supply the tragus, the pinna, and the lobule of the ear, and to some extent the external acoustic meatus.

(4) The **zygomatico-orbital** artery [a. zygomaticoorbitalis] (fig. 448), at times a branch of the deep temporal, passes forward along the upper border of the zygoma in the fat between the superficial and deep layers of the temporal aponeurosis, and, after giving branches to the orbicularis oculi, sends one or more twigs into the orbit through foramina in the zygomatic (malar) bone to anastomose with the lacrimal and palpebral branches of the ophthalmic.

(5) The **middle temporal** artery [a. temporalis media] (fig. 497), arises just above the zygoma, and, perforating the temporal aponeurosis and temporal muscle, ascends on the squamous portion of the temporal bone, and anastomoses with the posterior deep temporal artery.

(6) The **frontal** or **anterior terminal** branch [ramus frontalis] ramifies tortuously in an upward and forward direction over the front part of the skull. It lies first between the skin and temporal fascia and then between the skin and epicranial aponeurosis. It supplies the anterior belly of the epicranius (occipitofrontalis) and the orbicularis oculi muscles, and anastomoses with the supraorbital and frontal branches of the ophthalmic, and with the corresponding artery of the opposite side. The secondary branches given off from this vessel to the scalp run from before backward.

(7) The **parietal** or **posterior terminal** branch [ramus parietalis] ramifies on the side of the head between the skin and temporal fascia. Its branches anastomose, in front with the anterior terminal branch; behind, with the posterior auricular and occipital arteries; and above, across the vertex of the skull, with the corresponding artery of the opposite side.

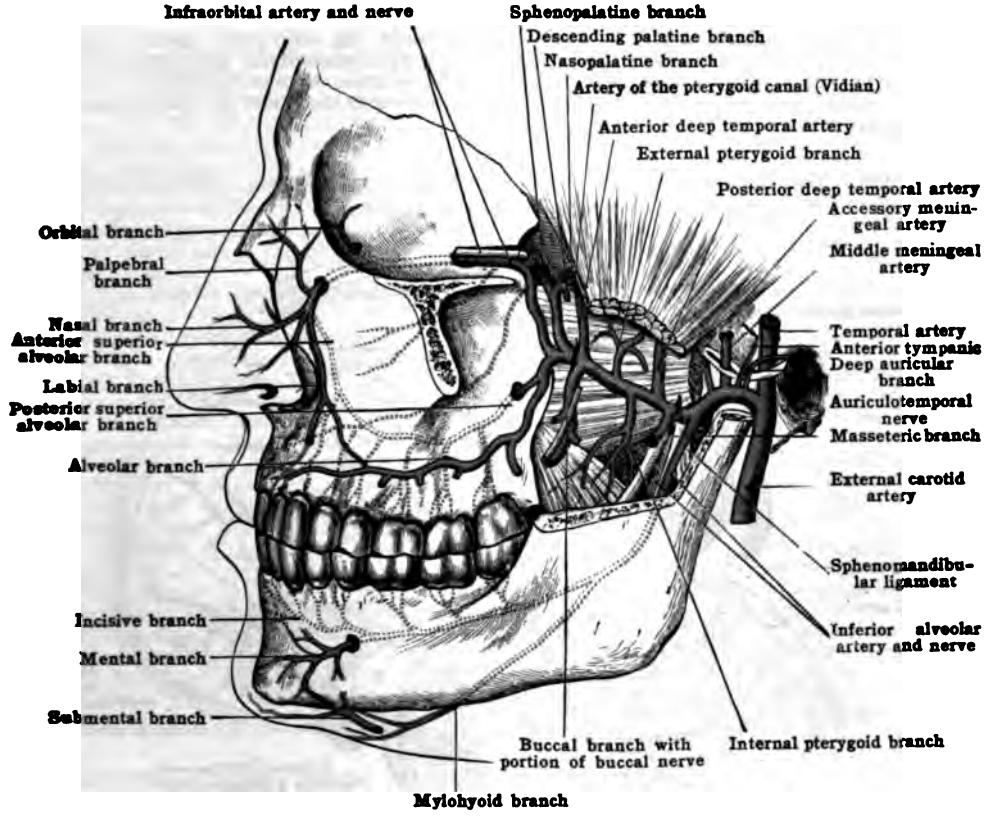
9. THE INTERNAL MAXILLARY ARTERY

The **internal maxillary** artery [a. maxillaris interna] (fig. 495) is the larger of the two terminal divisions of the external carotid. It arises opposite the neck of

mandible in the substance of the parotid gland, and, passing first between the mandible and the sphenomandibular ligament and then between the external and internal pterygoid muscles, sinks deeply into the pterygopalatine (sphenomaxillary) fossa, and there breaks up into its terminal branches. It is divided for description into three portions: mandibular, pterygoid, and pterygopalatine.

(1) In the **first part of its course** (the **mandibular portion**) the artery lies between the neck of the mandible and the sphenomandibular ligament, taking a horizontal course forward, nearly parallel to and a little below the auriculotemporal nerve and the external pterygoid muscle. It is here embedded in the parotid gland, and usually crosses in front of the inferior alveolar (dental) nerve.

FIG. 495.—LEFT INTERNAL MAXILLARY ARTERY. (Walsham.)



(2) In the **second part of its course** (the **pterygoid portion**) the artery may be placed superficial or deep to the external pterygoid muscle. In the first case it passes between the two pterygoid muscles and the ramus of the jaw, and then turns upward over the lateral surface of the external pterygoid, medial to the temporal muscle, to reach the interval between the two heads of the external pterygoid, and sinks into the pterygopalatine fossa. In the second case it passes medially to the external pterygoid, and is covered by that muscle till it reaches the interval between its two heads, where, forming a projecting loop, it turns into the pterygopalatine fossa.

(3) In the **third part of its course** (the **pterygopalatine portion**) the artery lies in the pterygopalatine fossa beneath the maxillary division of the fifth nerve and in close relationship with the sphenopalatine (Meckel's) ganglion, and there breaks up into its terminal branches.

BRANCHES OF THE INTERNAL MAXILLARY ARTERY

The branches of the internal maxillary artery are:—

(A) **From the first part:**—(1) The deep auricular; (2) the anterior tympanic; (3) the middle meningeal; *(4) the inferior* alveolar (dental); (5) the accessory

meningeal (sometimes). All these vessels pass through bony or cartilaginous canals.

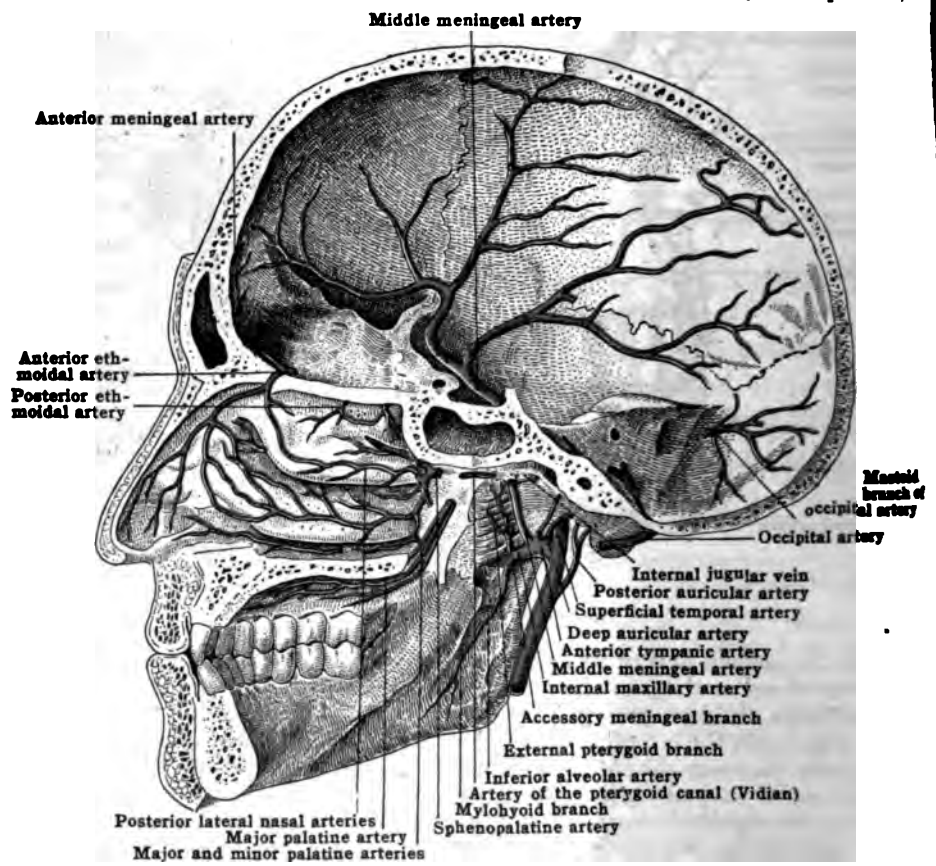
(B) **From the second part:**—(1) The masseteric; (2) the posterior deep temporal; (3) the pterygoid; (4) the buccal; and (5) the anterior deep temporal. All these branches supply muscles.

(C) **From the third part:**—(1) The posterior superior alveolar (dental); (2) the infraorbital; (3) the descending palatine; (4) the a. canalis pterygoidei or Vidian; and (5) the sphenopalatine. All these branches pass through bony canals.

Branches of the First Part of the Internal Maxillary Artery

(1) The **deep auricular** artery [a. auricularis profunda] (fig. 495) passes upward in the substance of the parotid gland behind the capsule of the temporomandibular joint, and, perforating the bony or cartilaginous wall of the external acoustic meatus, supplies the skin of that passage and the membrana tympani. It at times gives a branch to the joint as it passes behind the temporomandibular articular capsule.

Fig. 496.—The Middle Meningeal Artery within the Skull. (After Spalteholz.)



(2) The **anterior tympanic** artery [a. tympanica anterior] is a long slender vessel, which runs upward behind the condyle of the jaw to the petrotympanic (Glaserian) fissure, through which it passes to the interior of the tympanum. Here it supplies the lining membrane of that cavity and anastomoses with the other tympanic arteries, forming with the posterior tympanic branch of the stylomastoid artery a vascular circle around the membrana tympani. This circle is more distinct in the fetus than in the adult.

(3) The **middle meningeal** artery [a. meningea media] is the largest branch of the internal maxillary artery. It comes off from the vessel as it lies between the sphenomandibular ligament and the ramus of the jaw, and under cover of the external pterygoid passes directly upward to the foramen spinosum, through which it enters the interior of the cranium. In this part of its course it is crossed by the chorda tympani nerve; and just before it enters the foramen *embraced by the* two heads of origin of the auriculotemporal nerve (fig. 495).

The trunk of the mandibular division of the fifth nerve, as it emerges from the foramen vale, lies in front of the artery. As the artery passes upward it is surrounded by filaments of he sympathetic nerve, and is accompanied by two veins. On entering the skull it ramifies etween the bone and dura mater, supplying both structures. It at first ascends for a short istance in a groove on the greater wing of the sphenoid, and then divides into two branches, an nterior and a posterior.

The **anterior branch** passes upward, in the groove on the greater wing of the sphenoid, on to the parietal bone at its anterior and inferior angle; at this spot the groove becomes deepened and often bridged over by a thin plate of bone, being converted for 6 to 12 mm. (¼ to ½ in.) or more into a distinct canal. The situation of the artery is here indicated on the exterior of the skull by a spot 3.7 cm. (1½ in.) behind, and about 2.5 cm. (1 in.) above, the zygomatic process of the frontal bone. The anterior branch is continued along the anterior border of the parietal bone nearly as far as the superior sagittal sinus, and gives off in its course, but especially posteriorly, large branches which ramify in an upward and backward direction in grooves on the parietal bone (fig. 496).

The **posterior branch** passes backward over the squamous portion of the temporal bone; and thence on to the parietal bone, behind the anterior branch. This branch and its collaterals extend upward as far as the sagittal sinus, and backward as far as the transverse (lateral) sinus.

In addition to its terminal anterior, and terminal posterior branches, the middle meningeal gives off:—(*a*) **Ganglionic** branches to the semilunar (Gasserian) ganglion and its sheath of dura mater. (*b*) **A superficial petrosal** branch [ramus petrosus superficialis], which enters the hiatus of the facial canal in company with the large superficial petrosal nerve and anastomoses with the terminal branch of the stylomastoid artery. (*c*) **A superior tympanic** artery [a. tympanica superior], which enters the canal for the tensor tympani, and supplies that muscle. (*d*) An **orbital** or **lacrimal** branch, which enters the orbit at the outermost part of the superior orbital (sphenoidal) fissure, or sometimes through a minute foramen, just lateral to that fissure, and anastomoses with the lacrimal branch of the ophthalmic; (*e*) **Anastomotic** or **perforating** branches which pierce the greater wing of the sphenoid bone, and anastomose with the deep temporal arteries.

(4) The **inferior alveolar** artery [a. alveolaris inferior] (fig. 495), arising from the internal maxillary as it lies between the sphenomandibular ligament and neck of the jaw, courses downward to the mandibular foramen, which it enters in company with, and a little behind and lateral to, the inferior alveolar nerve. It then passes along the canal in the interior of the bone, giving off branches to the molar, premolar, and canine teeth. On reaching the mental foramen it divides into two branches, the incisive and the mental. The incisive continues its course in the bone, supplies branches to the incisor teeth, and anastomoses with the artery of the opposite side. The **mental** branch [ramus mentalis] passes through the mental foramen in company with the mental branch of the inferior alveolar (dental) nerve, and emerges on the chin under cover of the quadratus labii inferioris. It anastomoses above with the inferior labial (coronary), and below with the submental, and also with the inferior labial. Near its origin the artery gives off (*a*) **a lingual** or **gustatory** branch which accompanies and supplies the lingual nerve, and ends in the mucous membrane of the mouth; and, just before it enters the mandibular (dental) foramen in the lower jaw, (*b*) **mylohyoid** branch [ramus mylohyoideus], which accompanies the nerve of that name along the groove in the lower jaw, and after supplying the mylohyoid muscle, anastomoses with the sublingual and submental arteries.

(5) **The accessory or small meningeal** branch [ramus meningeus accessoria] arises either from the internal maxillary a little in front of the middle meningeal, or as a branch of the latter itself. It passes upward along the course of the mandibular division of the fifth nerve, and, entering the skull through the foramen ovale, is distributed to the semilunar (Gasserian) ganglion, to the walls of the cavernous sinus and to the dura mater in the neigborhood.

Branches of the Second Part of the Internal Maxillary Artery

The branches of the second portion of the internal maxillary all supply muscles. They are: —(1) The masseteric; (2) the posterior deep temporal (3) the pterygoid ; (4) the buccal; and (5) the anterior deep temporal.

(1) The **masseteric** artery [a. masseterica] comes off from the internal maxillary as the latter is passing from between the neck of the jaw and the sphenomandibular ligament. It passes, with the masseteric nerve through the mandibular (sigmoid) notch in the mandible and supplies the masseter muscle. Some filaments perforate the muscle and anastomose with the transverse facial and with the masseteric branches of the external maxillary (facial).

(2) The **posterior deep temporal** artery [a. temporalis profunda posterior] arises, as a rule, from the internal maxillary in common with the masseteric, or a little beyond that branch. It passes upward beneath the temporal muscle in a slight groove on the anterior margin of the squamous portion of the temporal bone, supplying the temporal muscle, the pericranium and the external layer of the bone. It anastomoses with the other temporal arteries.

(3) The **pterygoid** branches [rami pterygoidei] are short trunks which pass into and supply the internal and external pterygoid muscles.

(4) The **buccal** artery [a. buccinatoria] (fig. 495) courses forward and downward with the buccal nerve to the buccinator muscle, lying in close contact with the medial side and anterior margin of the tendon of the temporal muscle and coronoid process of the lower jaw. It supplies the buccinator muscle and mucous membrane of the mouth, and anastomoses with the external maxillary (facial), transverse facial, and infraorbital arteries.

(5) The **anterior deep temporal** artery [a. temporalis profunda anterior] ascends beneath the temporal muscle in a slight groove on the greater wing of the sphenoid bone. It supplies the muscle, pericranium, and subjacent bone, and gives off small branches which pass through

minute foramina in the zygomatic (malar) bone. Some of these last branches enter the orbit and anastomose with the lacrimal artery; others emerge on the face and anastomose with the transverse facial artery.

Branches of the Third Part of the Internal Maxillary Artery

The branches of the third part of the internal maxillary artery, like those of the first part, all pass through bony canals. They are the following:—(1) The posterior superior alveolar (dental); (2) the infraorbital; (3) the descending palatine; (4) the artery of the pterygoid canal (Vidian); and (5) the sphenopalatine.

(1) The **posterior superior alveolar (dental)** artery [a. alveolaris superior posterior] arises from the internal maxillary as the latter is passing into the pterygopalatine (sphenomaxillary) fossa, and descends in a tortuous manner in a groove on the back of the body of the maxilla. It gives off branches to the maxillary sinus, to the molar and premolar teeth, the gums, and to the buccinator muscle.

(2) The **infraorbital** artery [a. infraorbitalis] arises from the internal maxillary, generally as a common trunk with posterior alveolar (dental). It then passes forward and a little upward through the pterygopalatine (sphenomaxillary) fossa; then forward in company with the infraorbital branch of the fifth nerve, first along the groove, and then through the canal in the orbital plate of the maxilla; and finally, emerging on the face at the infraorbital foramen, under cover of the quadratus labii superioris, is distributed to the structures forming the upper lip, the lower eyelid, the lacrimal sac, and the side of the nose. It anastomoses with the superior labial (coronary) and angular branches of the external maxillary (facial), with the nasal and lacrimal branches of the ophthalmic, and with the transverse facial. It gives off small branches supplying the fat of the orbit and the inferior rectus and inferior oblique muscles. The **anterior superior alveolar** branch [a. alveolaris superior anterior] passes downward through a groove in the anterior wall of the maxilla, together with the anterior alveolar branch of the infraorbital nerve, and supplies branches to the incisor and canine teeth and the mucous membrane of the maxillary sinus. It has also **nasal** branches which pass through the foramina in the nasal process of the maxilla.

(3) The **descending palatine** artery [a. palatina descendens] descends in the pterygopalatine canal with the anterior palatine branch of the sphenopalatine ganglion. On emerging on the palate at the greater (posterior) palatine foramen, it divides into the following branches —(*a*) The **major palatine** artery [a. palatina major], which courses forward in the mucoperiosteum at the junction of the hard palate with the alveolar process as far as the incisive (anterior palatine) foramen, where it anastomoses with the sphenopalatine artery; and (*b*) **minor palatine** arteries [aa. palatinæ minores], which pass backward and downward into the soft palate, contributing to the supply of that structure, and anastomosing with the ascending palatine artery. After the operation for cleft palate, serious hemorrhage occasionally occurs from the major palatine artery. The foramen is situated a little behind, and medial to, the last molar tooth, and almost immediately in front of the hamular process (fig. 496).

(4) The **arteria canalis pterygoidei or Vidian** artery is a long slender branch which passes backward through the pterygoid (Vidian) canal in company with the nerve of the same name into the cartilage of the lacerated foramen. It gives off branches which supply the roof of the pharynx, and anastomose with the ascending pharyngeal and sphenopalatine arteries; also a branch which is distributed to the auditory (Eustachian) tube; and one which enters the tympanum, and anastomoses with the other tympanic arteries.

(5) The **sphenopalatine** [a. sphenopalatina], the terminal branch of the internal maxillary, passes with the nasopalatine branch of the sphenopalatine ganglion from the pterygopalatine (sphenomaxillary) fossa into the nose through the sphenopalatine foramen. Crossing the roof of the nose in the mucoperiosteum, it passes on to the septum, and then runs forward and downward in a groove on the vomer toward the incisive (anterior palatine) foramen, where it anastomoses with the major palatine artery, which enters the nose through the lateral compartment of that foramen (the canal of Stenson). In this course it gives off branches to the roof and contiguous portions of the pharynx, and to the sphenoidal cells. It has also **posterior lateral nasal** branches [aa. nasales post. laterales], which ramify over the nasal conchæ (turbinate bones) and lateral walls of the nose, and give twigs to the ethmoidal and frontal sinuses and the lining membrane of the maxillary sinus; and **posterior septal** branches [aa. nasales post. septi], which run upward and forward, giving small twigs to the mucous membrane covering the upper part of the septum, and which pass through the cribriform plate of the ethmoid and anastomose with the ethmoidal arteries (perforating or meningeal branches).

THE INTERNAL CAROTID ARTERY

The **internal carotid** artery [a. carotis interna] (figs. 497 and 498) arises with the external carotid at the bifurcation of the common carotid, opposite the upper border of the thyroid cartilage, on a level with the fourth cervical vertebra. It is at first placed a little laterally to the external carotid, but as it ascends in the neck the external carotid becomes more superficially placed, in front of the internal. The internal carotid passes up the neck, in front of the transverse processes of the upper cervical vertebræ, lying upon the longus capitis (rectus capitis ant. major), to the carotid foramen, thence through the carotid canal in the petrous portion of the temporal bone. It makes at first a forward and medial

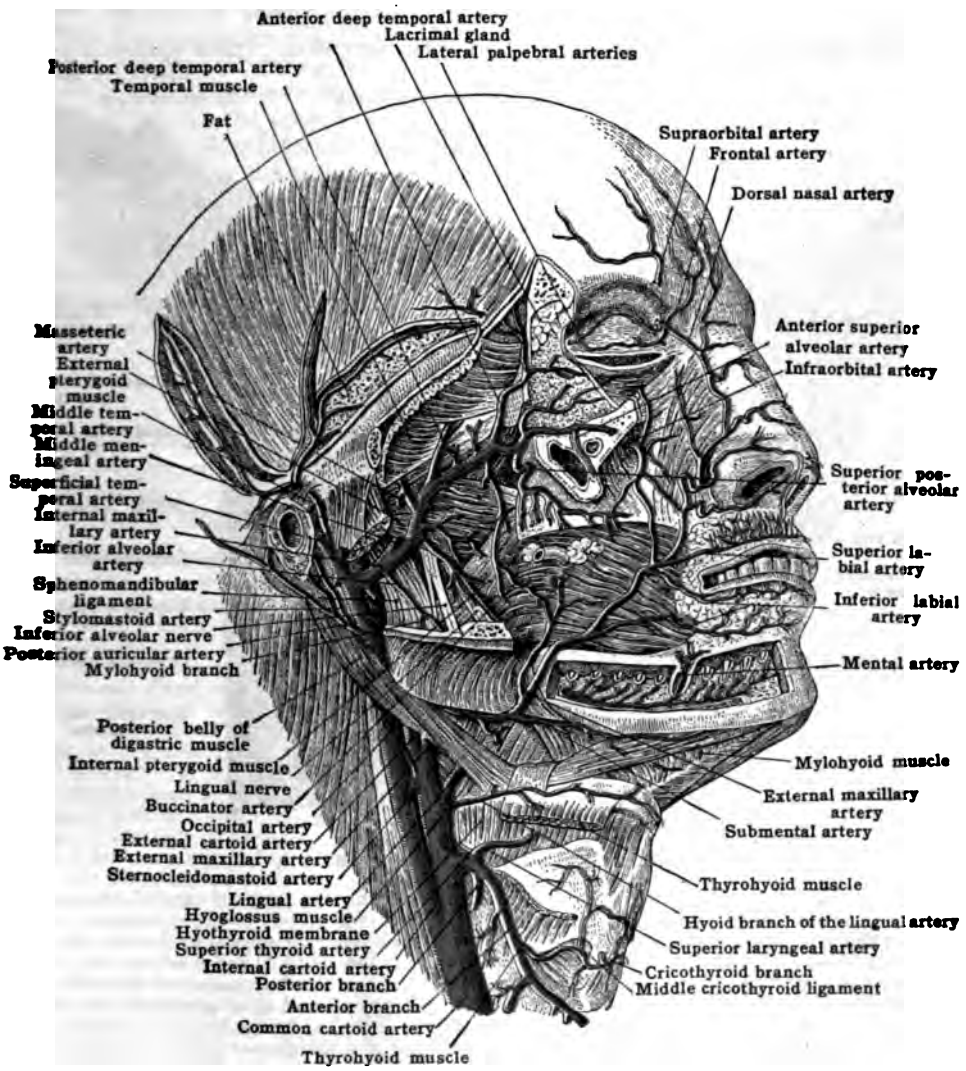
turn and then a second turn upward, and enters the cranium through the foramen lacerum. Within the cranium, it makes a sigmoid curve on the side of the body of the sphenoid bone, and terminates, after perforating the dura mater, by dividing opposite the anterior clinoid process, in the lateral fissure (fissure of Sylvius), into the anterior and middle cerebral arteries.

In its course up the neck it often forms one or more curves, especially in old people. Between the internal and the external carotids, at their angle of divergence, is situated the carotid body or gland [glomus caroticum].

1. The Cervical Portion

Relations.—In the neck (fig. 497) the artery is at first comparatively superficial, having in front of it, as it lies in the superior carotid triangle, the skin, superficial fascia, platysma and

Fig. 497.—The Carotid Arteries. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



deep fascia, and the overlapping edge of the sternomastoid muscle. Higher up, as it sinks beneath the parotid gland, it becomes deeply placed, and is crossed by the posterior belly of the digastric and stylohyoid muscles, the hypoglossal nerve, and the occipital and posterior auricular arteries. Still higher it is separated from the external carotid artery, which here gets in front of it, by the styloglossus and stylopharyngeus muscles, the glossopharyngeal nerve, the pharyngeal branch of the vagus nerve, and by the stylohyoid ligament.

Behind, it lies upon the longus capitis (rectus capitis anticus major), which separates it from the transverse processes of the three upper cervical vertebræ, on the superior cervical

ganglion of the sympathetic nerve, and on the vagus nerve. Near the base of the skull, the hypoglossal, vagus, glossopharyngeal, and accessory nerves cross obliquely behind it, and separate it from the internal jugular vein, which, as the artery is about to enter the carotid canal, also forms one of its posterior relations.

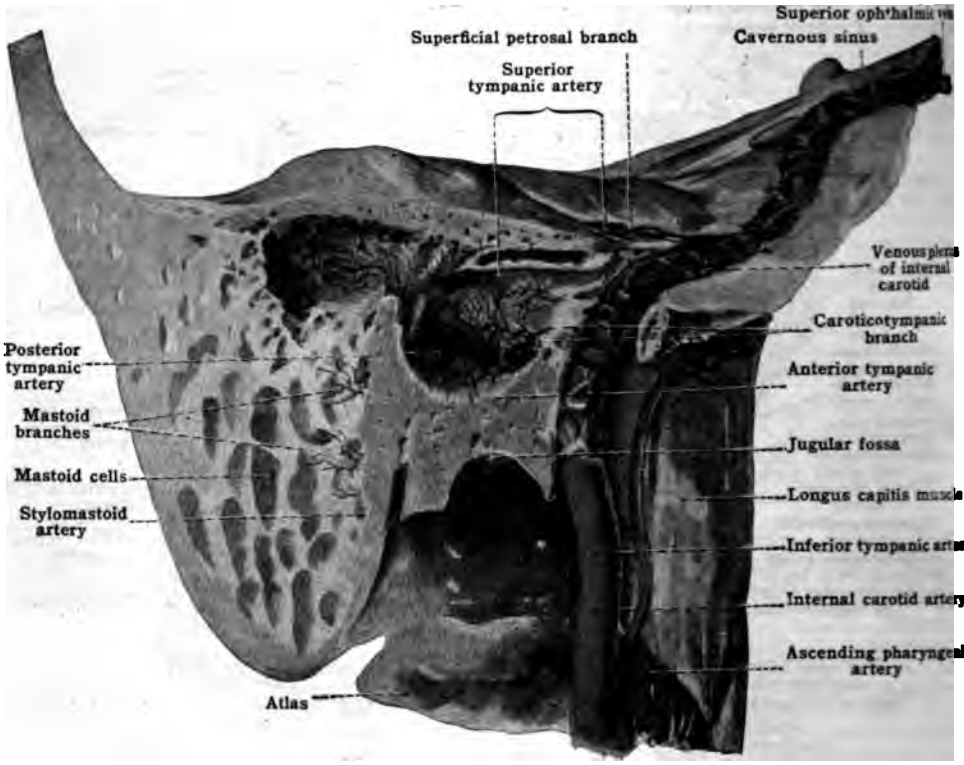
On its **lateral side** are the internal jugular vein and vagus nerve.

On its **medial side** it is in relation with the pharynx, the superior constrictor muscle separating it from the tonsil. The ascending pharyngeal and ascending palatine arteries, and the auditory (Eustachian) tube and levator veli palatini muscles, are also medial to it.

2. The Petrosal Portion

The **petrosal portion** (fig. 498) is situated in the carotid canal in the petrous portion of the temporal bone. It is here separated from the walls of the canal by a prolongation downward of the dura mater. In this part of its course it first ascends in front of the tympanum and cochlea of the internal ear; it then turns forward and medially, lying a little to the medial side of and behind the auditory (Eustachian) tube, and enters the cranial cavity by turning upward through the foramen lacerum, lying upon the lingula of the sphenoid bone. In this part of its course it is accompanied by the ascending branches from the superior cervical ganglion of the sympathetic. These form a plexus about the artery, but are situated chiefly on its lateral side. It is also surrounded by a number of small veins, which receive tributaries from the tympanum and open into the cavernous sinus and internal jugular vein.

Fig. 498.—The Internal Carotid Artery in the Canal. (After Spalteholz.)



3. The Intracranial Portion

On entering the cranium through the foramen lacerum, the **internal carotid first ascends** upon the medial side of the lingula along the lateral part of the **body of the sphenoid. It then** follows the carotid sulcus forward and slightly downward along the **medial wall of the cavernous** sinus (fig. 498). Here it has the sixth nerve immediately lateral to it, **and is covered by the lining membrane of the sinus.** Again turning upward, it pierces the **dura mater on the medial side** of the anterior clinoid process, and passes between the second **and third nerves to the anterior** perforated substance. At the medial end of the lateral (Sylvian) **fissure it pierces the arachnoid** and divides into its two terminal branches, the anterior and middle **cerebral. As it lies in the** foramen lacerum the artery is crossed on its lateral side by the **great superficial petrosal nerve** as the latter goes to join the great deep petrosal from the carotid **plexus to form the nerve of** the pterygoid canal (Vidian).

Branches of the Internal Carotid Artery

The **cervical portion** has no branches. The **petrosal portion gives off the** caroticotympanic. The **branches of the intracranial portion are:—(2) ophthal-**

[illegible]ic; (3) posterior communicating; (4) choroid; (5) anterior cerebral; (6) middle [illegible]erebral.

As the internal carotid artery lies on the medial side of the cavernous sinus, it also gives off [illegible]he following small branches—branches to the walls of the cavernous sinus, to the pituitary body, [illegible]e the semilunar (Gasserian) ganglion and to the dura mater. These anastomose with anterior [illegible]branches of the middle meningeal.

1. THE CAROTICOTYMPANIC ARTERY

The **caroticotympanic** enters the tympanum through a small foramen in the posterior wall of the carotid canal, and contributes its quota to the blood-supply of that cavity. It anastomoses with the tympanic branches of the stylomastoid, internal maxillary, and middle meningeal arteries.

2. THE OPHTHALMIC ARTERY

The **ophthalmic** artery (fig. 499) arises from the internal carotid immediately below the anterior clinoid process just as the latter vessel is passing through the dura mater. Entering the orbit through the optic foramen below and laterally to the optic nerve, it at once perforates the sheath of dura mater which is prolonged through the optic foramen on both artery and nerve. It then runs in a gentle curve with a lateral convexity below the optic nerve and lateral rectus, being here crossed by the nasociliary (nasal) nerve. Turning forward and upward, it passes over the optic nerve, to its medial side. Thence it runs obliquely beneath the superior rectus in front of the nasociliary (nasal) nerve under the lower border of the superior oblique, but above the medial rectus, and continues its course under the pulley for the superior oblique and reflected tendon of that muscle to the medial palpebral region, where it divides into the frontal and dorsal nasal branches.

Branches of the Ophthalmic Artery

The **branches of the ophthalmic artery** are:—(1) the lacrimal; (2) the supra-orbital; (3) the central artery of the retina; (4) the muscular; (5) the ciliary; (6) the posterior ethmoidal; (7) the anterior ethmoidal; (8) the medial palpebral; (9) the frontal; and (10) the dorsal nasal.

(1) **The lacrimal artery** [a. lacrimalis], is usually the first and often the largest branch of the ophthalmic. It arises between the superior and lateral rectus on the lateral side of the optic nerve from the ophthalmic, soon after that vessel has entered the orbit. At times it is given off from the ophthalmic, or from the middle meningeal artery outside the orbit, and then usually passes into that cavity through the superior orbital (sphenoidal) fissure. It runs forward along the lateral wall of the orbit with the lacrimal nerve, above the upper border of the lateral rectus, to the lacrimal gland, which it supplies. In this course it furnishes the following branches:—(*a*) **Recurrent,** one or more branches which pass backward through the superior orbital (sphenoidal) fissure, and anastomose with the lacrimal branch of the middle meningeal artery. The anastomosis is sometimes of large size, and then takes the chief share in the formation of the lacrimal artery. (*b*) **Muscular** branches, distributed chiefly to the lateral rectus. (*c*) **Zygomatic branches**—small twigs, which pass through the zygomatico-orbital (malar) canals, and anastomose with the orbital branch of the middle temporal, and with the transverse facial on the cheek. (*d*) **Lateral palpebral** arteries [aa. palpebrales laterales] which are distributed to the upper and lower eyelids and to the conjunctiva. (*e*) **Ciliary.** See Ciliary Arteries below.

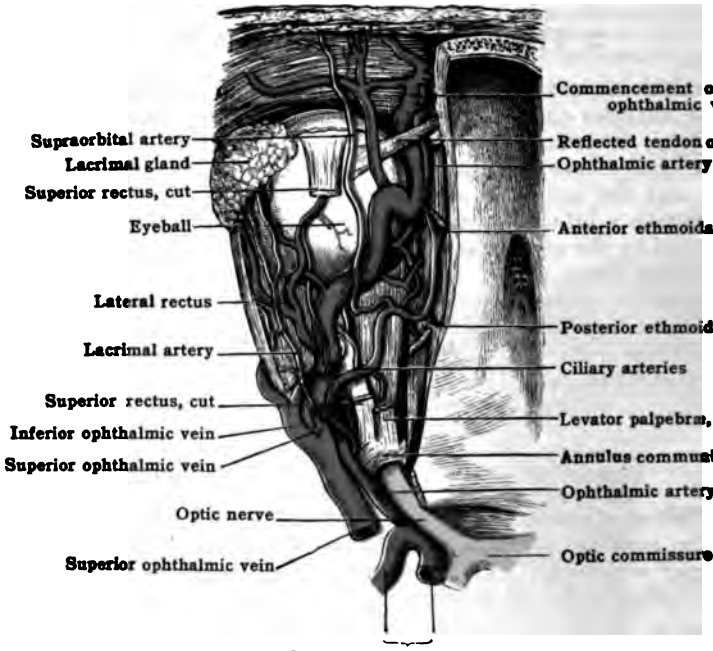
(2) **The supraorbital artery** [a. supraorbitalis] usually arises from the ophthalmic as the latter vessel is about to cross over the optic nerve. Passing upward to the medial side of the superior rectus and levator palpebræ, it runs along the upper surface of the latter muscle with the frontal nerve in the orbital fat, but beneath the periosteum, to the supraorbital notch. On emerging on the forehead beneath the orbicularis oculi, it divides into a superficial and a deep branch, the former ramifies between the skin and epicranius (occipitofrontalis), the latter between the epicranius and the pericranium. Both branches anastomose with the anterior branches of the superficial temporal, the angular branch of the external maxillary (facial), and the transverse facial artery. The branches of the supraorbital are:—(*a*) **periosteal,** to the periosteum of the roof of the orbit; (*b*) **muscular,** to the levator palpebræ and superior rectus; (*c*) **diploic,** given off as the artery is passing through the supraorbital notch and, entering a minute foramen at the bottom of the notch, is distributed to the diploë and frontal sinuses; (*d*) **trochlear,** to the pulley of the superior oblique; (*e*) **palpebral,** to the upper eyelid.

(3) **The arteria centralis retinæ,** a small but constant branch, comes off from the ophthalmic close to the optic foramen, and, perforating the optic nerve about 6 mm. (¼ in.) behind the globe, runs forward (in the substance of the nerve) to the eyeball, supplying the retina. Its further description is given in the section on the Eye.

(4) The **muscular** branches [rami musculares] are very variable in their origin an bution. They may be roughly divided into superior and inferior sets. Those of the set supply the superior oblique, the levator palpebræ, and superior rectus. The infer forward, between the optic nerve and the inferior rectus, supplying that muscle, the rectus, and the inferior oblique. From the muscular branches are given off the anterio arteries. (See CILIARY ARTERIES.)

(5) The **ciliary arteries** are divided into three sets:—The **short posterior**, the **long p** and the **anterior**. (i) The **short posterior** [aa. ciliares posteriores breves], five or six in n come off chiefly from the ophthalmic as it is crossing the optic nerve. They run forwar the nerve, dividing into twelve or fifteen small vessels, which perforate the sclerotic the entrance of the optic nerve, and are distributed to the choroid coat. (ii) The **long p** ciliary arteries [aa. ciliares posteriores longæ], usually two, sometimes three, in number, from the ophthalmic on either side of the optic nerve, and run forward with the short c

FIG. 499.—THE LEFT OPHTHALMIC ARTERY AND VEIN, VIEWED FROM ABOVE



the sclerotic. On piercing the sclerotic, they course forward, one on either side of th between the sclerotic and the choriod to the ciliary processes and iris. Their further tion is given under the anatomy of the EYE. (iii) The **anterior ciliary arteries** [aa. ci teriores] are derived from the muscular branches and from the lacrimal. They run to along the tendons of the recti, forming a zone of radiating vessels beneath the con Some of them, the **episcleral arteries** [aa. episclerales], perforate the sclerotic abou (¼ in.) behind the cornea, and supply the iris and ciliary processes. It is these vessel enlarged and congested in iritis, forming the circumcorneal zone of redness so charac that disease. They then differ from the tortuous vessels of the conjunctiva in that straight and parallel. The remainder constitute the **anterior conjunctival arteries** junctivales anteriores].

(6) The **posterior ethmoidal** artery [a. ethmoidalis posterior] (fig. 499) runs me tween the superior oblique and medial rectus, and, leaving the orbit by the posterior canal, together with the posterior ethmoidal branch of the nasociliary (nasal) ner the posterior ethmoidal cells, whence it passes through a transverse slit-like apertur the sphenoid bone and cribriform plate of the ethmoid bone into the cranium. It gi ethmoidal branches to the posterior ethmoidal cells; (*b*) **meningeal branches to the d** lining the cribriform plate; and (*c*) **nasal** branches, which pass through the cribriform the superior meatus and upper nasal conchæ, and anastomose with the nasal branch sphenopalatine artery (fig. 496).

(7) The **anterior ethmoidal** artery [a. ethmoidalis anterior] (figs. 496, 499), a larg than the posterior ethmoidal, arises in front of the latter, passes medially between th oblique and medial rectus, and, leaving the orbit through the anterior ethmoidal cana pany with the anterior ethmoidal nerve, enters the cranial cavity. After running a tance beneath the dura mater on the cribriform plate of the ethmoidal bone, it passe nose through the horizontal slit-like aperture by the side of the crista galli. Its branch passes along the groove on the under surface of the nasal bone, and emerges on between the bone and lateral cartilage, terminating in the skin of that organ. It giv following branches in its course:—(i) **Ethmoidal**, to the anterior ethmoidal cells; (ii

ngeal artery, [a. meningea anterior] to the dura mater of the anterior fossa; (iii) nasal hes to the middle meatus and anterior part of the nose; (iv) frontal branches to the frontal ss; (v) cutaneous, or terminal branches to the skin of the nose.

i) The medial palpebral arteries [aa. palpebrales mediales] arise either separately or by a mon trunk from the ophthalmic artery opposite the pulley for the superior oblique. They one above and one below, the medial palpebral ligament and then skirt along the upper and r eyelids respectively, near the free margin between the palpebral tarsi and the orbicularis le, and form a superior and an inferior tarsal arch [arcus tarseus superior, inferior] by bomosing with the lateral palpebral branches of the lacrimal. The upper medial palpebral y anastomoses with the supraorbital artery and orbital branch of the temporal artery; the r with the infraorbital, the angular branch of the external maxillary (facial), and the trans- facial arteries. A branch from the lower palpebral artery passes with the ductus naso- malis as far as the inferior meatus. Small twigs, the posterior conjunctival arteries [aa. nctivales posteriores], are also given to the caruncula lacrimalis and conjunctiva.

9) The frontal artery [a. frontalis] the upper of the terminal branches of the ophthalmic, es the superior tarsus at the medial angle of the orbit, passes upward over the frontal bone ath the orbicularis oculi, supplies the structures in its neighborhood. It anastomoses its fellow of the opposite side, with the supraorbital, and with the anterior division of the rficial temporal artery.

10) The dorsal nasal [a. dorsalis nasi], the lower of the terminal branches of the ophthalmic, s the orbit at the medial angle by perforating the tarsus above the medial palpebral liga- t. It then descends along the dorsum of the nose, beneath the integuments, and anasto- s with the angular and lateral nasal branches of the external maxillary (facial). It gives lacrimal branch as it crosses the lacrimal sac.

3. THE POSTERIOR COMMUNICATING ARTERY

The **posterior communicating** artery [a. communicans posterior] (fig. 500) s from the internal carotid just before the division of that vessel into the rior and middle cerebral arteries; occasionally it arises from the middle bral.

t is as a rule a slender vessel which runs backward over the optic tract and pedunculus ori along the side of the hippocampal gyrus to join the posterior cerebral. At times, how- it is of considerable size, and contributes chiefy to form the posterior cerebral, the portion e latter vessel between the basilar and posterior communicating being then as a rule reduced mere rudiment. It gives off the following branches:—(*a*) the **hippocampal**, to the gyrus at name; and (*b*) the **middle thalamic**, to the optic thalamus.

4. THE CHOROID ARTERY

The **choroid** artery [a. chorioidea] is a small but constant vessel which arises rule from the back part of the internal carotid just laterally to the origin of the erior communicating.

passes backward on the optic tract and the pedunculus cerebri, at first lying parallel to and e lateral side of the posterior communicating artery. It then dips under the edge of the ate gyrus and, entering the choroid fissure at the lower end of the inferior cornu of the l ventricle, ends in the choroid plexus and supplies the hippocampus and fimbria.

5. THE ANTERIOR CEREBRAL ARTERY

The **anterior cerebral** artery [a. cerebri anterior] (figs. 500, 503), one of the inal branches into which the internal carotid divides in the lateral fissure ire of Sylvius), supplies a part of the cortex of the frontal and parietal lobes e brain and a small part of the basal ganglia. It passes at first anteriorly and ially across the anterior perforated substance between the olfactory and optic es to the longitudinal fissure where it approaches its fellow of the opposite side communicates with it by a short transverse trunk, about five mm. long, rn as the **anterior communicating** artery [a. communicans anterior] (fig. 500). ard from this point it runs side by side with its fellow in the longitudinal re round the genu of the corpus callosum; then, turning backward, it continues g the upper surface of that commissure, and, after giving off large branches to rontal and parietal lobes, anastomoses with the posterior cerebral artery.

6. THE MIDDLE CEREBRAL ARTERY

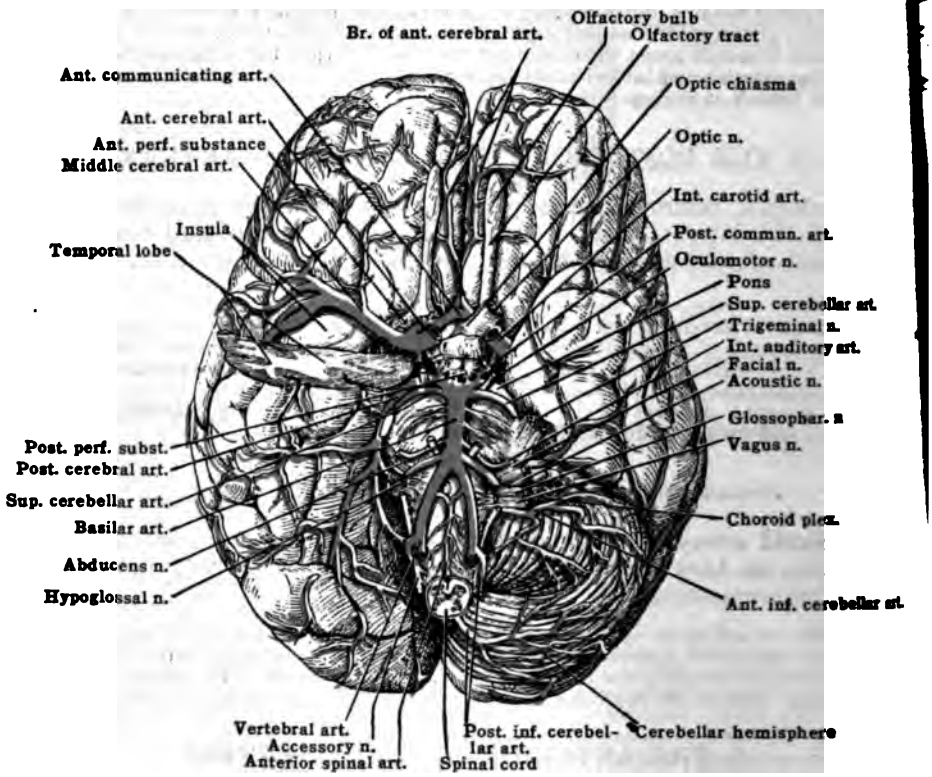
The **middle cerebral** artery [a. cerebri media] (figs. 500, 504), the larger of the inal divisions of the internal carotid, supplies the basal ganglia and a part of

the cortex of the frontal and parietal lobes. It passes obliquely upward and lateralward into the lateral (Sylvian) fissure, and opposite the insula divides into cortical branches.

Circulus Arteriosus

The four arteries which supply the brain, namely, the two internal carotid arteries and the two vertebrals (which unite to form the basilar), form a remarkable anastomosis at the base of the brain known as the circle of Willis [circulus arteriosus (Willisi)]. This so-called circle, which has really the form of a heptagon, is formed, **in front,** by the anterior communicating artery uniting the anterior cerebral arteries of opposite sides; **laterally,** by the internal carotids and the posterior communicating arteries stretching between these and the posterior cerebrals; **behind,** by the two posterior cerebrals diverging from the bifurcation of the basilar artery (fig. 500).

Fig. 500.—The Arteries at the Base of the Brain.



The free anastomosis between the two internal carotid and the two vertebral arteries serves to equalize the flow of blood to the various portions of the brain. Should one or more of the arteries entering into the formation of the circle be temporarily or permanently obstructed, blood would be transmitted to the deprived part through some of the collateral arteries. Thus, if one carotid or one vertebral were obstructed, the parts supplied by that vessel would receive their blood through the circle from the remaining pervious vessels. One vertebral artery alone has indeed been found equal to the task of carrying sufficient blood for the supply of the brain after ligature of both the carotids and the other vertebral artery. Further, the circulus arteriosus is the only medium of communication between the ganglionic or central and the peripheral or cortical branches of the cerebral arteries, and between the various ganglionic branches themselves. The ganglionic and the cortical branches form separate and distinct systems, and do not anastomose with each other; the ganglionic arteries, moreover, are so-called end-vessels, and do not anastomose with the neighboring ganglionic branches. The three cerebral arteries, anterior, middle, and posterior may be regarded as branches of the circulus arteriosus (circle of Willis). (For details concerning the distribution of the cerebral arteries see p. 602.)

THE SUBCLAVIAN ARTERY

The **subclavian artery** on the right side [a. subclavia **dextra**] arises at the bifurcation of the innominate opposite the upper limit of the right sternoclavicular articulation. On the left side it arises from the arch of the aorta, and, as far as the *medial border* of the scalenus anterior, is situated deeply in the chest.

beyond the medial border of the scalenus anterior the artery has the same rela- s on both sides. It courses from this point beneath the clavicle in a slight e across the root of the neck to the lateral border of the first rib, there to end ie axillary artery. Thus the course of the artery in the neck will be indicated a line drawn from the sternoclavicular joint in a curve with its convexity ard to the middle of the clavicle. The height to which the artery rises in the : varies. It is perhaps most commonly about 1.2 cm. (½ in.) above the clav-

If the curved line above mentioned is drawn to represent part of the cir- ference of a circle having its center at a point on the lower margin of the icle 3.7 cm. (1½ in.) from the sternal end of that bone, the line of the artery be sufficiently well indicated for all practical purposes. In its course the ry arches over the dome of the pleura and gains the groove on the upper ace of the first rib by passing between the scalenus anterior and medius mus- . The artery is accompanied by the subclavian vein, the latter vessel lying ront of the scalenus anterior, anterior to the artery, and on a slightly lower ie. .

The subclavian artery is divided into three portions—as it lies medial to, pos- or to, or lateral to, the scalenus anterior muscle.

THE FIRST OR THORACIC PORTION OF THE LEFT SUBCLAVIAN ARTERY

The left subclavian artery [a. subclàvia sinistra] (fig. 501) arises from the left of the arch of the aorta. The first part of the left subclavian is consequently ger than the first part of the right, which arises at the bifurcation of the ominate artery. The artery at its origin is situated deeply in the thorax, as it arises from the aorta is on a plane posterior to and a little to the left of thoracic portion of the left common carotid. It first ascends almost vertically at the root of the neck curves laterally over the apex of the left pleura and to the interval between the anterior and middle scalene muscles. Beyond medial border of the scalenus anterior—that is, in the second and third ions of its course—its relations are similar to those of the right subclavian ry.

elations.—In front the left subclavian artery is covered by the left pleura and lung, and superficially by the sternothyroid, sternohyoid, and sternomastoid muscles. It is crossed le above its origin by the left innominate vein, and higher in the neck near the scalenus ior by the internal jugular, vertebral, and subclavian veins. The phrenic nerve crosses rtery medially to the scalenus anterior, and then descends parallel with it, but on an ior plane, to cross the arch of the aorta. The vagus nerve descends parallel with the y between it and the left common carotid, coming into contact with its anterior surface before crossing the arch of the aorta. The left cervical cardiac nerves of the sympathetic descend in front of it on their way to the cardiac plexus. The left *ansa subclavia* also loops ont of the subclavian artery. The left common carotid is situated anteriorly and to its The thoracic duct arches over the artery just medially to the scalenus anterior, to y its contents into the confluence of the internal jugular and subclavian veins (fig. 486). ehind and somewhat medial to it are the esophagus, thoracic duct, inferior cervical gang- of the sympathetic, longus colli muscle, and vertebral column. To some extent it is over- d posteriorly by the left pleura and lung. On its right side are the trachea and the rent (laryngeal) nerve, and, higher up, the esophagus and thoracic duct. On its left side he left pleura and lung.

Branches.—The vertebral, internal mammary, and thyrocervical trunk roid axis) usually arise from the first portion on the left side. (See p. 673.)

THE FIRST PORTION OF THE RIGHT SUBCLAVIAN ARTERY

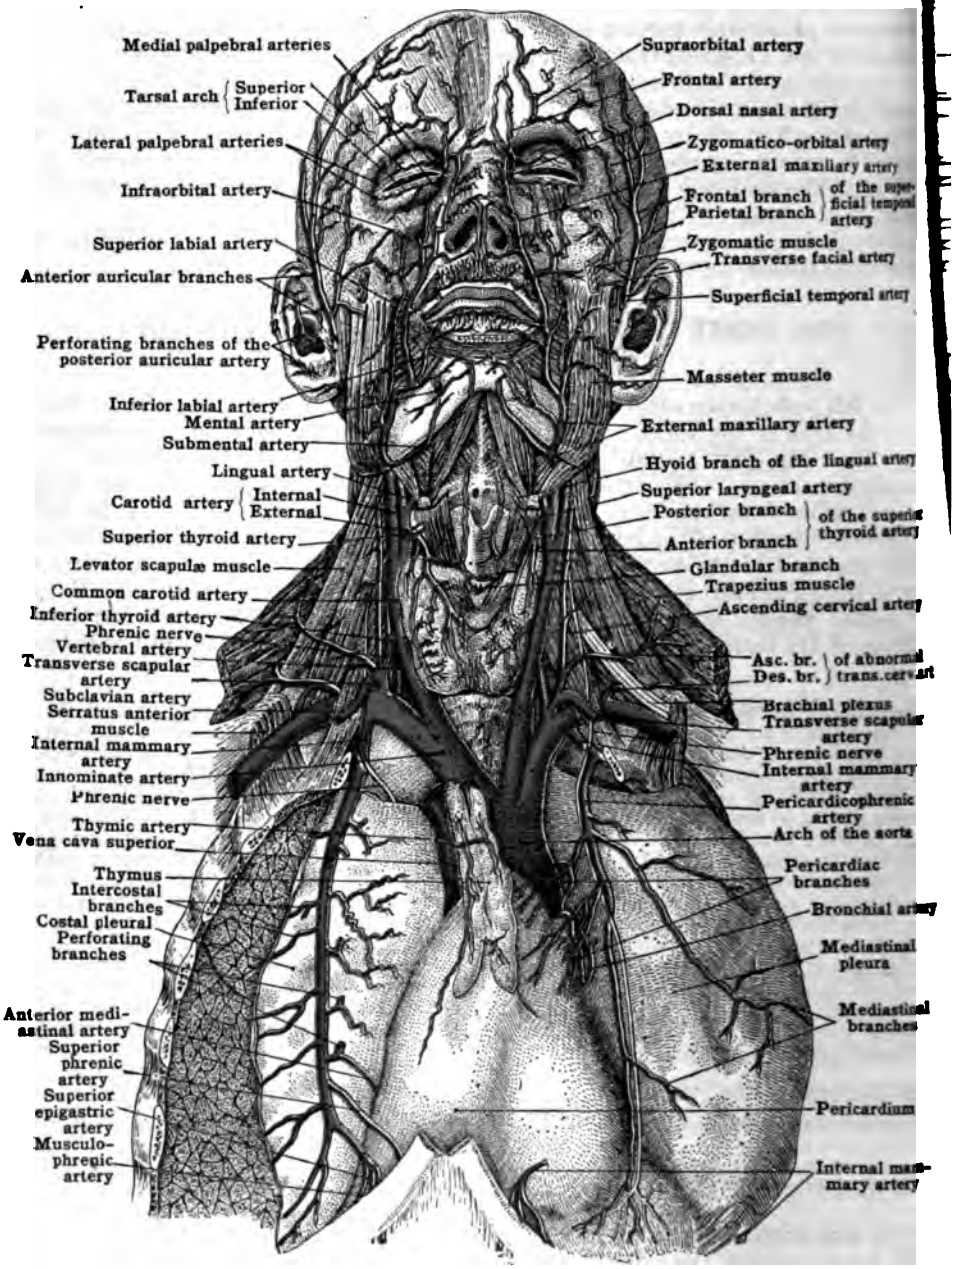
The first portion of the right subclavian artery (fig. 501) extends from its origin ie bifurcation of the innominate, behind the upper margin of the right sterno- icular joint, upward and laterally in a gentle curve over the apex of the right and pleura to the medial border of the scalenus anterior. It measures about . (1¼ in.). In this course it ascends in the neck a variable distance above the icle, deeply placed and surrounded by important structures.

elations.—In front it is covered by the integument, the superficial fascia, the platysma, nterior layer of the deep fascia, the clavicular origin of the sternomastoid, the sternohyoid sternothyroid muscles, and the deep cervical fascia. It is crossed by the commencement

of the innominate, by the internal jugular, and by the vertebral veins; and, in a mediolateral direction, by the vagus and phrenic nerves, and the superior cardiac branches of the sympathetic nerve. A loop of the sympathetic nerve itself also crosses the artery, and forms with the trunk of the sympathetic a ring around the vessel known as the **ansa subclavia** (annulus of Vieussens).

Behind, but separated from the artery by a cellular interval, are the longus colli muscle, the transverse process of the seventh cervical or first thoracic vertebra, the main chain of the

FIG. 501.—THE SUBCLAVIAN ARTERY. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



sympathetic nerve, the inferior cardiac nerves, the recurrent (laryngeal) nerve, and the apex of the right lung and pleura.

Below, it is in contact with the pleura and lung and the loop of the recurrent (laryngeal) nerve, which winds round the artery from the vagus and ascends behind it to the larynx. The subclavian vein is below the artery and on an anterior plane.

Branches.—The vertebral, internal mammary, superficial cervical, and thyro-cervical trunk (thyroid axis) arise from this part of the vessel on the right side.

Not uncommonly a small aberrant artery also takes origin from this portion of the artery descends to the left behind the esophagus to join a branch of the aorta opposite the third urth thoracic vertebra. This vessel is probably the remains of the right dorsal aorta.

THE SECOND PORTION OF THE SUBCLAVIAN ARTERY

The second portion of the subclavian artery lies behind the scalenus anterior scle. It measures about 2 cm. (¾ in.) in length and here reaches highest in the ck. The subclavian vein is separated from the artery by the scalenus anterior, d lies on a lower and anterior plane (fig. 507).

Relations.—**In front** it is covered by the skin, superficial fascia, platysma, anterior layer deep fascia, the clavicular origin of the sternomastoid, posterior layer of deep fascia, and the scalenus anterior. The phrenic nerve—which, in consequence of its oblique course idially downward, crosses a portion of both the first and second part of the subclavian—is arated from the second portion by the scalenus anterior muscle, as is also the subclavian in which courses on a somewhat lower plane. **Behind** the artery are the apex of the pleura d lung, and a portion of the scalenus medius; also the scalenus minimus (partially or entirely rous, known as Sibson's fascia, see. p. 389). **Above** is the brachial plexus. **Below** are the ura and lung.

One branch only—the costocervical trunk (superior intercostal)—is, as a le, given off from this portion of the subclavian; occasionally the transverse rvical or the descending branch of the transverse cervical (posterior scapular tery) arises from it.

THE THIRD PORTION OF THE SUBCLAVIAN ARTERY

The third portion of the subclavian artery extends from the lateral margin of scalenus anterior muscle to the lateral border of the first rib. It is more superal than either the first or second portion and is in relation with less important uctures. It is the longest of the three portions of the subclavian artery, and in a triangle—the subclavian triangle—bounded by the sternomastoid, the ohyoid, and the clavicle (fig. 488).

As a rule it gives off no branches. The descending branch of the transverse cervical artery es from it sometimes however, in which case the ascending branch arises from the thyrorical trunk. (See fig. 501.)

Relations.—**In front** it is covered by skin, superficial fascia, platysma and the supraclavicular ves of the cervical plexus; the anterior layer of deep fascia which descends from the omoid to the clavicle; and the posterior layer of deep fascia which descends from the omohyoid the first rib and passes over the scalenus anterior and phrenic nerve. Between the two ers of fascia is a variable amount of cellular tissue and fat, and running in this is the transse scapular (suprascapular) artery. The subclavian is crossed by this artery unless the arm rawn well downward. Close to the lateral margin of the sternomastoid, the external jugu- vein pierces the fascia, and crosses the subclavian artery to open into the subclavian vein. this vein lies between the two layers of fascia, it receives on its lateral side the transverse pular (suprascapular), transverse cervical, and other veins of the neck, which together form lexus of large veins in front of the artery. The nerve to the subclavius, and, when present, accessory branch from this nerve to the phrenic, also here cross in front of the artery. In y muscular subjects the clavicular head of the sternomastoid may be larger than usual, and such a case will form one of the coverings of the artery.

Behind, the artery is in contact with the scalenus medius, and with the lower trunk of the achial plexus.

Below, the artery rests in the posterior of the two grooves on the upper surface of the first

Above is the brachial plexus of nerves and the posterior belly of the omohyoid muscle. e trunk formed by the fifth and sixth cervical nerves is also above the artery, but on a somet anterior plane. The seventh cervical nerve is close to the vessel, and has been mistaken the artery in the application of a ligature.

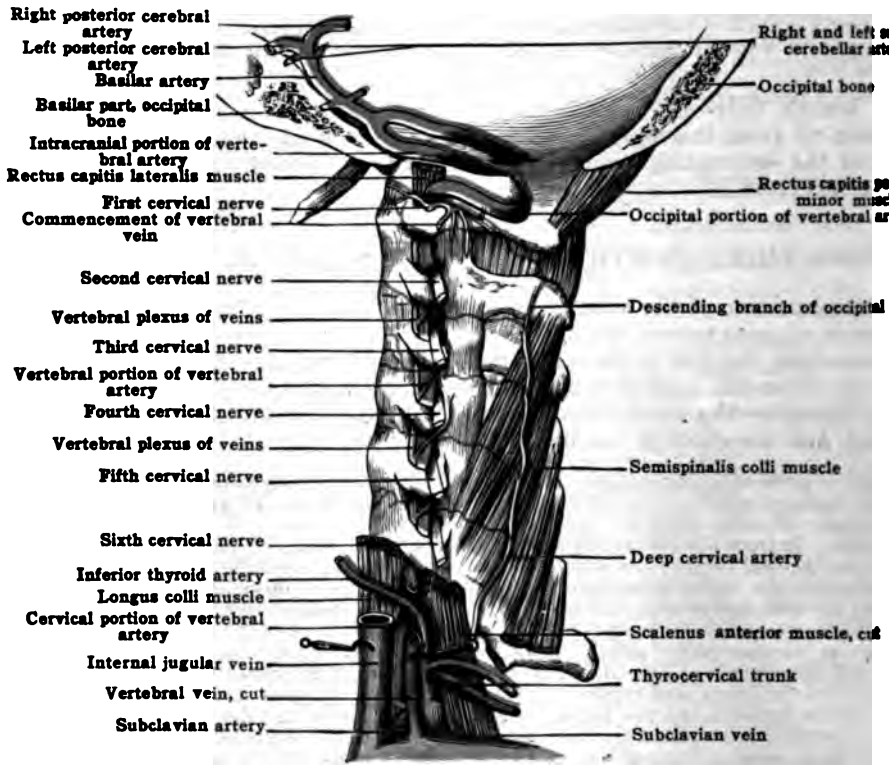
The branches of the subclavian artery will be described in the following der:—(1) The vertebral artery; (2) the thyrocervical trunk; (3) the internal ammary artery; (4) the costocervical trunk.

1. THE VERTEBRAL ARTERY

The vertebral artery [a. vertebralis] (fig. 502) the first, largest, and most conant branch, arises from the upper and posterior part of the first portion of the bclavian; on the right side, about 2 cm. (¾ in.) from the origin of the latter ves-

sel from the innominate, on the left side, from the most prominent part of the arch of the subclavian, close to the medial edge of the scalenus anterior muscle. It first ascends vertically to the foramen transversarium of the sixth cervical vertebra, and, having passed through that foramen and those of the next succeeding cervical vertebræ as high as the epistropheus (axis), it turns laterally and then ascends to reach the foramen in the transverse process of the atlas; after passing through that foramen it turns backward behind the articular process, lying in the groove on the posterior arch of the atlas. It next pierces the posterior occipitoatlantoid membrane and the dura mater, and enters the cranium through the foramen magnum. Here it passes upward, at first lying by the side of the medulla, then in front of that structure, and terminates at the lower portion of the pons by anastomosing with the vertebral of the opposite side to form the basilar

FIG. 502.—THE LEFT VERTEBRAL ARTERY. (Walsham.)
The internal jugular and vertebral veins are hooked aside to expose the artery.



The vertebral artery may be divided for purposes of description into four parts: the **first,** or **cervical,** extending from its origin to the transverse process of the sixth cervical vertebra; the **second,** or **vertebral,** situated in the foramina transversaria; the **third,** or **occipital,** contained in the suboccipital triangle; and the **fourth,** or **intracranial,** within the cranium.

The first or cervical portion.—The artery here lies between the scalenus anterior and longus colli muscles. In front it is covered by the vertebral and internal jugular veins, and is crossed by the inferior thyroid artery, and on the left side, in addition, by the thoracic duct, which runs over it mediolaterally. Behind, the artery lies on the transverse process of the seventh cervical vertebra and the sympathetic nerve. To its medial side is the longus colli. To its lateral side is the scalenus anterior. It gives off as a rule no branch in this part of its course. Occasionally, however, a small branch passes into the foramen transversarium of the seventh cervical vertebra.

The second or vertebral portion.—As the artery passes through the foramina transversaria, it is surrounded by a plexus of veins and by branches of the sympathetic nerve. The cervical nerves lie behind it. Between the transverse processes it is in contact with the intertransverse muscles.

The third or occipital portion.—The artery here lies in the suboccipital triangle, bounded by the superior oblique, inferior oblique, and rectus capitis posterior major muscles. As it winds round the groove on the atlas, it has the rectus capitis lateralis, the articular process, the posterior occipitoatlantoid membrane in front of it; the superior oblique, the rectus

apitis posterior major, and the semispinalis capitis (complexus) **behind** it. Separating it **om the arch of the atlas**, is the first cervical or suboccipital nerve.

The **fourth** or **intracranial portion** extends from the aperture in the dura mater to the **ower** border of the pons, where it pierces the arachnoid and unites with its fellow to form the **asilar** artery. It here winds round from the side to the front of the medulla, lying in the **ertebral** groove on the basilar part of the occipital bone. In this course it passes beneath **the** first process of the ligamentum denticulatum, and between the hypoglossal nerve in front, **and** the anterior roots of the suboccipital nerve behind.

Branches of the Vertebral Artery

The first part of the vertebral artery gives no branches. The second and third parts give off *muscular* branches to the semispinalis and posterior recti and oblique muscles. The second part also gives off five or six, (1) Spinal branches. The fourth part gives off the following: (2) Posterior meningeal; (3) posterior spinal; (4) anterior spinal; and (5) posterior inferior cerebellar.

(1) The **spinal** branches [rami spinales] run through the intervertebral foramina into the **vertebral canal**, and there divide into two branches: one of which ramifies on the backs of **the bodies of the cervical vertebræ**; while the other runs along the spinal nerves, supplies the **cord** and its membranes, and anastomoses with the arteries above and below.

(2) The **meningeal** [ramus meningeus] is a small branch given off as the vertebral artery pierces the dura mater to enter the cranium. It supplies the bone and dura mater of the posterior fossa of the skull, and anastomoses with the posterior meningeal branches derived from the occipital and ascending pharyngeal arteries. It gives branches to the falx cerebelli.

(3) The **posterior spinal** artery [a. spinalis posterior] runs downward obliquely along the side of the medulla to the back of the cord, down which it passes behind the roots of the spinal nerves, being reinforced by spinal branches accompanying these nerves, in the neck, the thoracic, and in the lumbar region. It can be traced as low as the end of the spinal cord.

(4) The **anterior spinal** artery [a. spinalis anterior] comes off from the vertebral a little below its termination in the basilar artery. Descending with a medial slant in front of the medulla, it unites on a level with the foramen magnum with its fellow of the opposite side. The single vessel thus formed runs downward in front of the spinal cord beneath the pia mater as far as the termination of the cord, being reinforced by the spinal branches on the way down. The spinal arteries are described in detail with the anatomy of the spinal cord.

(5) The **posterior inferior cerebellar** [a. cerebelli inferior posterior] (fig. 500)—the largest branch of the vertebral—arises from that vessel just before it joins its fellow to form the basilar artery. At times it may come off from the basilar itself. It runs, at first laterally across the restiform body between the origin of the vagus and hypoglossal nerves, and, descending toward the vallecula, there divides into two branches, medial and lateral. (*a*) The *medial branch* runs backward between the vermis and the lateral hemisphere of the cerebellum. It supplies the vermis, and anastomoses with the artery of the opposite side, and with the superior vermian of the superior cerebellar. (*b*) The *lateral branch* runs laterally and, ramifying over the under surface of the cerebellar hemisphere, supplies its cortex and anastomoses along its lateral margin with the superior cerebellar arteries.

From the undivided trunk of the posterior inferior cerebellar artery branches are given to the **medulla oblongata**, supplying the choroid plexus and the fourth ventricle.

THE BASILAR ARTERY

The **basilar artery** [a. basilaris] is formed by the confluence of the right and left vertebral arteries, which meet at an acute angle at the lower border of the pons. It runs forward and upward in a slight groove in the middle line of the pons, and divides at the upper border of that structure at the level of the tentorial notch into the two posterior cerebral arteries, which take part in the formation of the circle of Willis (fig. 500).

Branches of the Basilar Artery

The branches of the basilar artery are:—(1) Pontine; (2) internal auditory; (3) anterior inferior cerebellar; (4) superior cerebellar; (5) posterior cerebral.

(1) The **pontine** branches [rami ad pontem] are numerous small vessels which come off at **right angles** on either side of the basilar artery, and, passing laterally over the pons, supply that **structure** and adjacent parts of the brain.

(2) The **internal auditory** artery [a. auditiva interna], a long slender vessel, accompanies **the auditory** nerve into the internal acoustic meatus (figs. 500, 555). It here lies between the **facial and auditory nerves**, and at the bottom of the meatus passes into the internal ear, and **anastomoses with the other auditory** arteries. (See INTERNAL EAR.)

(3) The **anterior inferior cerebellar** [a. cerebelli inferior anterior] arises from the basilar **soon after its origin, passes** laterally and backward across the pons, and then over the brachium **pontis to the front part** of the under surface of the cerebellum. It anastomoses with the **posterior inferior cerebellar** artery (fig. 500).

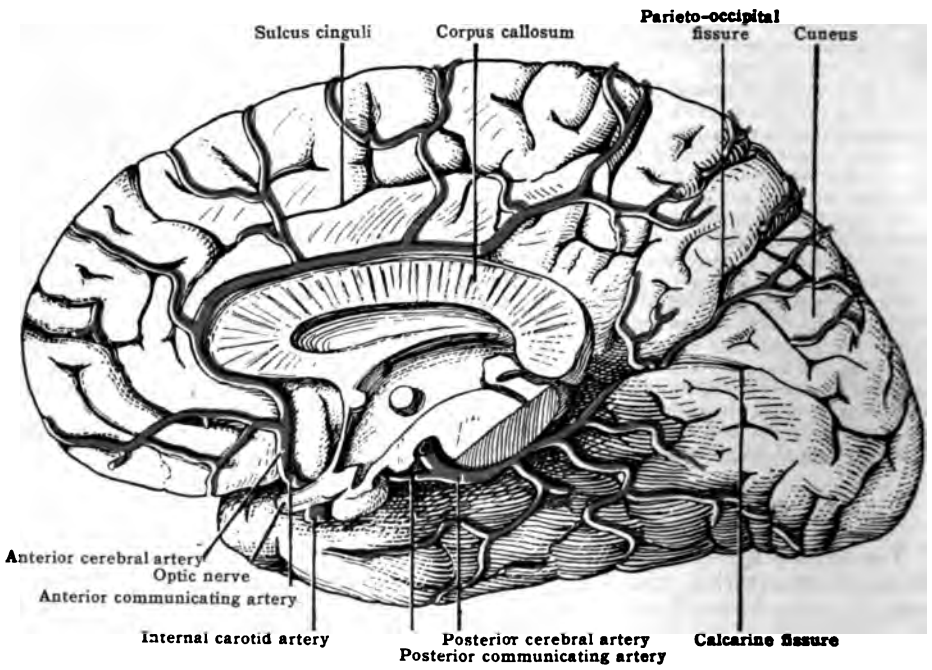
(4) The **superior cerebellar** [a. cerebelli superior] comes off from the basilar immediately behind its bifurcation into the posterior cerebral arteries. It courses laterally and backward over the pons, in a curve roughly corresponding to that of the posterior cerebral artery, from which it is separated by the third cranial nerve; but, soon sinking into the groove between the pons and the pedunculus cerebri, it curves round the latter onto the upper surface of the cerebellum, lying nearly parallel to the fourth nerve. Here it divides into two branches, medial and lateral. (*a*) The *medial branch* courses backward along the superior vermis, anastomosing with its fellow of the opposite side, and, at the posterior notch of the cerebellum, with the inferior vermian branch of the posterior inferior cerebellar artery. (*b*) The *lateral* runs to the circumference of the cerebellum, anastomosing with the lateral branch of the inferior posterior cerebellar artery.

Branches are given off from the main trunk of the superior cerebellar artery, or from its medial branch to the anterior velum (valve of Vieussens), the corpora quadrigemina, the pineal body, and the choroid plexus.

(5) The **posterior cerebral** arteries [aa. cerebri posteriores] are the two terminal branches into which the basilar bifurcates at the upper border of the pons, immediately behind the posterior perforated substance. Each artery runs at first laterally and a little forward across the pedunculus cerebri immediately in front of the third nerve, which separates it from the superior cerebellar artery. After receiving the posterior communicating artery, which runs backward from the internal carotid, the posterior cerebral turns backward onto the lower surface of the cerebral hemisphere, where it breaks up into branches for the supply of the temporal and occipital lobes.

The **branches of the posterior cerebral artery** are described below in connection with those of the other cerebral arteries.

FIG. 503.—THE ARTERIES OF THE MEDIAL SURFACE OF THE BRAIN. (After Spalteholz.)



DISTRIBUTION OF THE CEREBRAL ARTERIES

Although the brain receives its blood supply from two distinct sources, namely, from the internal carotids and from the vertebrals, it is convenient to consider together the distribution of the various cerebral branches derived from these stems. The formation of the circulus arteriosus (circle of Willis) and the origin of the anterior, middle and posterior cerebral arteries have already been described (pp. 595, 596). The detailed distribution of these vessels will now be considered. In general, their branches may be divided into *central* or *ganglionic* and *peripheral* or *cortical*.

The **anterior cerebral artery** has but a limited central distribution. It gives off a few inconstant branches which enter the anterior perforated substance and supply the anterior end of the caudate nucleus. One or two of these run to the corpus callosum and septum pellucidum. The **anterior communicating** branch is a transverse trunk which connects the two arteries and thereby completes the circulus arteriosus in front. It lies in front of the optic chiasm, and varies considerably in length and size. It may give off some of the branches to the anterior perforated substance. The **cortical branches** supply the gyrus rectus, the olfactory lobe and a part of the orbital gyri on the ventral surface. On the medial surface branches supply the cortex as far back as the parieto-occipital fissure. These branches are given off as the artery

round the corpus callosum and some of them curve over onto the lateral surface and he superior and middle temporal convolutions. Branches from the anterior cerebral lso supply the corpus callosum (fig. 503).

middle cerebral artery gives off most of the branches to the basal ganglia and supplies ter part of the lateral surface of the brain. It runs through the lateral fissure (fissure ns) (fig. 504). The *branches* of the middle cerebral include the following:

central branches are:—(i) The **caudate,** two or three small branches, which arise from lial aspect of the artery and pass through the medial part of the floor of the lateral fissure of Sylvius) to the head of the caudate nucleus. (ii) The **anterolateral** are numerous rteries which pass through the anterior perforated substance and supply the caudate (except its head), the internal capsule, and part of the optic thalamus. (iii) The **ostriate,** a larger branch of the anterolateral set, passes through a separate aperture in ral part of the anterior perforated substance, runs upward between the lenticular nucleus, t supplies, and the external capsule, perforates the internal capsule, and terminates in the nucleus. It has been so frequently found ruptured in apoplexy that it is called by t the 'artery of cerebral hemorrhage.' (iv) Sometimes a more or less distinct branch, **enticulo-optic,** is distributed to the lateral and hinder portion of the lenticular nucleus lateral portion of the optic thalamus.

cortical branches come off opposite the insula. They supply the insula, the inferior gyri, the central gyri (anterior and posterior), the parietal lobules, superior and infe- supramarginal, angular, and superior temporal gyri.

posterior cerebral give off both central and cortical branches. The **central branches posteromedial,** posterior choroid, and the posterolateral. The **posteromedial** enter the r perforated substance and supply the medial portion of the optic thalamus, and the

Middle cerebral artery

f the third ventricle; the **posterior choroid** pass through the transverse fissure to the tela idea (velum interpositum) and chorioid plexus; the **posterolateral** run to the posterior f the optic thalamus and give branches to the cerebral peduncles and the corpora gemina.

e cortical branches of the posterior cerebral supply the entire occipital lobe and all of the ral lobe except the superior temporal gyrus (fig. 503).

regard to the cerebral arteries in general it may be said that there is no anastomosis en the cortical and central branches, the two forming distinct and separate systems. rtical may or may not anastomose with each other, but the communication between the oring cortical branches is seldom sufficient to maintain the nutrition of an area when sel that normally supplies it is obstructed. The central branches are so-called end- and do not anastomose with each other. Hence obstruction of the middle cerebral leads to softening of the area supplied by its central branches, but not always to softening region supplied by its cortical branches. Indeed, the cortical region may escape com-, although the central area is irreparably disorganized. The gross anastomosis of the ior cerebral with the anterior cerebral arteries through the circulus arteriosus has already lescribed (p. 596). To sum up the distribution of the cerebral arteries, the branches of are divided into the central, or ganglionic and the peripheral or cortical. The central

branches arise at the commencement of the cerebral arteries about the circulus arterio the cortical are derived chiefly from the termination of these vessels.

(A) The **central branches** are divided into four sets—two medial and two la The **two medial** are—(1) The **anteromedial,** which arise from the anterior cerebral anterior communicating, and supply the fore end of the caudate nucleus, and (2) the **medial,** which arise from the posterior cerebral and supply the medial part of the optic and neighboring wall of the third ventricle. 2. The **two lateral** are:—(1) The **ante** arise from the middle cerebral, and, passing through the anterior perforated substanc the lenticular nucleus, the posterior part of the caudate nucleus, the internal and capsules, and the lateral part of the optic thalamus. (2) The **posterolateral** arise posterior cerebral, and supply the hinder part of the optic thalamus, the pedunculus cer the corpora quadrigemina.

(B) The **cortical branches** ramify in the pia mater, giving off branches to the cort stance, some of which extend through it to the underlying white substance.

It will be seen that the middle cerebral supplies the somesthetic area of the co also supplies the cortical auditory center, and, in part, the higher visual center. The cerebral supplies only a small part of the somesthetic area, namely, the part of the l that occupies the paracentral lobule and the highest part of the anterior central gyr posterior cerebral supplies the visual path from the middle of the tract backward, and vision center in the occipital lobe. It supplies also the corpora quadrigemina and the part of the internal capsule.

The branches which supply the cerebellum and brain stem are described in connect the vertebrals on page 601.

2. THE THYROCERVICAL TRUNK

The **thyrocervical trunk** [truncus thyreocervicalis] or **thyroid axis** aris the upper and front part of the subclavian artery, usually opposite the i mammary, and near the medial margin of the scalenus anterior. It is thick trunk, and divides almost immediately into three radiating bra namely, the **inferior thyroid,** the **transverse scapular,** and the **transverse** figs. 489, 501). It may give off also the **ascending cervical.**

THE INFERIOR THYROID ARTERY

The **inferior thyroid** artery [a. thyreoidea inferior] is the largest of th branches into which the thyrocervical trunk (thyroid axis) divides, a arise in a common trunk with the transverse scapular, or as a direct branc subclavian. It ascends tortuously passing medially in front of the v artery, the recurrent (laryngeal) nerve and the longus colli muscle, and the common carotid and the sympathetic nerve or its middle cervical g to the thyroid gland, where it anastomoses with the superior thyroid art the inferior thyroid of the opposite side.

The branches of the inferior thyroid artery are:—(1) Muscular; (2) eso and pharyngeal; (3) tracheal; (4) inferior laryngeal; (5) glandular; and cending cervical.

(1) The **muscular** branches supply the scalenus anterior, longus colli, sternohyoid thyroid, and omohyoid muscles, and the inferior constrictor muscle of the pharynx.

(2) The **esophageal and pharyngeal** branches [rami œsophagei et pharyngei] of th thyroid artery supply the esophagus and pharynx and anastomose with the othe supplying those structures.

(3) The **tracheal** branches [rami tracheales] ramify on the trachea, where they an with the tracheal branches of the superior thyroid and bronchial arteries.

(4) The **inferior laryngeal** artery [a. laryngea inferior] passes along the trachea to of the cricoid cartilage in company with the recurrent (laryngeal) nerve. It enters t beneath the inferior constrictor. Its further distribution in that organ is descri LARYNX.

(5) The **glandular** branches [rami glandulares] supply the thyroid gland.

(6) The **ascending cervical** artery [a. cervicalis ascendens] (figs. 489, 501) is given the thyrocervical trunk or from the inferior thyroid as that vessel is passing beneath th sheath. It ascends between the scalenus anterior and the longus capitis (rectus capiti major), lying parallel and medial to the phrenic nerve and behind the internal jug It anastomoses with the vertebral, ascending pharyngeal, and occipital arteries, and branches to the deep muscles of the neck [rami musculares], to the spinal canal [rami and to the phrenic nerve. Two veins accompany the ascending cervical artery and e innominate vein.

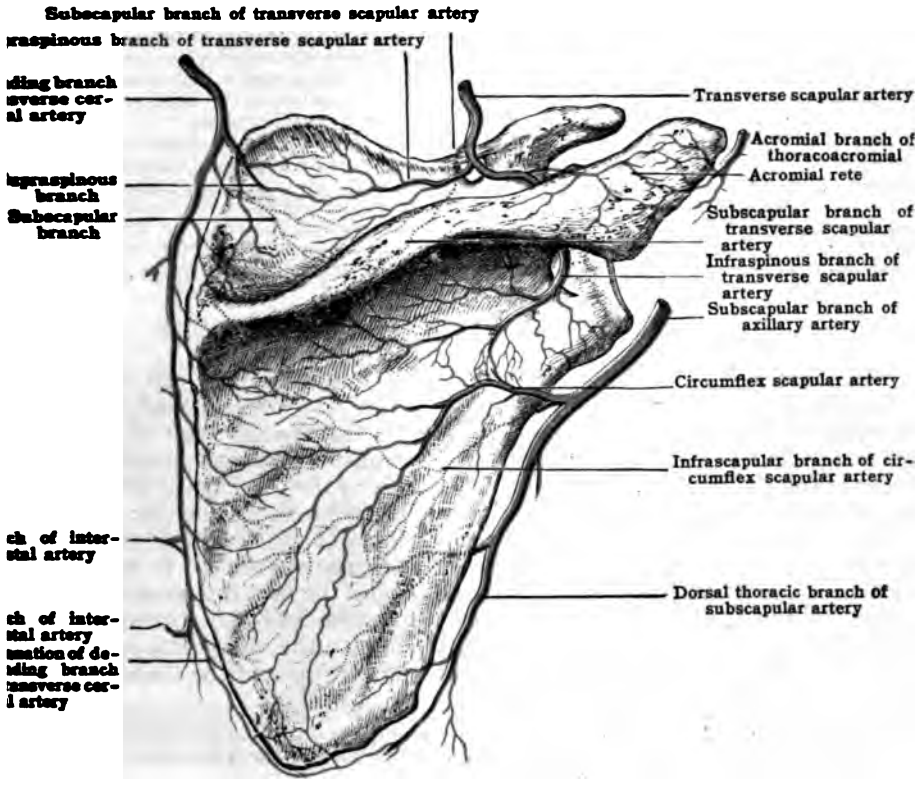
THE TRANSVERSE SCAPULAR ARTERY

The **transverse scapular** or suprascapular [a. transversa scapulæ] arter laterally across the root of the neck, lying first beneath the sternomast

n the subclavian triangle behind the clavicle and subcalvius muscle. At teral angle of this space it is joined by the suprascapular nerve, sinks th the posterior belly of the omohyoid, and passes over the ligament bridge scapular notch, the nerve passing through the notch (fig. 505). It then es in the supraspinous fossa of the scapula, and, winding downward round ne of the spine over the neck of the scapula, enters the infraspinous fossa, erminates by anastomosing with the circumflex (dorsal) scapular artery, he descending branch of the transverse cervical (posterior scapular) artery.

it lies under cover of the sternomastoid muscle, it crosses the phrenic nerve and the ns anterior; and as it courses through the subclavian triangle, it is separated by the cervical which descends from the omohyoid to the first rib, from the subclavian artery and brachial of nerves. It is one of the chief vessels by which the collateral circulation is carried on igature of the subclavian in the third part of its course. At the lateral part of the sub- triangle it is covered by the trapezius, and after passing over the transverse scapular nt it pierces the supraspinous fascia and passes beneath the supraspinatus muscle, rami- between it and the bone. In the infraspinous fossa it lies between the infraspinatus and ne. The artery is accompanied by two veins.

505.—Scheme of Anastomoses of the Right Scapular Arteries. (Walsham.)



he branches of the transverse scapular are:—(1) the nutrient, to the clavicle; (2) the mial [ramus acromialis] to the arterial rete or plexus on the acromial process, to reach h it pierces the trapezius; (3) the articular, to the acromioclavicular joint and shoulder-; (4) the subscapular, given off as the artery is passing over the transverse scapular ment, descends to the subscapular fossa between the subscapularis and the bone, and tomoses with the infrascapular branch of the circumflex (dorsal) scapular artery, and with ubscapular and transverse cervical arteries; (5) the supraspinous branches, which ramify he supraspinous fossa, and supply the supraspinatus muscle and the periosteum, and the ient artery to the bone; (6) the infraspinous branches, which ramify in a similar way in infraspinous fossa, giving off twigs to the infraspinatus muscle, the periosteum, and the

THE TRANSVERSE CERVICAL ARTERY

The transverse cervical artery [a. transversa colli], somewhat larger than the sverse scapular (suprascapular), runs like the latter vessel laterally across oot of the neck, but on a slightly higher transverse plane, and a little above the

clavicle. At its origin from the thyrocervical trunk (thyroid axis) it lie the sternomastoid; on leaving the cover of this muscle, it crosses the upp of the subclavian triangle, lying here only beneath the platysma and c fascia; further laterally, it passes beneath the anterior margin of the trape omohyoid muscle, and at the lateral margin of the levator scapulæ divide descending (posterior scapular) and an ascending (superficial cervical) l In this course it crosses the phrenic nerve, the scalenus anterior, the b plexus, and the scalenus medius. Sometimes it passes between the cord brachial plexus.

The **branches of the transverse cervical artery** are:—(1) a descendin terior scapular); and (2) an ascending (or superficial) cervical. The d ing branch occasionally arises from the third portion of the subclavian ar

(1) The **descending branch, or posterior scapular** [ramus descendens] the apparent c tion of the transverse cervical artery, begins at the lateral border of the levator scap continuing its course beneath this muscle to the medial angle of the scapula, turns d and skirts along the vertebral border of the bone, between the serratus anterior (mu front and the levator scapulæ and rhomboideus minor and major behind, to the inferi where it anastomoses with the subscapular artery. It gives off the following branc **Supraspinous**, which ramifies between the supraspinous muscle and the trapezius, a branches through the muscle into the fossa, to anastomose with the transverse scapula (*b*) **Infraspinous** branches, one or more of which enter the infraspinous fossa, and an with the circumflex (dorsal) scapular. (*c*) **Subscapular** branches, which enter the sul fossa, and anastomose with the branches of the transverse scapular and subscapular (*d*) **Muscular** branches, to the muscles between which it runs and to the latissimus dorsi branches anastomose with muscular branches of the intercostal arteries.

(2) The **ascending branch** or **superficial cervical artery** [r. ascendens], smaller descending branch, ascends under the anterior margin of the trapezius, lying upon th scapulæ and splenius muscles. It supplies branches to the trapezius, levator scap splenius muscles, and the posterior chain of lymphatic glands. It anastomoses superficial ramus of the descending branch of the occipital between the splenius a spinalis capitis (complexus). It is accompanied by two veins. This artery may aris from the thyrocervical trunk, or from the third part of the subclavian artery.

3. THE INTERNAL MAMMARY ARTERY

The **internal mammary** artery [a. mammaria interna] (figs. 501, 506) c from the lower part of the first portion of the subclavian, usually oppo thyrocervical trunk (thyroid axis), close to the medial edge of the s anterior. It descends with a slight inclination forward and medialward cover of the clavicle, and enters the thorax behind the cartilage of the first thence passes down behind the cartilages of the next succeeding ribs, about (½ in.) from the lateral margin of the sternum, to the sixth interspace, divides into the **superior epigastric** and the **musculophrenic.** It is acco by two veins, which unite into one trunk behind the first intercostal mus passes to the medial side of the artery to open into the correspondi innominata, or occasionally on the right side into the vena cava superic artery may be divided into two portions, the *cervical* and the *thoracic.*

The **cervical portion** is covered by the sternomastoid muscle, subclavian vein, an jugular vein, and is crossed obliquely, in the lateromedial direction, by the phrenic r rests upon the pleura and courses around the upper part of the innominate vein. no branch from this part of the artery.

The **thoracic portion** lies behind the cartilages of the six upper ribs, and in the i between the ribs has in front of it the pectoralis major and the internal intercost and external intercostal ligaments. Behind, it is in contact above with the pleura separated from it lower down by slips of the transversus thoracis (triangularis ste the left side, the artery between the fourth and sixth ribs may be said to be in th mediastinum, the pleura here forming a notch for the heart. In the first, second, spaces the artery, if wounded, can easily be tied; but in the fourth space the opera tended with more difficulty. The remaining spaces are so narrow that a portion of th would have to be removed to expose the vessel.

The **branches of the internal mammary artery** (fig. 501) are:—(1) T cardiophrenic; (2) the anterior mediastinal and thymic; (3) the bronc the pericardiac; (5) the sternal; (6) the anterior intercostals; (7) the per (8) the lateral costal; (9) the superior epigastric; and (10) the musculop

(1) The **pericardiophrenic** artery [a. pericardiophrenica], is a long slender ves comes off from the internal mammary just after it has entered the chest, and desc the phrenic nerve, at first between the pleura and innominate vein; then (on the r

...een the pleura and the vena cava superior; and lastly, between the pleura and the peri-...um to the diaphragm, where it anastomoses with the other diaphragmatic arteries. It ... branches both to the pleura and pericardium.

(2) The anterior mediastinal and thymic arteries [aa. mediastinales anteriores et thymicæ] ... off irregularly from the internal mammary. They are of small size, and supply the con-...ive tissue, fat, and lymphatics in the superior and anterior mediastina and the remains of ... thymus gland.

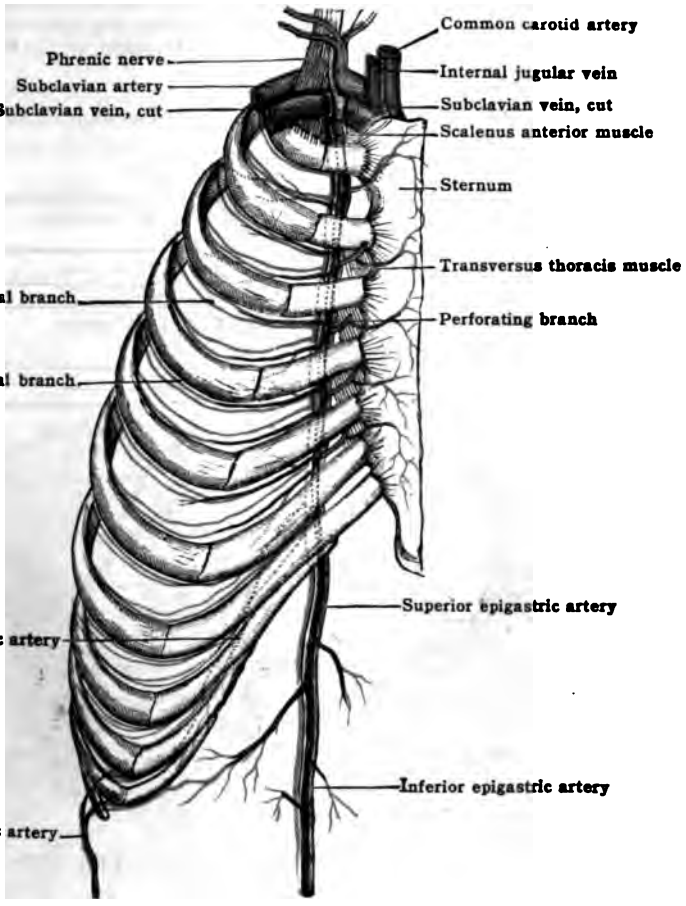
(3) The bronchial branches [rami bronchiales] are often wanting. When present they are ...plied to the bronchi and the lower part of the trachea.

(4) The pericardiac branches are distributed to the anterior surface of the pericardium.

(5) The sternal branches [rami sternales] enter the nutrient foramina in the sternum, and ...o supply the transversus thoracis (triangularis sterni).

(6) The anterior intercostal branches [rami intercostales] (figs. 507, 518)—two in each of ... five or six upper intercostal spaces—run laterally from the internal mammary artery, ...ng the lower border of the rib above and the upper border of the rib below, and anastomose

FIG. 506.—THE RIGHT INTERNAL MAMMARY ARTERY. (Walsham.)



with the corresponding anterior and collateral branches of the aortic intercostals. The pair of branches for each intercostal space sometimes arises by a common trunk. The branches lie at first between the internal intercostal muscles and the pleura; afterward between the external and internal intercostal muscles. They supply the contiguous muscles, the pectoralis major, and the ribs.

(7) The perforating or anterior perforating branches [rami perforantes]—five or six in number, one corresponding to each of the five or six upper spaces—come off from the front of the internal mammary, and, perforating the internal intercostal muscles, pass forward between the costal cartilages to the pectoralis major, which they supply [*rami musculares*]. The terminal twigs perforate the muscle close to the sternum, and are distributed to the integument [*rami cutanei*]. The second, third, and fourth perforating supply the medial and deep surfaces of the mammary gland, and become greatly enlarged during lactation [*rami mammarii*].

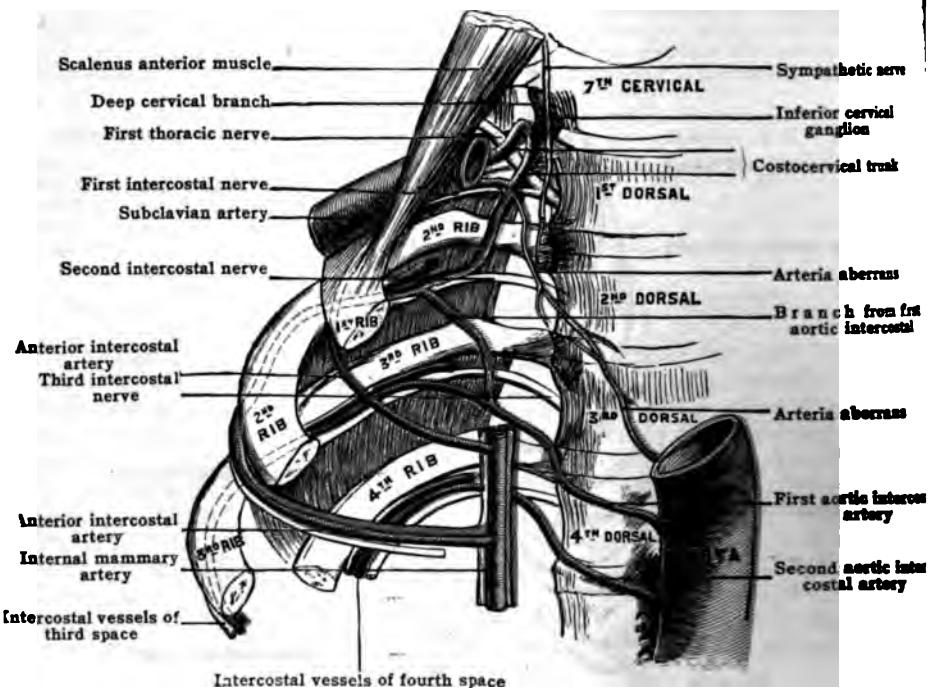
(8) The lateral costal branch [ramus costalis lateralis] is given off close to the first rib, and descends behind the ribs laterally to the costal cartilages. It anastomoses with the upper intercostal arteries. This vessel is often of insignificant size, or absent.

(9) The superior epigastric artery [a. epigastrica superior] (fig. 506), or medial terminal branch of the internal mammary artery, leaves the thorax behind the seventh costal cartilage

by passing through the costoxiphoid space in the diaphragm. It is the direct prolongation of the internal mammary downward. In the abdomen it descends behind the rectus muscle between its posterior surface and its sheath, and, lower, entering the substance of the muscle anastomoses with the inferior epigastric, a branch of the external iliac. It gives off the following small branches:—(*a*) The **phrenic**, to the diaphragm; (*b*) the **xiphoid**, which crosses in front of the xiphoid cartilage, and anastomoses with the artery of the opposite side; (*c*) the cutaneous, which perforate the anterior layer of the sheath of the rectus and supply the integument; (*d*) the **muscular**, to the rectus muscle, some of which perforate the rectus sheath laterally, and are distributed to the oblique muscles; (*e*) the **hepatic** (on the right side only), which passes up the falciform ligament to the liver, and anastomose with the hepatic artery; (*f*) the perforating, which perforate the posterior layer of the sheath of the rectus, and ramify on the peritoneum.

(10) The **musculophrenic** artery [a. musculophrenica], or **lateral terminal branch** of the internal mammary artery, skirts laterally and downward behind the costal cartilages of the false ribs along the costal attachments of the diaphragm, which it perforates opposite the ninth rib. It terminates, much reduced in size, at the tenth or eleventh intercostal space by anastomosing with the ascending branch of the deep circumflex iliac artery. It gives off in its course the following small branches:—(*a*) the **phrenic** for the supply of the diaphragm; (*b*) the **anterior intercostals**, two in number for each of the lower five or six intercostal spaces, which are distributed like those to the upper spaces, already described, and anastomose like them with the corresponding anterior branches of the lower aortic intercostals; (*c*) the **muscular** for the supply of the oblique muscles of the abdomen.

FIG. 507—THE RIGHT COSTOCERVICAL TRUNK. (Walsham.)



4. THE COSTOCERVICAL TRUNK

The **costocervical trunk** [truncus costocervicalis] (figs. 489, 507) is a short stem which arises usually from the back part of the second portion of the subclavian artery, behind the scalenus anterior on the right side, but commonly just medial to that muscle on the left side. Its course is upward and backward above the dome of the pleura and then downward to the thorax, before ending which it divides into its two terminal branches.

The **branches of the costocervical trunk** are:—(1) the superior intercostal and (2) the deep cervical.

(1) The **superior intercostal** [a. intercostalis suprema] (fig. 507) continues the direction of the costocervical trunk, passing downward into the thorax in front of the neck of the first rib. It sometimes terminates opposite the first intercostal space by becoming the first intercostal artery. Usually, however, it is prolonged downward over the neck of the second rib and supplies the second intercostal space in addition. It communicates with the highest aortic intercostal artery. As it crosses the neck of the first rib the superior intercostal lies upon the vena side of the first intercostal nerve and to the lateral side of the superior thoracic ganglion of sympathetic. The branches to the first and second intercostal spaces resemble in course

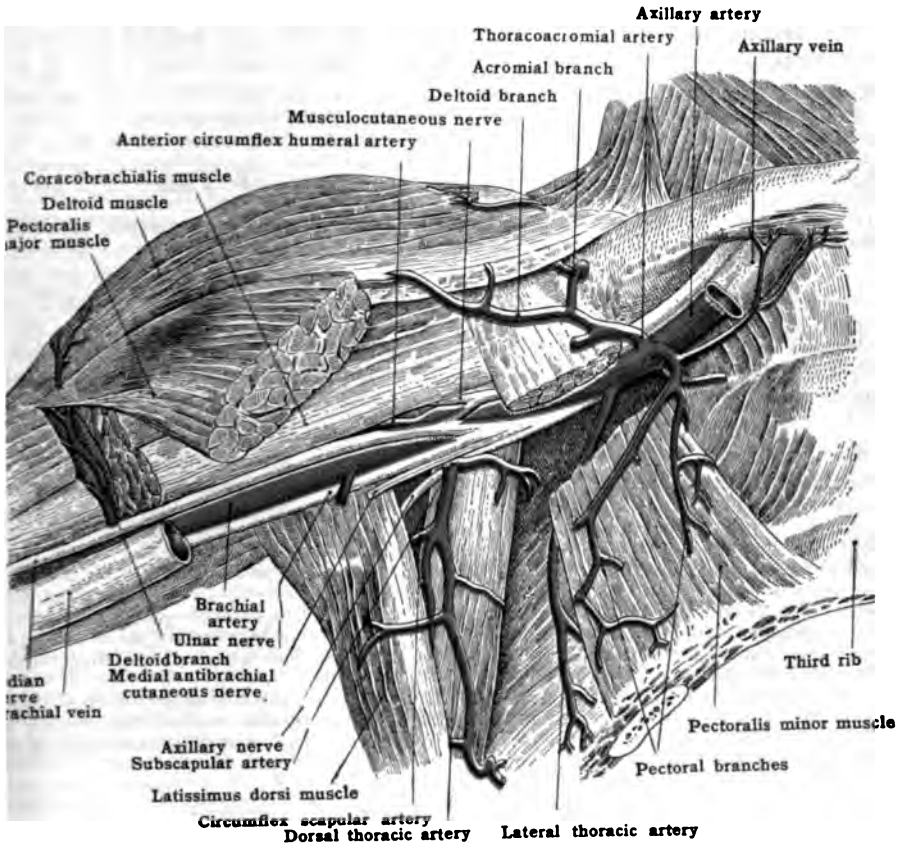
ution the succeeding intercostals derived from the thoracic aorta (see p. 625). Like the **intercostals** they give off **dorsal** [rr. dorsales] and **spinal branches** [rr. spinales]. An **arteria ima**, when present, arises from the medial side of the right superior intercostal, or from **ght** subclavian itself. It descends as a slender vessel into the thorax, passing downward **edially** behind the esophagus as far as the third or fourth thoracic vertebra, where in **cases** it anastomoses with a similar slender branch arising from the aorta below the liga**ım** arteriosum. This anastomosis represents the remains of the embryonic right dorsal

) **The deep cervical** artery [a. cervicalis profunda] passes directly backward, first between **venth** and eighth cervical nerves, and then between the transverse process of the seventh **al** vertebra and the neck of the first rib, having the body of the seventh cervical vertebra **medial** side, and the intertransverse muscle to its lateral side. It then turns upward **groove** between the transverse and spinous processes of the cervical vertebræ lying upon **emispinalis** colli and covered by the semispinalis capitis (complexus). Between these **les** it anastomoses with the deep branch of the descending branch (princeps cervicis) of **ecipital** artery. It gives off a spinal branch which enters the vertebral canal through **ıtervertebral** foramen with the eighth cervical nerve.

THE AXILLARY ARTERY

'he term axillary is applied to that portion of the main arterial stem of the **·r** limb that passes through the axillary fossa. The **axillary** artery [a. axillaris] 508) therefore is continuous with the subclavian above and with the brachial

FIG. 508.—THE AXILLARY ARTERY. (After Spaltcholz.)



w. It extends from the lateral border of the first rib to the lower edge of the **s** major muscle, and has the shoulder-joint and the neck of the humerus to **ateral** side. When the arm is placed close to the side of the body, the artery **ıs** a gentle curve with its convexity upward; but when the arm is carried out **ı** the side at right angles to the trunk in the ordinary dissecting position, the **els** takes a nearly straight course, which will then be indicated by a line drawn **ı** the middle of the clavicle to the groove on the medial side of the coraco-

in length.

Relations.—In front it is covered by the skin, superficial fascia, the lower part of th ysma, the deep fascia, the pectoralis major, the coracoclavicular (costocoracoid) fascia, th clavius muscle and by the clavicle when the arm hangs down by the side. The cephal thoracoacromial veins and the lateral anterior thoracic nerve, and the axillary lymphatic cross over it. A layer of the deep cervical fascia which has passed under the clavi descends in front of it.

Behind, it rests upon the first intercostal space and first intercostal muscle, the first tion and sometimes a portion of the second digitation of the serratus anterior (magnus) and a part of the second rib. The long thoracic nerve, on its way to the serratus a muscle, passes behind it. To its **lateral side,** and somewhat on a higher plane, are the the brachial plexus. To its **medial side,** and on a slightly anterior plane, is the axillar The medial anterior thoracic nerve courses between the vein and the artery.

The Second Part of the Axillary Artery

The **second part of the axillary artery** (fig. 508) lies behind the pec minor deep in the axilla. It measures 3 cm. (a little more than 1 in.) in l

Relations.—In front, in addition to the pectoralis minor, it is covered by the p major and the integument. **Behind** it is separated by a considerable interval, containi connective tissue and fat, from the subscapularis muscle; the posterior cord of the plexus lies immediately behind it. To the **medial side,** but separated from the artery medial cord of the brachial plexus, is the axillary vein. To the **lateral side** is the latera the brachial plexus, and at some little distance the coracoid process.

It is thus seen that the second portion of the axillary artery is surrounded on thr by the cords of the brachial plexus.

The Third Part of the Axillary Artery

The **third part of the axillary artery** (fig. 508) extends from the lower of the pectoralis minor to the lower border of the teres major. Its upper l deeply placed within the axilla, beneath the lower edge of the pectoralis muscle, but its lower half is not covered anteriorly by muscle. It m about 7.5 cm. (3 in.) in length.

Relations.—In front it has, in addition to the skin and superficial fascia, the p major above, and lower down the deep fascia of the arm. It is crossed obliquely by th root of the median nerve and by the lateral brachial vena comitans. **Behind,** it lie sively upon the subscapularis, the latissimus dorsi, and teres major muscles. From named muscle it is separated at first by a considerable mass of fat and cellular tissu radial (musculospiral) and axillary (circumflex) nerves intervene between the artery muscles. On its **lateral side** it is separated from the bone by the coracobrachialis, by w partly overlapped, this muscle and the short head of the biceps serving as a guide to th in ligature. For a part of its course it has also the musculocutaneous nerve and th

1. The **superior thoracic** [a. thoracalis suprema] is variously given off either directly from the axillary artery, or by a trunk common to it and to the thoracoacromial (see fig. 508). It passes behind the axillary vein across the first intercostal space, supplying the intercostal muscles and the upper portion of the serratus anterior, and anastomoses with the intercostal arteries. At times it sends a branch between the pectoralis major and minor, which then, as a rule, takes the place of the pectoral branch of the thoracoacromial.

2. The **thoracoacromial** or acromiothoracic axis [a. thoracoacromialis] arises from the first part of the axillary just above the upper border of the pectoralis minor. It is a short trunk, and, coming off from the front of the artery, pierces the coracoclavicular fascia, and then divides into three or four small branches, named from their direction:—(*a*) the acromial; (*b*) the deltoid; (*c*) the pectoral, and (*d*) the clavicular.

(*a*) The **acromial** branch [r. acromialis] passes laterally across the coracoid process, frequently through the deltoid muscle, which it supplies, and to the acromion. Here it forms by anastomosing with the anterior and posterior circumflex and transverse scapular (suprascapular) arteries, the so-called acromial rete, or plexus of vessels on the surface of the acromion (fig. 505).

(*b*) The **deltoid** branch [r. deltoideus] runs downward with the cephalic vein in the interval between the pectoralis major and the deltoid, and, supplying lateral offsets to these muscles and the adjacent integument, anastomoses with the anterior and posterior circumflex humeral arteries.

(*c*) The **pectoral** branch [r. pectoralis] passes between the pectoralis major and minor muscles, both of which it supplies. In the female, the branches which perforate the pectoralis major are often of large size, and supply the superimposed mammary gland.

(*d*) The **clavicular** branch passes upward beneath the clavicle, supplies the subclavius muscle, and anastomoses with the transverse scapular artery.

3. The **lateral thoracic** artery [a. thoracalis lateralis] descends along the lower border of the pectoralis minor, under cover of the pectoralis major, to the chest wall. It supplies both pectoral muscles and the serratus anterior (magnus), sends branches around the lower border of the pectoralis major to the mammary gland, and terminates in the intercostal muscles by anastomosing with the aortic intercostals and the internal mammary. It also furnishes branches to the lymph-nodes of the axillary fossa. The branches to the mammary gland in the female are often of large size.

4. The **subscapular** artery [a. subscapularis] is the largest branch of the axillary. It arises opposite the lower border of the subscapularis, and runs in a downward and medial direction along the anterior border of that muscle under cover of the latissimus dorsi. It supplies the subscapularis, teres major, latissimus dorsi, and serratus anterior (magnus) muscles, and gives branches to the nodes in the axillary fossa. It is accompanied by two veins, which usually unite and then receive the circumflex (dorsal) scapular vein, and open as a single vein of large size either into the axillary or at the confluence of the medial brachial vena comitans with the basilic vein.

About 2.5 or 3.7 cm. (1 or 1½ in.) from its origin, the subscapular artery divides into two end branches, (1) the circumflex (dorsal) scapular, and (2) the dorsal thoracic.

(1) The **circumflex scapular** artery [a. circumflexa scapulæ], or dorsal scapular, arising from the subscapular, usually at the point above mentioned, passes backward through the triangular space bounded by the subscapularis above, the teres major below, and the long head of the triceps laterally, and then between the teres minor and the axillary border of the scapula, which it commonly grooves. It thus reaches the infraspinous fossa, where, under cover of the infraspinatus, it anastomoses with the transverse scapular (suprascapular) artery and the descending branch of the transverse cervical (posterior scapular) (fig. 505). As it passes through the triangular space, it gives off a ventral branch which ramifies between the subscapularis and the bone, supplying branches to the subscapularis, to the scapula, and to the shoulder-joint. A second branch is often given off near the triangular space and passes downward between the teres major and teres minor, supplying both muscles (fig. 509).

(2) The **dorsal thoracic** artery [a. thoracodorsalis] continues in the course of the subscapular as far as the angle of the scapula, where it anastomoses with the circumflex scapular, the descending branch of the transverse cervical (posterior scapular), the lateral thoracic, and intercostal arteries.

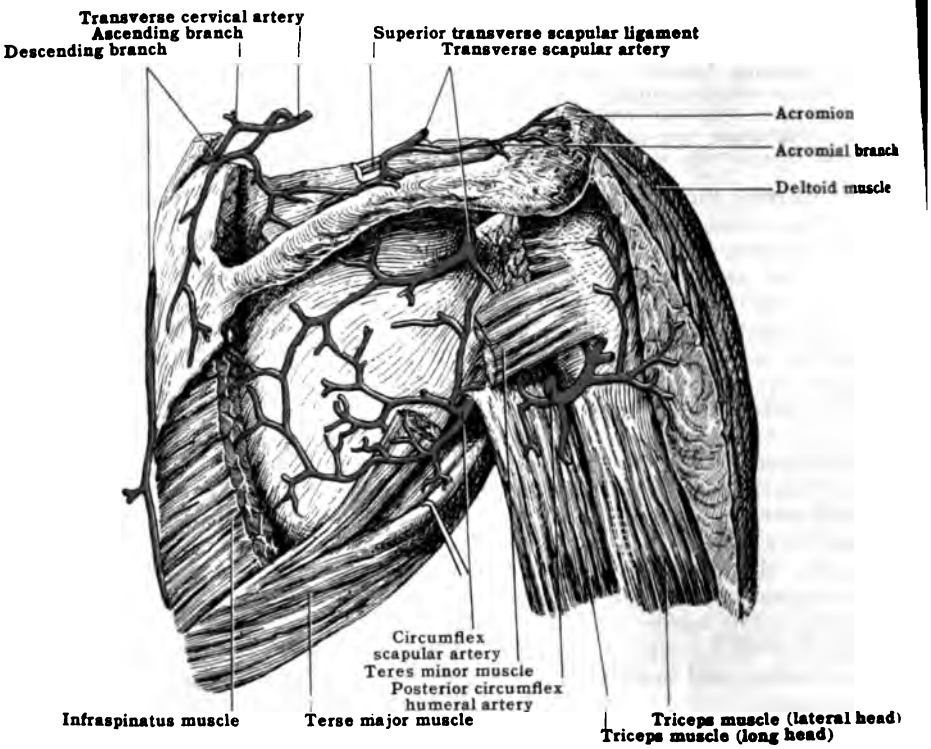
5. The **anterior circumflex humeral** artery [a. circumflexa humeri anterior], usually quite a small vessel, comes off from the lateral side of the axillary artery, generally opposite the posterior circumflex. It passes beneath the coracobrachialis and short and long heads of the biceps, winding transversely round the

front of the surgical neck of the humerus, across the intertubercular (bicipital) groove, and anastomoses with the posterior circumflex and thoracoacromial arteries. It gives off the following small branches:

(*a*) The **bicipital** or ascending, which runs up the intertubercular groove to supply the long tendon of the biceps and the shoulder-joint; and (*b*) a **pectoral** or descending branch, which runs downward along the insertion of the pectoralis major, and supplies the tendon of that muscle.

6. The **posterior circumflex humeral** artery [a. circumflexa humeri posterior] (fig. 509) arises from the posterior aspect of the axillary, just below the lower border of the subscapularis muscle. It passes through the quadrilateral space, bounded by the teres minor above, the latissimus dorsi and teres major below, the humerus laterally, and the long head of the triceps medially, and, winding round the back of the humerus beneath the deltoid, breaks up under cover of that muscle into a leash of branches, which for the most part enter its substance. The axillary (circumflex) nerve and two venæ comitantes run with it. It anastomoses with the anterior circumflex, the arteries on the acromion, and the profunda artery.

FIG. 509.—THE ARTERIES OF THE SHOULDER. (After Spalteholz.)



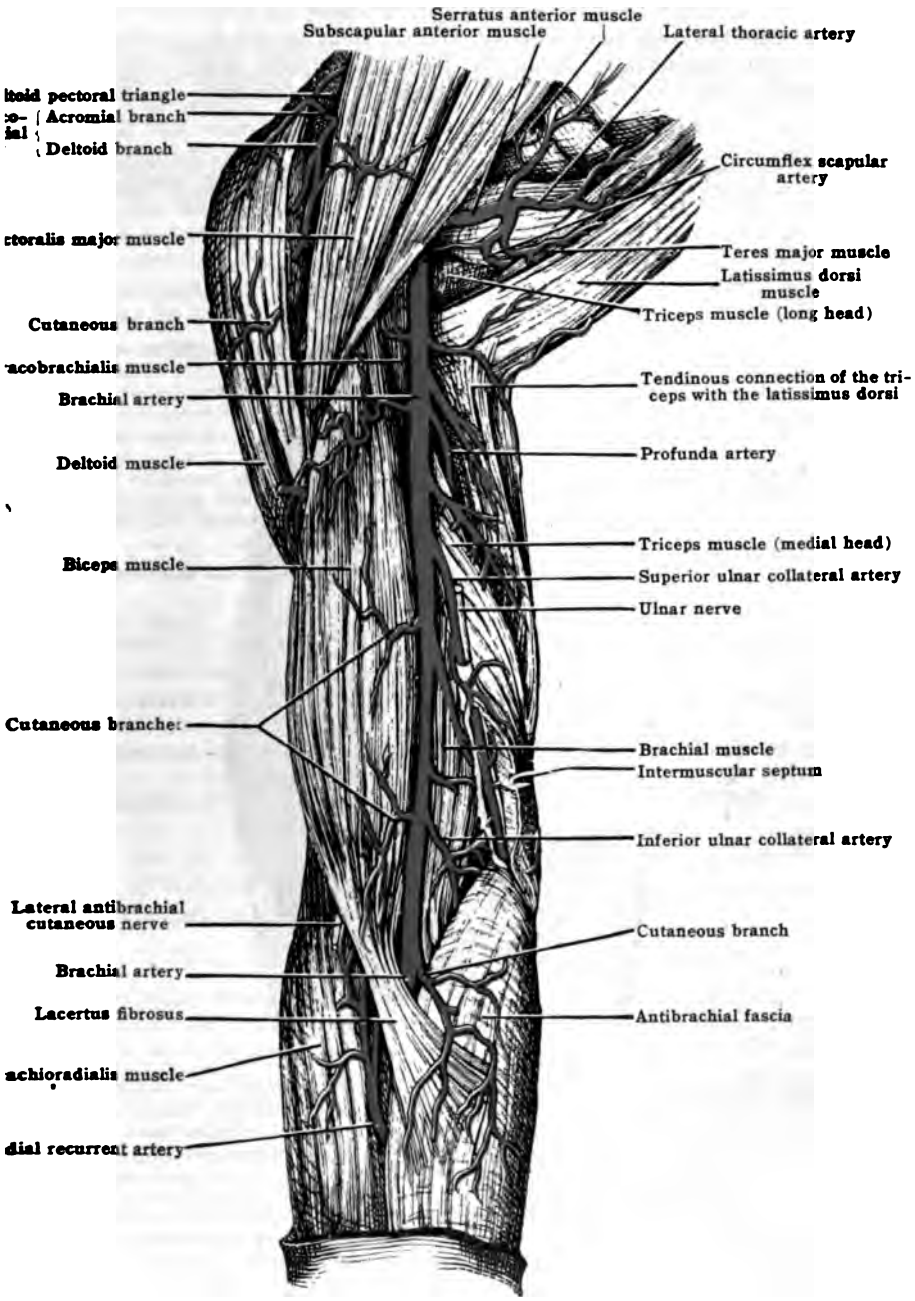
In addition to the leash of vessels to the deltoid, it gives off the following small branches —(*a*) **nutrient**, to the greater tuberosity of the humerus; (*b*) **articular**, to the back of the shoulder-joint; (*c*) **acromial**, to the plexus on the acromion; and (*d*) **muscular**, to the teres minor and long and short heads of the triceps. One or more of these branches to the triceps descend either between the lateral and long head or in the substance of that muscle, to anastomose with an ascending branch from the profunda artery. It is by means of this anastomosis that the collateral circulation is chiefly carried on when the axillary or the brachial artery is tied between the origins of the posterior circumflex and profunda arteries.

THE BRACHIAL ARTERY

The **brachial** artery [a. brachialis] (fig. 510), the continuation of the axillary extends from the lower border of the teres major to a little below the center of the crease at the bend of the elbow, where it divides, opposite the neck of the radius into the radial and ulnar arteries. The artery is at first medial to the humerus but as it passes down the arm it gradually gets in front of the bone, and at the

of the elbow it lies midway between the two epicondyles. Hence, in cong hemorrhage, the artery should be compressed laterally against the bone upper third, laterally and backward in its middle third, and directly back-

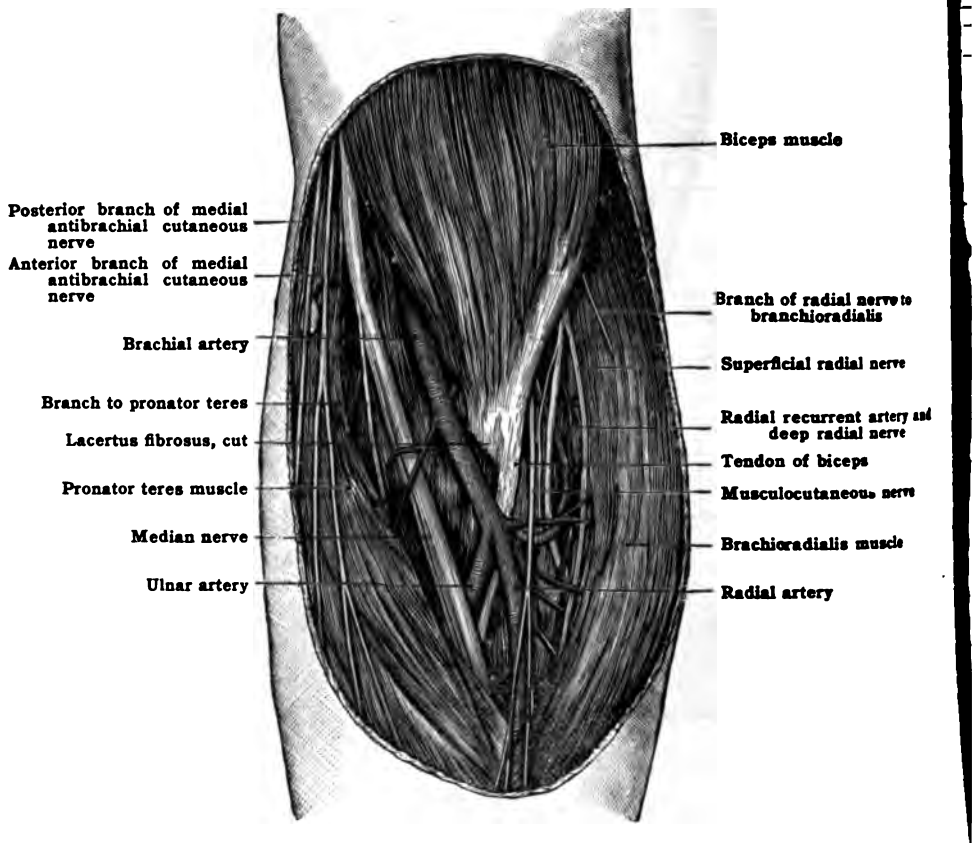
510.—The Brachial Artery. (After Toldt, 'Atlas of Human Anatomy,' Rebman London and New York.)



in its lower third. Throughout the greater part of its course the artery is ficial, being overlapped slightly on its lateral side by the coracobrachialis biceps muscles; but at the bend of the elbow it sinks deeply beneath the tus fibrosus of the biceps into the triangular interval (antecubital space)

between the brachioradialis and pronator teres, and at its bifurcation is more or less under cover of these muscles (fig. 511). The sheath of the brachial artery is closely incorporated with the fascia covering the biceps muscle. A line drawn from the groove on the medial side of the coracobrachialis and biceps muscles to a point midway between the epicondyles of the humerus will indicate its course. The brachial artery is accompanied by two veins which frequently communicate across it. In addition to the branches named below the artery gives off numerous muscular branches and, occasionally, the nutrient artery to the humerus. The muscular branches usually come off from the lateral side; one in particular, which supplies the biceps muscle, is frequently of large size.

FIG. 511.—THE BRACHIAL ARTERY AT THE BEND OF THE ELBOW, LEFT SIDE, FRONT VIEW
(From a mounted specimen in the Anatomical Department of Trinity College, Dublin.)



Relations.—**In front,** the artery is covered by the integument and superficial and deep fasciæ, and at the bend of the elbow by the lacertus fibrosus of the biceps, and in muscular subjects by the overlapping margins of the brachioradialis and pronator teres. In the middle third of the arm it is crossed obliquely from the lateral to the medial side by the median nerve, and at the bend of the elbow by the median cubital vein, the bicipital fascia intervening.

Behind, it lies successively on the long head of the triceps, from which it is separated by the radial (musculospiral) nerve and profunda artery, on the medial head of the triceps, on the insertion of the coracobrachialis, and thence to its bifurcation on the brachialis muscle.

Laterally the brachial artery is overlapped by the coracobrachialis above, and the muscular belly of the biceps below. The median nerve is in close contact with the lateral side of the artery in the upper third of its course, but in the middle third crosses the artery obliquely to gain the medial side. The tendon of the biceps lies laterally to the artery in its lower portion.

Medial to the artery in the upper part of its course are the medial antibrachial (internal) cutaneous and the ulnar nerves; the latter nerve, however, leaves the artery about the origin of the ulnar collateral (inferior profunda) branch, to pass, with that vessel, to the medial epicondyle. Lower down, the medial antibrachial cutaneous nerve also leaves the artery, by piercing the deep fascia. The median nerve is in close contact with the medial side of the artery in its lower third and at the bend of the elbow. The basilic vein is superficial to it, and a little to its medial side in the greater part of its course, but separated from it by the deep fascia. The brachial artery is accompanied by two or more venæ comitantes.

Branches of the Brachial Artery

The branches of the brachial artery are: (1) The profunda brachii; (2) the erior ulnar collateral (inferior profunda); (3) the inferior ulnar collateral astomotica magna); and (4) the terminal branches—the radial and ulnar ries.

(1) The Profunda Artery

The profunda brachii (superior profunda) is the largest branch of the brachial. rises from the medial and posterior aspect of the artery, a little below the infe- border of the tendon of the teres major. It at first lies to the medial side he brachial, but soon passes behind that vessel, and, sinking between the lial and long heads of the triceps with the radial (musculospiral) nerve, curves und the humerus in the groove for the nerve, lying between the bone and the ral head of the triceps. On reaching the lateral supracondyloid ridge of the nerus it perforates the lateral intermuscular septum, and, continuing forward ween the brachioradialis and brachialis to the front of the lateral epicondyle, s by anastomosing with the radial recurrent artery (figs. 510, 514). For stomoses, see fig. 1126.

It gives off the following branches:

(*a*) The **deltoid branch** [r. deltoideus] which may, however, arise from the brachial itself or n the superior ulnar collateral. It runs across the anterior surface of the humerus, under er of the coracobrachialis and biceps, and supplies the brachialis and deltoid.

(*b*) The **medial collateral artery** [a. collateralis media] runs in the substance of the medial d of the triceps as far as the elbow, where it often terminates in the articular rete.

(*c*) The **radial collateral artery** [a. collateralis radialis] arises about the middle of the upper ı. and runs behind the lateral intermuscular septum to the rete at the elbow-joint.

(*d*) A **nutrient humeral artery** [a. nutritia humeri], which may come from the brachial lf or from a muscular branch, enters a canal above and to the medial side of the sulcus for radial nerve.

(2) The Superior Ulnar Collateral Artery

The **superior ulnar collateral** artery [a. collateralis ulnaris superior] (inferior ofunda) arises from the medial side of the brachial, usually about the level of e insertion of the coracobrachialis, sometimes from a trunk common to it and the profunda brachii. It passes with the ulnar nerve medially and down- ırd through the medial intermuscular septum, and then along the medial head the triceps to the back of the medial epicondyle, where, under cover of the ep fascia and the origin of the flexor carpi ulnaris from the olecranon and dial epicondyle, it enters into the anastomoses around the elbow-joint. It quently supplies the nutrient artery to the humerus. It gives branches to the ceps, to the elbow-joint, and a branch which passes in front of the medial condyle to anastomose with the volar ulnar recurrent.

(3) The Inferior Ulnar Collateral Artery

The **inferior ulnar collateral** artery [a. collateralis ulnaris inferior] or anasto- tica magna arises from the medial side of the brachial, about 5 cm. (2 in.) above bifurcation into the radial and ulnar arteries, and, running medially and down- d across the brachialis, divides into two branches, a posterior and an anterior. **posterior** pierces the medial intermuscular septum, winds round the medial racondylar ridge of the humerus, and pierces the triceps, between which and bone it anastomoses with the articular branch of the profunda artery, and lesser extent with the interosseous recurrent, forming an arterial arch or rete ınd the upper border of the olecranon fossa. The **anterior** branch passes lially and downward between the brachialis and pronator teres, and anas- oses in front of the medial epicondyle, but beneath the pronator teres, with volar ulnar recurrent. From this branch a small vessel passes down behind medial epicondyle to anastomose with the dorsal ulnar recurrent and superior ır collateral arteries (fig. 514).

THE ULNAR ARTERY

The ulnar artery [a. ulnaris] (figs. 512 and 515), the larger of the two terminal ıches of the brachial, begins opposite the neck of the radius in the middle of the forearm. Thence through the proximal half of the forearm it runs

beneath the pronator teres and superficial flexor muscles, and, having reached the ulnar side of the forearm about midway between the elbow and the wrist, it passes directly downward, being merely overlapped by the flexor carpi ulnaris. Crossing the transverse carpal (anterior annular) ligament immediately to the radial side of the pisiform bone, it enters the palm, where it divides into two branches, which enter respectively into the formation of the superficial and deep volar arches. The artery is accompanied by two veins, which anastomose with each other by frequent cross-branches, and usually terminate in the brachial venæ comitantes. The ulnar nerve is at first some distance from the artery, but approaches the vessel at the junction of its proximal and middle thirds, and then lies close to its medial or ulnar side. The course of the artery in the distal two-thirds of the forearm is indicated by a line drawn from the front of the medial epicondyle to the radial side of the pisiform bone; and in the proximal third of the forearm by a line drawn in a gentle curve with its convexity to the medial side from 2.5 cm. (1 in.) below the center of the bend of the elbow to a point in the former line at the junction of its proximal and middle thirds. The artery throughout its course is best reached through the interval between the flexor carpi ulnaris and the flexor digitorum sublimis.

The relations of the artery will be given in detail in the forearm, and in the palm of the hand. The **relations in the forearm** are:

In front.—In the proximal half of the forearm the ulnar artery is deeply placed beneath the pronator teres, the flexor carpi radialis, the palmaris longus, and the flexor digitorum sublimis. In the distal half it is comparatively superficial, being merely overlapped above by the tendon of the flexor carpi ulnaris, while the last inch or so of the vessel is only covered as a rule by the skin and superficial and deep fasciæ. As the artery lies beneath the pronator teres, it is crossed from the medial to the lateral side by the median nerve, the deep head of origin of the muscle usually separating the nerve from the artery. The distal part of the artery is crossed by the palmar cutaneous branch of the ulnar nerve.

Behind.—For about 2.5 cm. (1 in.) of its course the artery lies upon the brachialis; but thence, as far as the transverse carpal (anterior annular) ligament, upon the flexor digitorum profundus, which separates it above from the interosseous membrane and bone, and at the wrist from the pronator quadratus. The artery is bound down to the flexor digitorum profundus by bands of fascia. To the **lateral side** in the distal two-thirds of its course is the flexor digitorum sublimis. To the **medial side** in the distal two-thirds is the flexor carpi ulnaris, the guide to the vessel. The ulnar nerve, as it enters the forearm from behind the medial epicondyle, is at first some distance from the artery, being separated from it in its proximal third by the flexor digitorum sublimis; but in its distal two-thirds is in close contact with the vessel on its ulnar side.

The **branches of the ulnar artery in the forearm** are: 1. The ulnar recurrent arteries. 2. The common interosseous. 3. Muscular. 4. Dorsal ulnar carpal. 5. Volar ulnar carpal.

1. The **ulnar recurrent** arteries [aa. recurrentes ulnares] are two, the volar, and dorsal. The *volar* is a small branch which arises from the medial side of the ulnar artery, or from the dorsal ulnar recurrent, and, running between the lateral edge of the pronator teres and the brachialis, anastomoses in front of the medial epicondyle with the inferior and superior ulnar collaterals. It supplies branches to the muscles between which it runs, and to the skin. The *dorsal*, larger than the volar, comes off from the medial side of the ulnar artery, either a little beyond the latter branch, or else as a common trunk with it, and, passing between the flexores digitorum sublimis and profundus, reaches the back of the medial epicondyle, where it lies with the ulnar nerve between the two heads of origin of the flexor carpi ulnaris. It supplies the contiguous muscles—the flexor carpi ulnaris, the palmaris longus, and the flexores digitorum sublimis and profundus—the elbow-joint, and the ulnar nerve, and anastomoses with the inferior and superior ulnar collaterals, and with the interosseous recurrent forming the so-called rete olecrani.

2. The **common interosseous** artery [a. interossea communis] is a short thick trunk 1.2 cm. ($\frac{1}{2}$ in.) or so in length, which comes off from the lateral and dorsal aspect of the ulnar artery about 2.5 cm. (1 in.) from its origin, and just before that artery is crossed by the median nerve. It passes backward and downward between the flexor pollicis longus and the flexor digitorum profundus, toward the triangular interval bounded by the upper border of the interosseous membrane, the oblique ligament, and the lateral border of the ulna, where it divides into the volar and dorsal interosseous arteries.

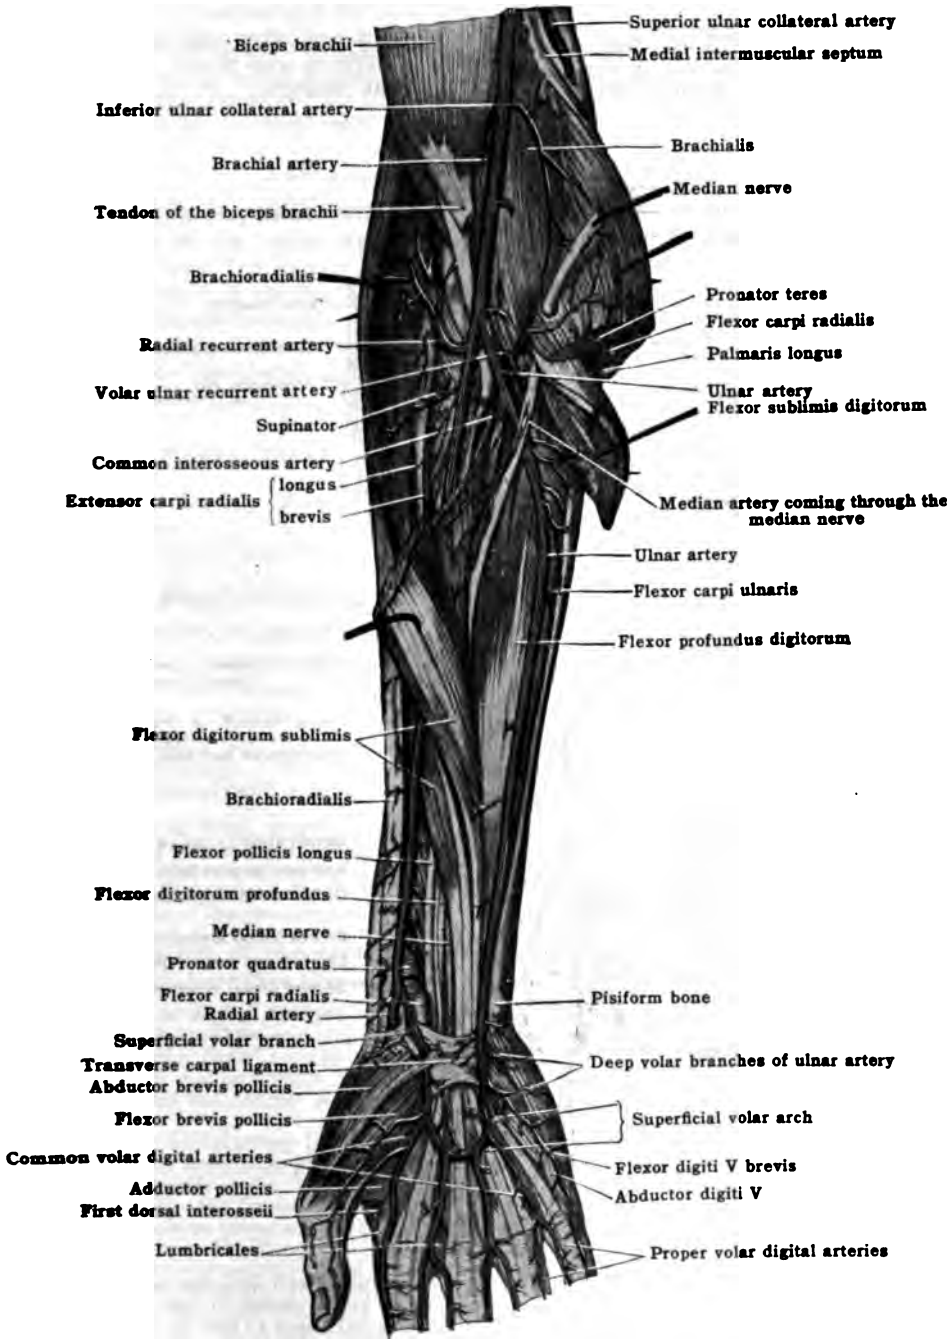
(*a*) The **volar interosseous** artery [a. interossea volaris], smaller than the dorsal, but apparently the direct continuation of the common trunk, passes distally in front of the interosseous membrane. It lies under cover of the overlapping edges of the flexor digitorum profundus and flexor pollicis longus, to both of which muscles it supplies branches. At the proximal border of the pronator quadratus it divides into two branches, the anterior and the posterior terminal (fig. 515).

The volar interosseous artery is accompanied by two veins and by the deep branch of the median nerve which lies to its radial side. The artery is bound down to the interosseous membrane by aponeurotic fibers.

The **branches of the volar interosseous artery** are: (i) The **median artery [a. mediana]** is a long slender vessel which arises from the proximal part of the artery. It passes forward

tween the flexor digitorum profundus and the flexor pollicis longus to the median nerve, with hich it descends beneath the transverse carpal (anterior annular) ligament into the palm, and en of large size sometimes enters into the formation of the superficial volar arch. At times e artery arises from the common interosseous. (ii) The **nutrient arteries** of the radius and na are usually derived from this vessel. (iii) The **volar terminal** division of the volar inter-

FIG. 512.—THE VOLAR ARTERIES OF THE FOREARM AND HAND. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)

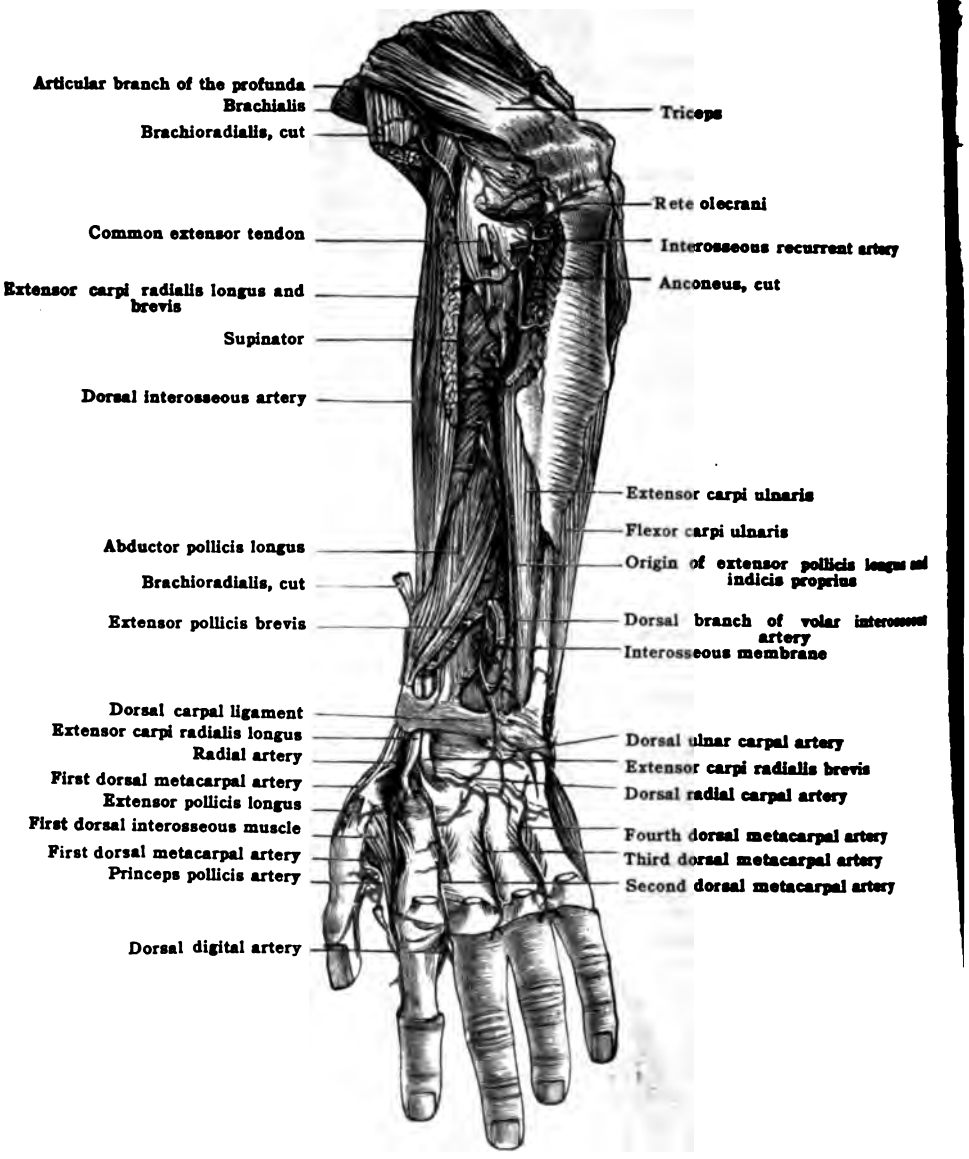


osseous artery passes either in front of or behind the pronator quadratus, but in either case in front of the interosseous membrane, and anastomoses with the volar carpal branches of the radial and ulnar arteries, and with the recurrent branches from the deep volar arch in the so-called **volar carpal rete.** (iv) **The dorsal terminal,** the larger division, pierces the interosseous membrane, and continues its course behind the interosseous membrane, under cover of the extensor muscles, to the back of the wrist, where it ends by anastomosing with the dorsal

carpal branches of the radial and ulnar arteries, in the so-called **dorsal carpal rete**. This branch anastomoses, as soon as it pierces the interosseous membrane, with the dorsal interosseous artery.

(*b*) The **dorsal interosseous** artery [a. interossea dorsalis], the larger division of the common interosseous, turns backward through the triangular interval bounded by the interosseous membrane, the oblique ligament, and the ulna. Emerging at the back of the forearm between the abductor pollicis longus and the supinator, under cover of the superficial extensors of the forearm, it passes between the superficial and the deep muscles, crossing the abductor pollicis longus, the extensor pollicis brevis, the extensor pollicis longus, and the extensor indicis pro-

FIG. 513.—THE BACK OF THE LEFT FOREARM, WITH THE DORSAL INTEROSSEOUS ARTERY AND BRANCHES OF THE RADIAL AT THE BACK OF THE WRIST.
(From a dissection in the Hunterian Museum.)



prius (fig. 513). It anastomoses with the dorsal carpal arteries and near the wrist joint, with the dorsal branch of the volar interosseous which here, as above described, has perforated the interosseous membrane. It is separated from the deep radial nerve at first by the radius and supinator, and on the back of the forearm by the extensores pollicis longus and indicis proprius.

The chief branch of the dorsal interosseous artery, the **interosseous recurrent artery** [a. interossea recurrens] arises from the dorsal interosseous as the latter emerges from beneath the supinator. It runs between the anconeus and supinator, usually under cover of the former, to the interval between the lateral epicondyle and the olecranon, where it anastomoses with the profunda, inferior ulnar collateral, radial recurrent, and dorsal ulnar recurrent arteries, and gives branches to the rete olecrani.

3. **The muscular** branches [rami musculares] are numerous. They supply the deep and superficial flexors of the fingers, the flexor carpi radialis and ulnaris, and the pronator radii teres.

4. **The dorsal ulnar carpal** [ramus carpeus dorsalis] comes off from the ulnar artery near the proximal border of the transverse carpal (anterior annular) ligament, and, winding medially round the end of the ulna or the ulnar collateral ligament of the wrist, beneath the flexor carpi ulnaris, ramifies on the back of the carpus beneath the extensor tendons. It forms by its anastomosis with the dorsal radial carpal, with the dorsal terminal branch of the volar interosseous and with the dorsal interosseous arteries a dorsal carpal arch or rete. The branches given off from the rete are described with the dorsal carpal branch of the radial artery.

5. **The volar ulnar carpal** [ramus carpeus volaris] is a small branch given off from the ulnar artery opposite the carpus. It passes beneath the flexor digitorum profundus to anastomose with the volar radial carpal, with terminal twigs of the volar branch of the volar interosseous, and with recurrent branches from the deep volar arch, forming an anastomotic arch across the front of the carpus—**the volar carpal arch** or **rete.**

The Ulnar Artery at the Wrist

The **ulnar artery at the wrist** may be said to extend from the proximal to the distal border of the transverse carpal (anterior annular) ligament upon which it rests. It here lies immediately to the radial side of the pisiform bone, and to the ulnar side of the hook of the hamate (unciform), the two bones forming for the vessel a protecting channel, which is further converted into a short canal by the expansion of the flexor carpi ulnaris passing from the pisiform to the hook of the hamate (unciform). The ulnar nerve in this situation is immediately to the ulnar side of the artery.

The Ulnar Artery in the Palm (Superficial Volar Arch)

The ulnar artery, on entering the palm, divides into two branches, the superficial and deep.

The **superficial branch** (fig. 516), the direct continuation of the vessel, anastomoses with the superficial volar, a branch of the radial, forming what is then known as the **superficial volar arch.** After descending a short distance toward the cleft between the fourth and fifth fingers, it turns toward the thumb, forming a curve with its convexity toward the fingers and its concavity toward the muscles of the thumb, and anastomoses opposite the cleft between the index and middle fingers, at the junction of the proximal with the middle third of the palm, with the superficial volar branch of the radial artery to complete the arch. A line drawn transversely across the palm on a level with the metacarpophalangeal joint of the thumb will roughly indicate the situation of the arch.

Relations.—In front, in addition to the skin and superficial fascia, the vessel is crossed successively, by the palmaris brevis, the palmar branch of the ulnar nerve, the palmar aponeurosis and the palmar branch of the median nerve. **Behind,** it rests successively upon the short muscles of the little finger, the digital branches of the ulnar nerve, the flexor tendons, and the digital branches of the median nerve.

The **branches of the superficial volar arch.** In addition to small muscular and cutaneous branches the superficial volar supplies:

The **common digital arteries** [aa. digitales volares communes]. These, usually three in number, arise from the convexity of the superficial arch and, running downward through the palm, give off the digital arteries proper to the radial side of the little finger and to both sides of the ring and middle fingers, and the ulnar side of the index finger. The radial side of the index finger and the thumb are supplied by the first volar metacarpal branch of the radial artery.

The proper digital artery for the ulnar side of the little finger passes distally over the hypothenar muscles and thence along the medial margin of the little finger. The remaining arteries pass distally in the three ulnar intermetacarpal spaces to within about 6 mm. (¼ in.) of the clefts between the figures, where they divide into branches, the **digital arteries proper** [aa. digitales volares propriæ] which supply the sides of contiguous fingers.

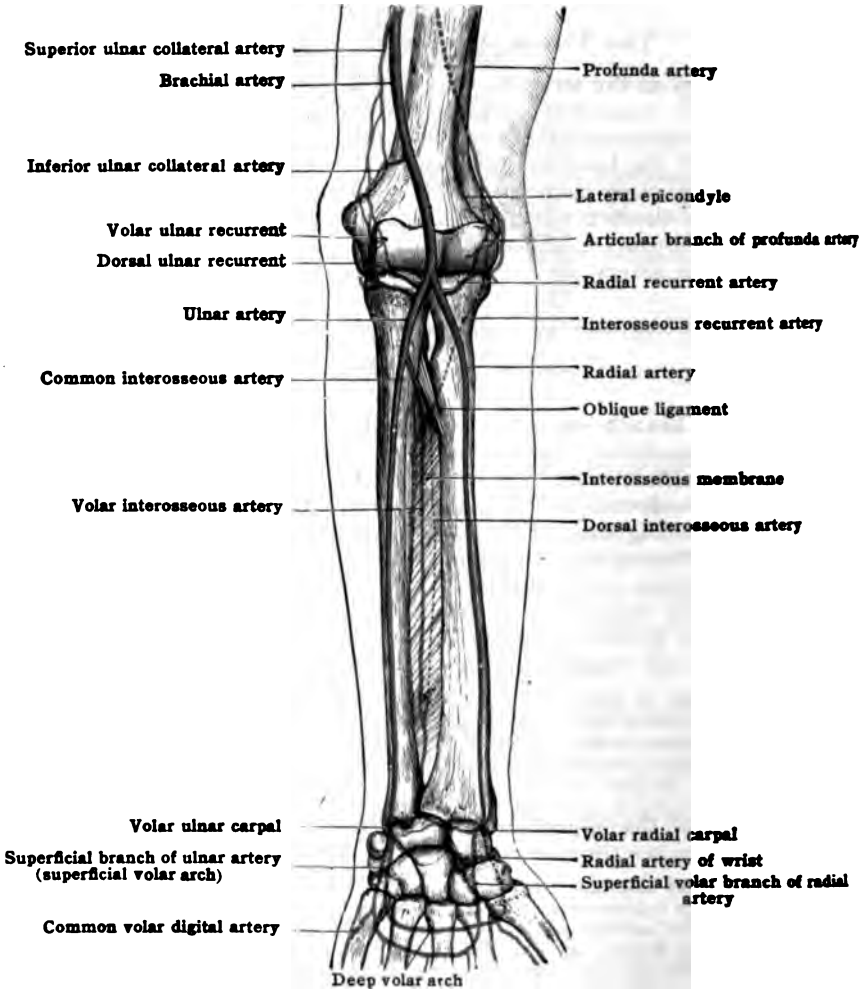
As the common digital arteries pass through the palm, they lie between the flexor tendons, on the digital nerves and lumbrical muscles, and beneath the palmar aponeurosis. Just before bifurcating they pass under the transverse fasciculi, and are joined by the volar metacarpal branches from the deep volar arch (fig. 516). Here they also receive the volar perforating branches from the dorsal metacarpal vessels. On the sides of the fingers the proper digital arteries lie between the palmar and dorsal digital nerves. They anastomose by small branches, forming an arch across the front of the bones on the proximal side of each interphalangeal joint. They supply the flexor tendons and the integument, and terminate in a plexiform manner beneath the pulp of the finger and around the matrix of the nail. A dorsal digital branch is given off to the back of the fingers about the level of the middle of the first phalanx, and a second but smaller dorsal digital branch about the level of the middle of the second phalanx.

The **deep branch** of the ulnar artery, also called the communicating arte sinks deeply into the palm between the abductor and flexor quinti digiti brev and joins the radial to form the deep volar arch. (See RADIAL ARTERY.)

THE RADIAL ARTERY

The **radial** artery—the smaller of the two arteries into which the brachi divides—appears as the direct continuation of the brachial. It runs, at fi curving laterally, along the radial side of the forearm as far as the styloid proce

FIG. 514.—DIAGRAM OF THE RELATION OF THE ARTERIES OF THE LEFT FOREARM TO THE BONES. (Walsham.)



then, curving over the radial collateral ligament and the lateral and back pa the wrist, enters the palm of the hand from behind between the first and se metacarpal bones, and ends by anastomosing with the deep branch of the to form the deep volar arch. Hence the artery is divisible into three p that in the forearm, that at the wrist, and that in the palm of the hand. course of the artery is indicated by a line drawn from a point 2.5 cm. (1 below the center of the elbow to a point situated just medial to the styloid pr of the radius.

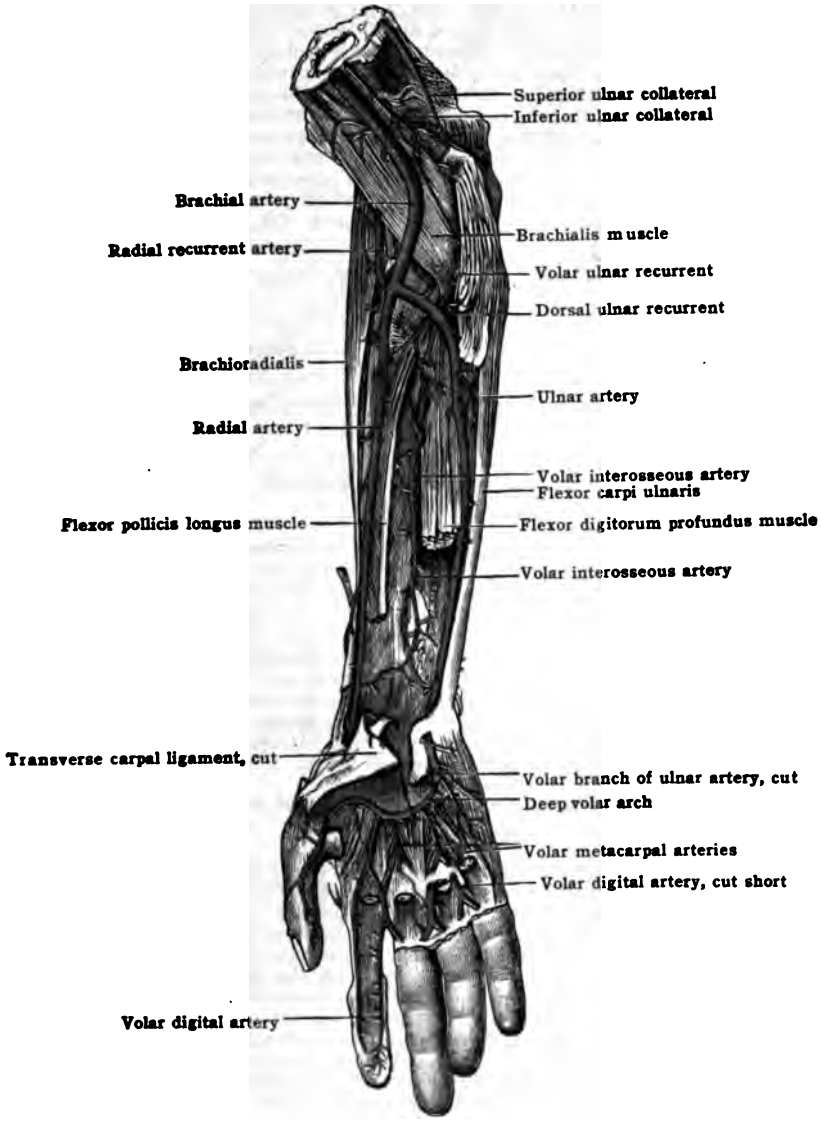
I. THE RADIAL ARTERY IN THE FOREARM

In its course through the forearm (fig. 572) the radial artery is found i most lateral of the intermuscular spaces, and it is necessary to divide onl

, superficial and deep fascia, and in addition in the upper third to separate brachioradialis from the pronator teres, to expose the vessel. There are two e comitantes.

telations.—In front, the artery is at first overlapped by the brachioradialis, but for the of its course it is merely covered by the skin, superficial and deep fasciæ, by some cutaneous s, and by cutaneous branches of the musculocutaneous nerve.
lehind, it lies successively on the tendon of the biceps, the supinator, from which it is rated by a layer of fat, the insertion of the pronator teres, the radial origin of the flexor

FIG. 515.—THE ARTERIES OF THE RIGHT FOREARM AND THE DEEP VOLAR ARCH.



orum sublimis, the flexor pollicis longus, the pronator quadratus, and the volar surface **ie distal end of the radius.** It is in this last situation, where the artery lies upon the bone **can therefore be easily pressed against it,** that the pulse is usually felt.
)n its lateral side it has, throughout the whole of its course, the brachioradialis muscle, **guide** to the artery in ligature, and, in its middle third, the superficial radial nerve as well. **s distal** third the superficial radial nerve is to its lateral side, but separated from it by the **hioradialis** and fascia.
)n its medial side, in the proximal third is the pronator teres, and in the distal third the **on** of the flexor carpi radialis, and throughout the whole of its course the medial vena **itans.**

The branches of the radial artery in the forearm are: (1) The radial re-**ent;** (2) the muscular; (3) the volar radial carpal; (4) the superficial volar.

(1) The **radial recurrent** [a. recurrens radialis] usually arises from the lateral side of the radial just beyond its origin from the brachial. It at first runs laterally on the supinator and then divides into three chief branches (figs. 1124, 1125). One of these continues laterally between the superficial (radial) and deep radial (posterior interosseous) nerves into the brachioradialis and extensor carpi radialis longus and brevis, and anastomoses with the interosseous recurrent. A second ascends between the brachialis and brachioradialis, with the radial (musculospiral) nerve, and anastomoses with the profunda artery. A third descends with the superficial radial nerve under cover of the brachioradialis, supplying that muscle. The radial recurrent also gives off branches to the elbow-joint.

(2) The **muscular branches** [rami musculares] come off irregularly to supply the contiguous muscles on the lateral side of the forearm.

(3) The **volar radial carpal** branch [ramus carpeus volaris] arises from the medial side of the radial artery about the level of the distal border of the pronator quadratus. It crosses the front of the radius beneath the flexor muscles, and anastomoses with the volar carpal branch of the ulnar, forming the volar carpal rete. This plexus is joined proximally by terminal twigs from the volar interosseous artery, and distally by recurrent branches from the deep volar arch. It supplies branches to the distal end of the radius, and to the wrist and carpal joints.

(4) The **superficial volar** branch [ramus volaris superficialis] leaves the radial artery as the latter vessel is about to turn over the radial collateral ligament to the back of the wrist. It courses forward over the short muscles of the ball of the thumb, and anastomoses with the superficial branch of the ulnar artery to complete the superficial volar arch. It supplies small branches to the muscles of the ball of the thumb, and frequently terminates in these muscles without joining the arch. Occasionally it passes beneath the abductor pollicis brevis.

II. The Radial Artery at the Wrist

The radial artery at the wrist winds over the radial side of the carpus, under the extensor tendons of the thumb, from a point a little beyond and medial to the styloid process of the radius to the base of the first interosseous space. It sinks between the two heads of the first dorsal interosseous muscle into the palm, to form, by anastomosing with the deep branch of the ulnar artery, the deep volar arch. A line drawn from a point 1.2 cm. (½ in.) to the medial side of the styloid process to the base of the first interosseous space will roughly indicate the course of the artery (fig. 516).

Relations.—The artery is covered successively by the abductor pollicis longus and extensor pollicis brevis, by branches of the superficial radial nerve and veins, and, just before it sinks between the two heads of the interosseous muscle, by the tendon of the extensor pollicis longus. The branches of the superficial radial nerve to the thumb and index finger cross it. It is at first somewhat deeply placed beneath the first-mentioned extensor muscles of the thumb; but subsequently it lies quite superficial, and can be felt pulsating in a little triangular depression bounded on either side by the extensores pollicis longus and brevis, and above by the lower end of the radius. The artery lies successively on the radial collateral ligament of the wrist, on the navicular (scaphoid), the greater multangular (trapezium), the base of the first metacarpal bone, and on the dorsal ligaments uniting these bones. It has usually with it two companion veins, and a few branches of the musculocutaneous nerve.

The **branches of the radial artery at the wrist** are: (1) The dorsal radial carpal; (2) the first dorsal metacarpal.

(1) The **dorsal radial carpal** branch [ramus carpeus dorsalis] arises from the radial as the latter vessel passes under the abductor pollicis longus, and runs medially beneath the extensor carpi radialis longus and brevis, and the extensor pollicis longus, across the dorsal surface of the carpus, to anastomose with the dorsal ulnar carpal and with the terminal twigs of the posterior branch of the volar interosseous artery. This anastomosis is called the **dorsal carpal rete** [rete carpi dorsale]. From this rete are given off the second, third, and fourth **dorsal metacarpal arteries** to the second, third, and fourth intermetacarpal spaces respectively. These vessels run distally on the dorsal interosseous muscles as far as the flexure of the fingers, and there divide into two branches (**dorsal digital**), which run along the sides of the dorsal aspect of the contiguous fingers. Near their proximal ends they anastomose with the **dorsal perforating branches of the deep volar arch.** Distally they are connected by **volar perforating** branches with the digital arteries or the corresponding spaces. The branches which run along the backs of the fingers anastomose with the dorsal branches of the first dorsal digital arteries derived from the volar common digital vessels (fig. 516).

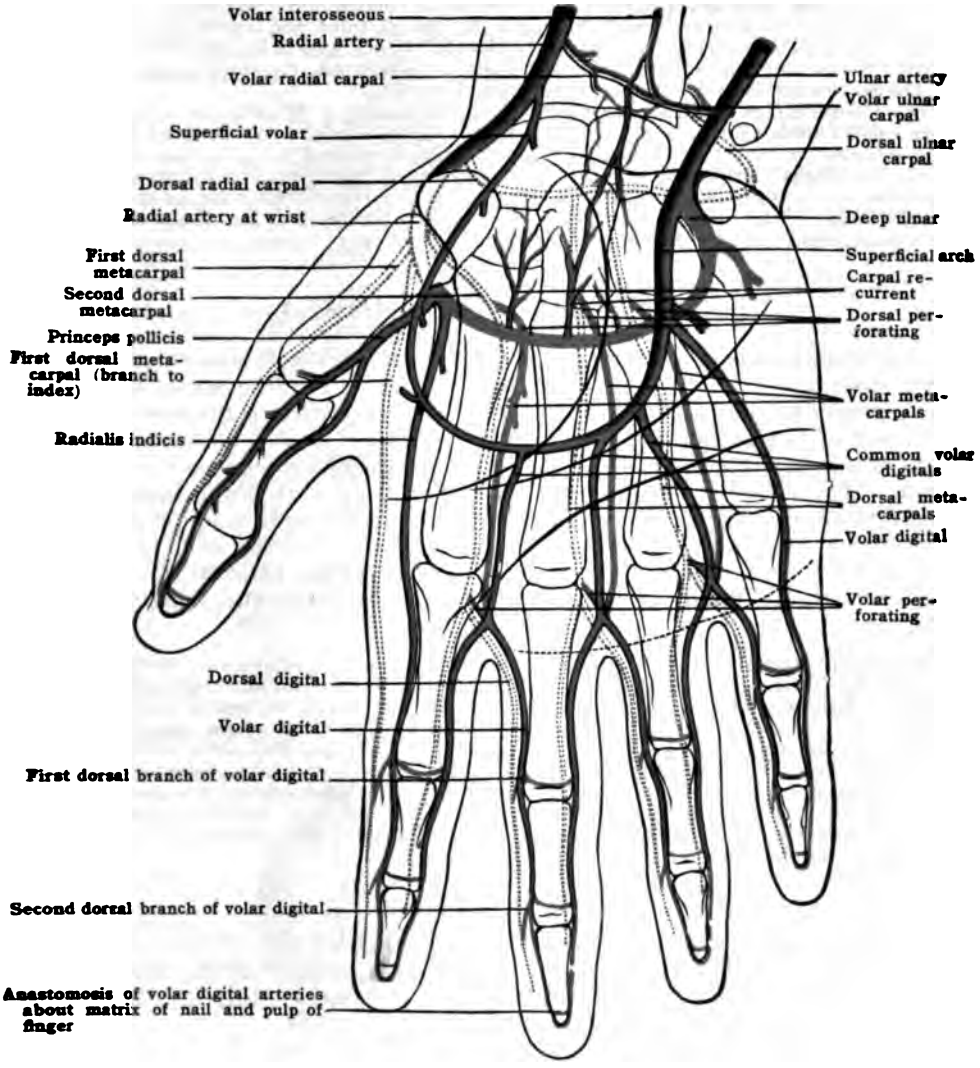
(2) The **first dorsal metacarpal** (fig. 516) is given off by the radial shortly before it passes between the two heads of the first dorsal interosseous muscle. It quickly divides into two branches which supply the dorsal surface of the thumb and the radial side of the index-finger toward its dorsal surface.

III. The Radial Artery in the Palm (Deep Volar Arch)

The radial artery enters the palm between the first and second metacarpal bones at the base of the first interosseous space, by passing between the two heads of the first dorsal interosseous muscle. It then runs medially between the

transverse and oblique heads of the adductor pollicis muscle and continuing its course in a slight curve with the convexity forward, across the base of the metacarpal bones and interosseous muscles, it anastomoses with the deep branch of the ulnar, forming the **deep volar arch** (arcus volaris profundus]. The arch may be said to extend from the first interosseous space to the base of the metacarpal bone of the little finger, and is a finger's breadth nearer the wrist than the superficial arch. It is covered by the superficial and deep flexor tendons, by the

FIG. 516.—ANASTOMOSES AND DISTRIBUTION OF THE ARTERIES OF THE HAND. (Walsham.)



superficial head of the flexor pollicis brevis, and by part of the flexor quinti digiti brevis. It is accompanied by the deep branch of the ulnar nerve, and two small venæ comitantes (figs. 515, 516).

The branches of the deep volar arch are: (1) The princeps pollicis; (2) the volaris indicis radialis; (5) the volar metacarpals (three in number); (4) the recurrent carpal; (3) the dorsal perforating. The first two are sometimes described as arising from the radial artery in the palm; the last three from the deep volar arch.

(1) **The arteria princeps pollicis** arises from the radial artery as it enters the palm between the two heads of the first dorsal interosseous muscle. It passes downward between the adductor pollicis transversus and the first dorsal interosseous muscle, parallel with the metacarpal bone, and between the two portions of the flexor pollicis brevis under cover of the flexor pollicis longus. Opposite the metacarpophalangeal joint it usually divides into two branches, one

of which is distributed to each side of the thumb on its volar aspect. These vessels anastomose with each other at the end of the thumb, like the other digital arteries.

(2) The **arteria volaris indicis radialis** comes off from the radial artery a little beyond the princeps pollicis, or as a common trunk with it, and passes forward between the first dorsal interosseous and adductor pollicis transversus, parallel with the radial side of the second metacarpal bone. After emerging from beneath the adductor pollicis transversus it continues its course along the radial side of the volar aspect of the index-finger, anastomosing in this course with the digital artery on the opposite side of the finger in a way similar to that of the other digital arteries. It frequently communicates, at the lower border of the adductor pollicis, with the superficial volar arch and princeps pollicis. It gives off a dorsal branch, which anastomoses with the branch from the first dorsal metacarpal to the index-finger.

(3) The **volar metacarpal** arteries [aa. metacarpeæ volares], three in number, come off from the convexity of the deep arch, and, running in the second, third, and fourth interosseous spaces on the interosseous muscles, terminate near the cleft of the fingers by anastomosing with the digital arteries from the superficial arch. These vessels supply the interosseous muscles and the bones, and the second, third, and fourth lumbricales.

(4) The **recurrent branches** come off from the concavity of the arch, and consist of two or three small vessels which run toward the wrist, and anastomose with the volar branch of the volar interosseous, and the volar radial and ulnar carpal arteries.

(5) The **dorsal perforating** branches [rr. perforantes], which are usually three in number, pass from the arch directly through the second, third, and fourth interosseous spaces between the two heads of the corresponding dorsal interosseous muscle, and join the proximal ends of the second, third, and fourth dorsal metacarpal arteries respectively.

THE THORACIC AORTA

The **thoracic aorta** [aorta thoracalis] (fig. 517) is the thoracic portion of the aorta descendens. It extends from the termination of the aortic arch at the lower border of the body of the fourth thoracic vertebra to the lower border of the body of the twelfth thoracic vertebra, where it passes between the medial crura of the diaphragm, and is thence continued under the name of the abdominal aorta. It is at first situated a little to the left of the vertebral column, but as it descends, approaches the front of the column, at the same time following its backward curve, and at the diaphragm is almost in the middle line. It lies in the posterior mediastinum, having the esophagus at first a little to the right of it, then in front, and finally (near the lower end of the esophagus) a little to the left side.

Relations.—In front the descending aorta is crossed from above downward by the root of the left lung, by the esophagus, which separates it from the pericardium and heart, and by the diaphragm. **Behind,** it lies upon the lower seven thoracic vertebræ, and is crossed obliquely opposite the seventh or eighth thoracic vertebra by the vena hemiazygos (azygos minor) and opposite the fifth or sixth vertebra by the accessory hemiazygos vein, or by one or more of the intercostal veins. On the **right side** it has, above, the esophagus and vertebral column; lower down the right pleura and lung. The vena azygos and thoracic duct also lie to the right, but on a somewhat posterior plane. On the **left side** it has the left lung and pleura above, and the esophagus below. The vena hemiazygos and the accessory hemiazygos vein are also to the left, but on a posterior plane.

Branches of the Thoracic Aorta

The **branches of the thoracic aorta** may be divided into (*A*) the visceral and (*B*) the parietal. The **visceral** are: (1) The pericardiac; (2) the bronchial; and (3) the esophageal. The **parietal** are: (1) The intercostal; (2) the superior phrenic; and (3) the arteria aberrans.

A. Visceral Branches

(1) The **pericardiac** branches [rami pericardiaci]—two or three small branches, irregular in their origin, course, and distribution—pass to the posterior surface of the pericardium to supply that structure, and anastomose with the other pericardiac branches. They give small twigs to the posterior mediastinal glands.

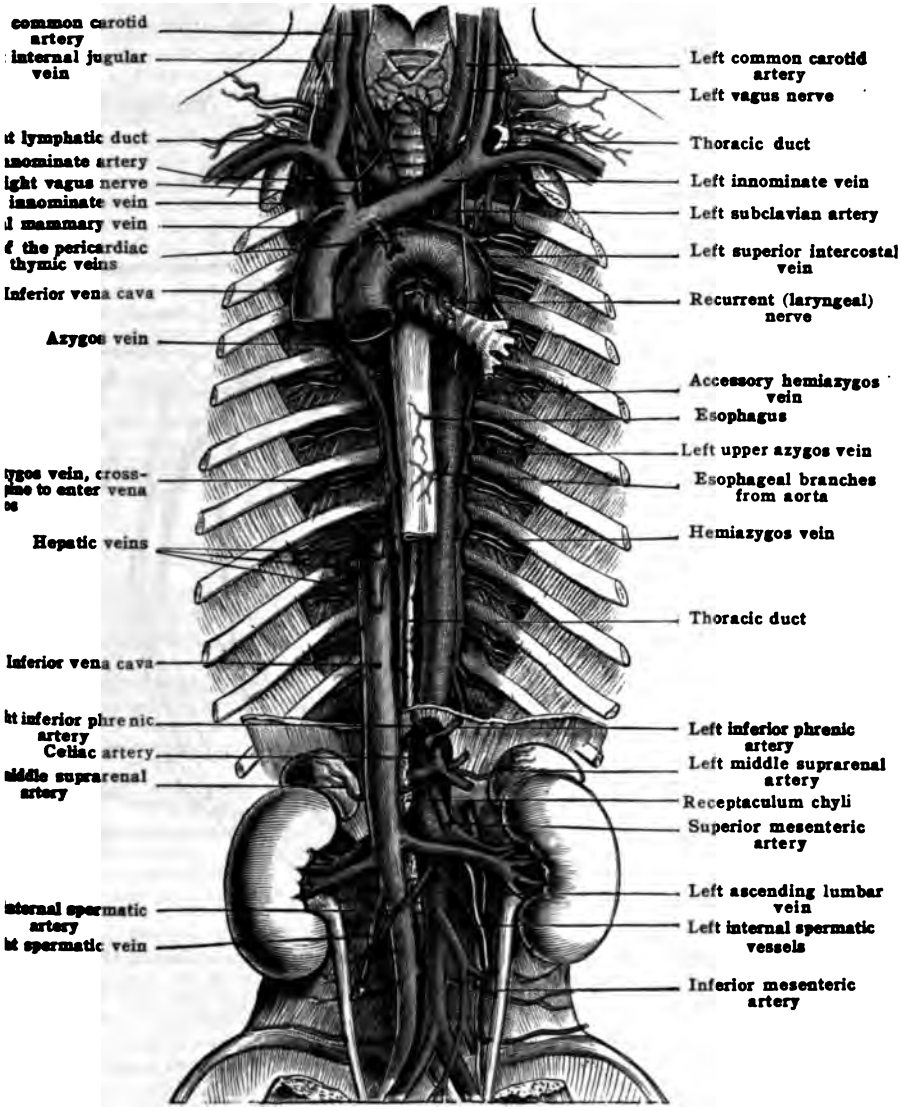
(2) The **bronchial** arteries [aa. bronchiales] supply the bronchi and the lung substance. They vary considerably in their origin, course, and distribution; they are usually three in number—one on the right side, and two on the left

(*a*) The **right bronchial** generally arises either from the first right aortic intercostal, or else as a common trunk with the left upper bronchial from the front of the aorta just below the level of the bifurcation of the trachea. It passes laterally on the back of the right bronchus, and is distributed to the bronchi and lung substance. (*b*) The **left upper bronchial** arises from the front of the aorta just below the bifurcation of the trachea, or as a common trunk with the right bronchial. (*c*) The **left lower bronchial** arises from the front of the aorta just below the level of

: **bronchus.** Like the corresponding artery on the right side, the left bronchial arteries erally on the left bronchus, and, after dividing and subdividing on the back of the bronchi, the bronchi themselves and the lung substance. Small twigs are given off from the ial arteries to the bronchial glands and to the esophagus.

) **The esophageal** arteries [aa. œsophageæ], four or sometimes five in number, ıt intervals from the front of the descending thoracic aorta, the first coming ıt below the left lower bronchial. They usually increase in size from above

. 517.—THE ARCH OF THE AORTA, THE THORACIC AORTA, AND THE ABDOMINAL AORTA, THE VENA CAVA SUPERIOR AND INFERIOR AND THE INNOMINATE AND AZYGOS VEINS.



ward, the upper coming off more toward the right side of the aorta, the lower toward the left side. They pass forward to the esophagus, supplying ube and anastomosing with each other and with the descending esophageal hes of the inferior thyroid above, and with the ascending esophageal hes of the phrenic and gastric arteries below, thus forming a chain of anas- ses along the whole length of the tube.

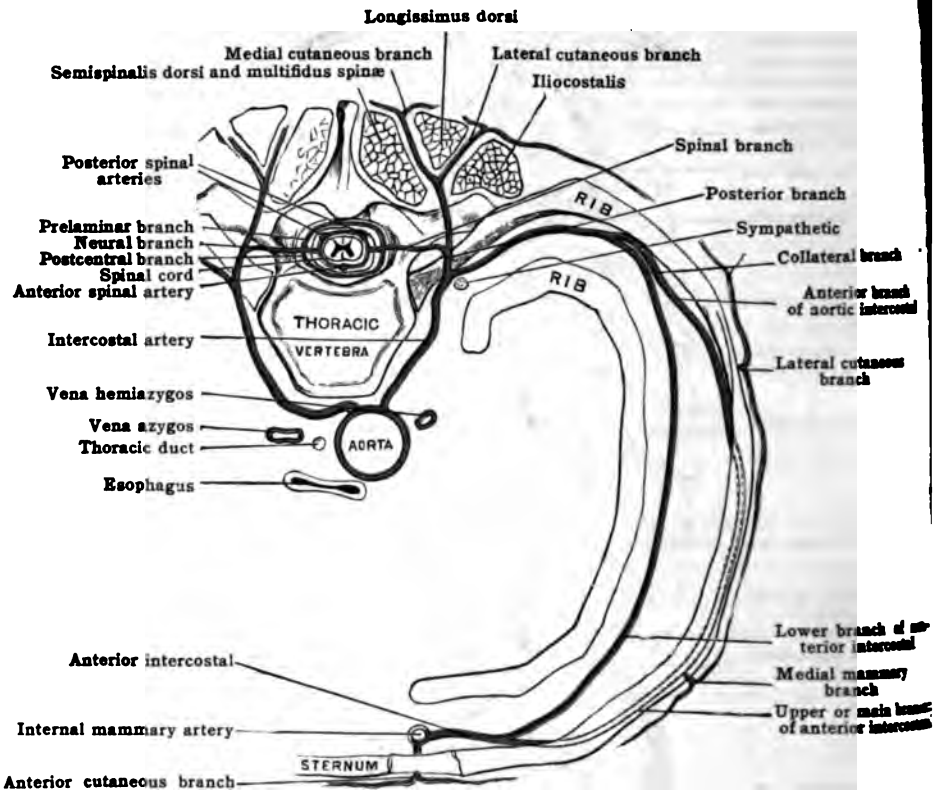
B. PARIETAL BRANCHES

) **The intercostal** arteries [aa. intercostales], usually ten in number on each upply the lower intercostal spaces, the two upper spaces (occasionally the

first only) being supplied from the costocervical trunk of the subclavian arte
The lowest artery accompanies the twelfth thoracic nerve below the last rib
is therefore called the **subcostal artery.** Its distribution is similar to that of
lumbar arteries (p. 630) except that it commonly crosses the anterior surfa
rather than the posterior, of the quadratus lumborum.

The intercostals arise in pairs from the back part of the aorta, and turning,
one to the right and the other to the left, wind backward over the front and si
of the vertebral bodies to reach the intercostal spaces. In fetal life these arte
run almost transversely backward, or even with a slight inclination downwa
to the intercostal spaces; but after the first year, in consequence of the disprop
tionate growth of the aorta and vertebral column, the upper intercostals ha
to ascend to reach their respective spaces.

FIG. 518.—SCHEME OF INTERCOSTAL ARTERY. (Walsham.)



The arteries in their course around the vertebræ differ on the two sides of the body. On the **right side** the arteries—and especially the upper, in consequence of the aorta lying a little to the left side of the spine in the upper part of its course—are longer than the left. They wind over the front and right side of the vertebræ, being crossed by the thoracic duct and vena azygos (major), and covered by the right pleura and lung. The upper are also crossed by the esophagus. They give off small branches to the bodies of the vertebræ and anterior longitudinal ligament. On the **left side,** as the intercostals wind around the sides of the bodies of the vertebræ, the lower ones are crossed by the vena hemiazygos (azygos minor), the two upper by the left superior intercostal vein, and the two next by the accessory hemiazygos, when this is present. They are all covered by the left pleura and lung (fig. 518).

The **branches of the intercostal arteries** are: (a) anterior, (b) posterior.

(*a*) The **anterior** branches [rami anteriores] at first cross the intercostal space obliquely, in consequence of the downward direction of the ribs, toward the angle of the rib above, and thence are continued forward in the costal groove. They anastomose with the superior branches of the anterior intercostal branches of the internal mammary in the upper spaces, and of the musculophrenic in the lower spaces. They lie at first on the external intercostal muscle, being covered in front by the pleura and lung, the endothoracic fascia, and the subcostal muscles. Opposite the heads of the ribs they are crossed by the sympathetic nerve. At the angle of the ribs they pass under cover of the internal intercostal muscles, and thence to the termination lie between the two intercostal muscles. They are accompanied by a nerve and

vein lying above and the nerve below, except in the upper spaces, where the artery, ascend to reach the space, at first lies below the nerve which runs more horizontally. rmost branch anastomoses with the costocervical artery from the subclavian, and at plies almost entirely the second intercostal space. The arteries to the tenth and paces on reaching the end of the costal cartilages pass between the abdominal muscles, omose with the inferior epigastric artery from the external iliac, and with the lumbar om the abdominal aorta. The artery beneath the twelfth rib anastomoses with the teries and with the deep circumflex iliac.

anterior branch gives off the following: (i) The **collateral** branch which comes off angle of the rib and runs forward, between the external and internal intercostals, upper border of the lower rib enclosing the space. It is smaller than the main anterior id anastomoses with the lower anterior intercostal in each space. (ii) **Muscular** [rami musculares] supply the intercostal, pectoral and abdominal muscles. (iii) l **cutaneous** branches [rami cutanei laterales] run with the corresponding branches of ostal nerves through the external intercostal and serratus anterior muscles. They le into *anterior* and *posterior* branches which turn forward and backward, respectively, the integument. The anterior branches from the third, fourth and fifth spaces *eral mammary* branches [rr. mammarii laterales] to the lateral region of the breast. ior **cutaneous** branches [rami cutanei anteriores] pierce the external intercostal liga- the pectoralis major near the sternum. They are distributed to the skin and give *mmary* branches [rr. mammarii mediales] to the medial region of the breast.

e **posterior** branches [rami posteriores].—These large branches are given off from the ls opposite the quadrilateral space bounded by the transverse process of the vertebra e neck of the rib below, the body of the vertebra medially, and the anterior costo- ligament laterally. Passing backward toward this space with the dorsal branch responding intercostal nerve, they divide opposite the intervertebral foramen into a and a spinal branch. (i) The **muscular** branch [r. muscularis] passes backward he quadrilateral space, and soon subdivides into a medial and a lateral branch. The ses between the longissimus dorsi and iliocostalis, and, after supplying these muscles, **medial cutaneous** branch [r. cutaneus medialis]. The latter branch pierces the multi- s, and, emerging between the longissimus dorsi and semispinalis dorsi near the spinous gives off a **lateral cutaneous** branch [r. cutaneus lateralis].

e **spinal** branch [r. spinalis] enters the intervertebral foramen with the spinal nerve esponding segment. The disposition of the spinal branches of the intercostal arteries to that of the corresponding branches which enter the canalis vertebralis in other

ARTERIES OF THE VERTEBRAL CANAL

arteries are derived from the vertebral, ascending cervical and costocervical arteries, lorsal rami of the intercostal (fig. 518) and lumbar arteries, and from the iliolumbar l sacral arteries. They divide into three branches, postcentral, prelaminar and

ostcentral branch divides on the lateral part of the posterior longitudinal ligament ending and a descending branch by which means a bilateral series of anastomosing formed throughout the length of the canal. From the concavities of the opposite nsverse connecting stems are formed which are again connected by a median longitu- nel.

elaminar branches also divide and form an anastomosis in front of the laminæ and flava. This is similar in character to the postcentral, but much less regular.

ural branches enter the dura mater and are usually small and end by supplying the s. A variable number of these (5–10 on a side) are larger than the others and rein- ngitudinal anterior and posterior spinal arteries given off from the vertebrals within m. (For arteries of the spinal cord, see Section VIII.)

he **superior phrenic** arteries [aa. phrenicæ superiores], are small twigs ff from the thoracic aorta immediately above the diaphragm. They are ed to the vertebral portion of the diaphragm on its upper surface.

he **arteria aberrans** is a small twig which, arising from the thoracic ar the right bronchial artery, passes upward and to the right behind the s and trachea, and is occasionally found to anastomose on the esophagus arteria aberrans of the right superior intercostal artery (see p. 608). It is as the remains of the right aortic dorsal stem (fig. 546).

he **mediastinal** branches [rami mediastinales], numerous, but small, are ed to the pleura, and the vessels, nerves and lymph-nodes of the posterior ium.

THE ABDOMINAL AORTA

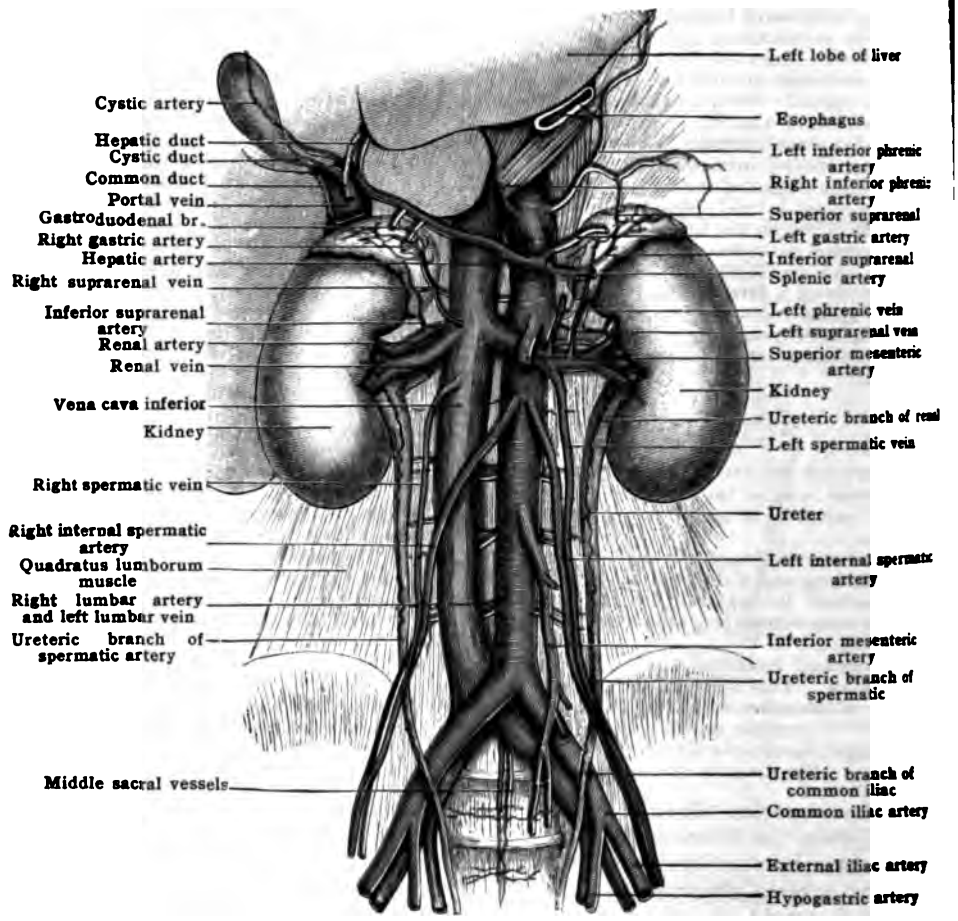
bdominal aorta [aorta abdominalis] (fig. 519), the abdominal portion of nding aorta, begins at the aortic opening in the diaphragm opposite the rder of the twelfth thoracic vertebra, and ends usually opposite the he fourth lumbar vertebra by dividing into the right and left common

iliac arteries. It is at first centrally placed between the medial crura of the diaphragm, but as it descends it deviates a little to the left side.

The place at which the aorta bifurcates may be somewhat roughly indicated on the surface of the abdomen by a point about 2.5 cm. (1 in.) below and a little to the left of the umbilicus. The level of its bifurcation may be more accurately determined by drawing a straight line between the highest points of the iliac crests.

Relations.—In front, the aorta is successively crossed from above downward by the left lobe of the liver, the celiac (solar) plexus, the lesser omentum, the termination of the esophagus in the stomach, the ascending layer of the transverse mesocolon, the splenic vein or commencement of the portal vein, the pancreas, the left renal vein, the third portion of the duodenum, the mesentery, the aortic plexus of the sympathetic nerve, the internal spermatic or ovarian arteries, the inferior mesenteric artery, the median lumbar lymphatic nodes and lymphatic vessels, and the small intestines. Of these structures the celiac (solar) plexus, the aortic

FIG. 519.—THE ABDOMINAL AORTA AND ITS BRANCHES, WITH THE VENA CAVA INFERIOR AND ITS TRIBUTARIES.



plexus, the splenic vein or the commencement of the portal vein, **the pancreas**, the left renal vein, the duodenum, the lymphatics, the spermatic or ovarian **arteries, and the peritoneal** reflexions are in direct contact with the aorta.

Behind, the aorta lies upon the bodies of the lumbar vertebræ and **intervening intervertebral** cartilages, the anterior longitudinal ligament, the origin of the left **medial crus of the diaphragm** and the left lumbar veins.

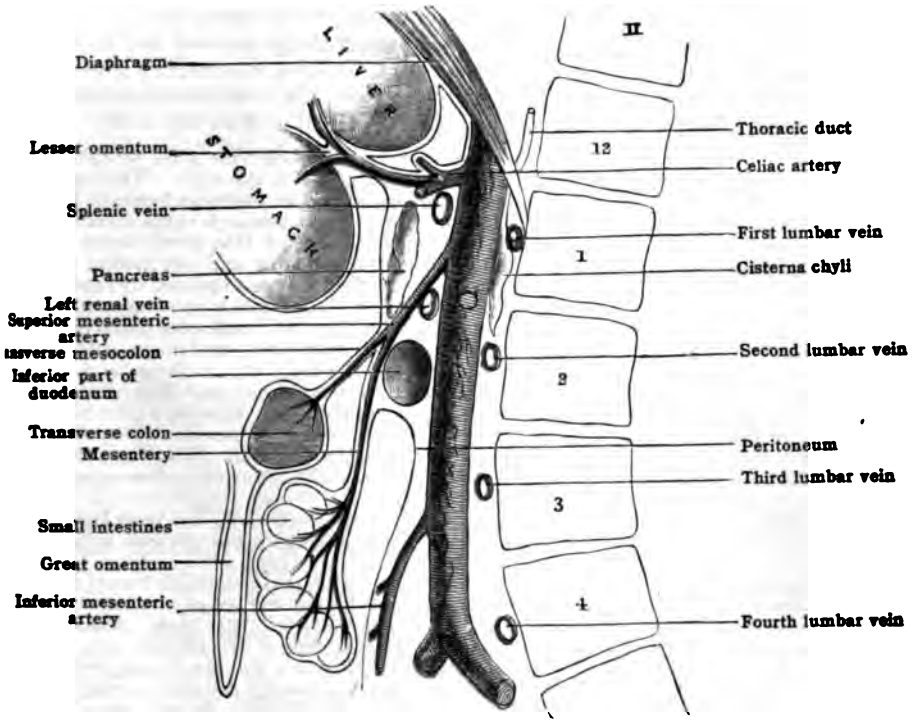
On the **right side** from above downward are the right medial **crus of the diaphragm**, the great splanchnic nerve, the caudate lobe of the liver, the **cisterna chyli and beginning of the** thoracic duct (the two latter structures are on a posterior plane), **the right celiac** (semilunar) ganglion, and the inferior vena cava. Inferiorly, the vena cava **is in contact with the aorta** and on a somewhat posterior plane. Superiorly, the vena cava **is separated from the aorta by** the right medial crus of the diaphragm, and the caval opening **of the diaphragm is on a plane** anterior to the aortic.

On the **left side** are the left medial crus of the diaphragm, **the left splanchnic nerve, and** the left celiac (semilunar) ganglion. The pancreas is also in **contact with the aorta on the** left side, and the small intestines are separated from it only by **peritoneum.**

Branches of the Abdominal Aorta

The branches of the abdominal aorta usually arise in the following order from **ve** downward (figs. 519, 520):
(1) Right and left inferior phrenic; (2) celiac; (3) right and left middle supra-**al**; (4) right and left first lumbar; (5) superior mesenteric; (6) right and **renal**; (7) right and left internal spermatic; (8) right and left second lumbar; **inferior** mesenteric; (10) right and left third lumbar; (11) right and left fourth **ıbar**; (12) right and left common iliac; (13) middle sacral.
The above branches may be divided into the (A) parietal, (B) the visceral, and) the terminal.
The **parietal branches** are distributed to the abdominal walls. They are the ht and left phrenics, and the four right and left lumbars.

Fig. 520.—Scheme of the Abdominal Aorta. (Walsham.)



The **visceral branches** supply the viscera. Three of these are given off singly n the front of the aorta, namely, the celiac, the superior mesenteric, and the erior mesenteric; and three are given off in pairs, namely, the two suprarenals, two renals, and the two spermatics.
The **terminal branches** are the middle sacral and the right and left common c arteries.

A. The Parietal Branches of the Abdominal Aorta

1. THE INFERIOR PHRENIC ARTERIES

The inferior phrenic artery [a. phrenica inferior] usually arises from the aorta t passes between the medial crura of the diaphragm. At times it comes off n the celiac artery; or when it arises as two separate vessels, either the right eft vessel may come from this artery, or from other of the upper branches of abdominal aorta.

The right phrenic (fig. 520) passes over the right crus of the diaphragm behind the vena cava then upward and to the right between the central and right leaflets of the central tendon of muscle, where it divides into an **anterior** and a **posterior** branch. The former courses riorly and medially and anastomoses with the anterior branch of the left phrenic, with the

musculophrenic branches of the internal mammary, and with the pericardiophrenic arteries; the latter passes posteriorly and laterally toward the ribs, and anastomoses with the intercostal arteries. Besides the two terminal branches and branches for the supply of the diaphragm itself the right phrenic gives off the **right superior suprarenal** [ramus suprarenalis superior] to the right suprarenal gland, as well as branches to the vena cava, to the liver, and to the pericardium.

The **left phrenic** crosses the left crus of the diaphragm behind the esophagus, and, like the right artery, divides into an anterior and posterior branch and gives off a left suprarenal branch. The distribution and anastomoses are similar on the two sides.

2. THE LUMBAR ARTERIES

The **lumbar** arteries [aa. lumbales] (fig. 519), usually eight in number, four on each side, come off in pairs from the posterior aspect of the abdominal aorta, opposite the bodies of the four upper lumbar vertebræ. A fifth pair of lumbar arteries, generally of small size, frequently arises from the middle sacral artery opposite the fifth lumbar vertebra. The lumbar arteries, which are rather longer on the right than on the left side, in consequence of the aorta lying a little to the left of the median line, wind more or less transversely around the bodies of the vertebræ to the space between the transverse processes, where they give off each a dorsal branch, and then, coursing forward between the abdominal muscles, terminate, by anastomosing with the other arteries of the abdominal wall.

Relations.—As they wind around the bodies of the vertebræ they pass beneath the sympathetic trunk, and the upper two beneath the crura of the diaphragm. The right arteries also pass beneath the vena cava inferior, and the two upper on that side beneath the cisterna chyli. The arteries on both sides then dip beneath the tendinous arch thrown across the sides of the bodies of the vertebræ by the psoas, and continue beneath this muscle until they arrive at the interval between the transverse processes of the vertebræ and the medial edge of the quadratus lumborum. While under cover of the psoas they are accompanied by rami communicantes of the sympathetic and by the lumbar veins. A little anterior to the transverse processes they are crossed by branches of the lumbar plexus of nerves, and here usually cross in front of the ascending lumbar vein. They now pass behind the quadratus lumborum, with the exception sometimes of the last, which may pass in front of the muscle. At the lateral edge of the quadratus they run between the transversus and the internal oblique, and then, after perforating the internal oblique, between the internal and external oblique. Finally, much diminished in size, they enter the rectus, and give off one or more anterior cutaneous branches, which accompany the last thoracic and the iliohypogastric nerves to the skin. They anastomose with the lower intercostals, iliolumbar, deep circumflex iliac, and inferior epigastric arteries.

The **branches of the lumbar arteries** are:

(*a*) **Vertebral** branches which supply the bodies of the vertebræ and their ligaments.

(*b*) **Muscular** branches to the psoas, quadratus lumborum, and oblique muscles of the abdomen.

(*c*) The **dorsal** branch [r. dorsalis]. This is of large size, and passes backward in company with the dorsal nerve between the transverse processes above and below, the intertransversalis medially and the quadratus lumborum laterally, to the muscles of the back. On reaching the interval between the longissimus dorsi and multifidus spinæ, it divides into a lateral and a medial branch. The former ends in the multifidus, the latter and larger supplies the sacrospinalis, and gives branches which accompany the termination of the dorsal nerves to the skin. Just before the artery passes between the transverse processes it gives off a **spinal branch** [r. spinalis], which accompanies the lumbar nerve through the intervertebral foramen into the vertebral canal (see p. 627).

(*d*) **Renal** branches of small size pass forward in front of the quadratus lumborum to the capsule of the kidney. They anastomose with the renal artery. A communication is thus established between the renal arteries and the arteries supplying the lumbar region.

B. THE VISCERAL BRANCHES OF THE ABDOMINAL AORTA

THE CELIAC ARTERY

The **celiac** artery [a. cœliaca] or **celiac axis**, is a short thick trunk given off from the front of the aorta between the medial crura of the diaphragm a little below the aortic opening. It passes horizontally forward above the upper margin of the pancreas for about half an inch, and then breaks up into three branches for the supply of the stomach, duodenum, spleen, pancreas, liver, and gall-bladder (fig. 521).

Relations. In front is the lesser omentum; behind, the aorta; above, the right lobe of the liver; below, the pancreas; to the right, the right celiac (semilunar) ganglion and caudate lobe of the liver; to the left, the left celiac (semilunar) ganglion and the cardiac end of the stomach. It is closely surrounded by the dense celiac (solar) plexus of sympathetic nerves.

Branches of the celiac artery. The celiac artery divides into (1) the left gastric, (2) the hepatic, and (3) the splenic arteries.

1. The Left Gastric Artery

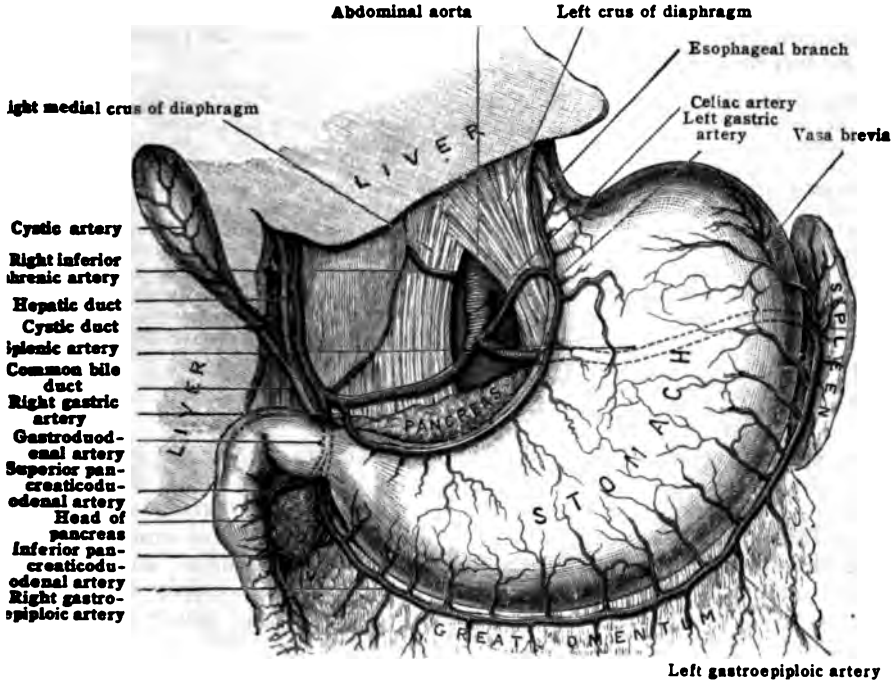
The left gastric [a. gastric sinistra] (fig. 521), the smallest of the three branches ne celiac artery, courses at first upward and to the left toward the cardiac end he stomach, where it turns sharply round, and then, following the lesser rature of the stomach, descends from left to right toward the pylorus. It stomoses with the right gastric branch of the hepatic artery, which has ceeded from the opposite direction, the two branches thus forming a con- ıous arterial arch corresponding to the lesser curvature of the stomach.

The artery at first lies behind the posterior layer of the omental bursa of peritoneum (fig. ', but on reaching the cardiac end of the stomach it passes, between the layers of peritoneum cted from the diaphragm onto the esophagus, into the lesser omentum in which it then ı to its terminal anastomosis with the pyloric. It is surrounded by a plexus of sympathetic ves. It supplies both surfaces of the stomach around the lesser curvature and gives off small phageal branches [rami œsophagei] which anastomose with the esophageal branches from thoracic aorta.

2. The Hepatic Artery

The hepatic artery [a. hepatica] is the largest branch of the celiac artery in the ıs, but intermediate in the adult between the left gastric and the splenic. arises on the right side of the celiac artery, and, winding upward and to the

Fig. 521.—The Celiac Artery and its Branches.



t to the porta (portal fissure) of the liver, there breaks up into two chief ıches for the supply of the right and left lobes of that organ. It at first courses ard and to the right along the upper border of the head of the pancreas, be l the posterior layer of the peritoneal omental bursa, to the upper margin of duodenum, where it passes forward beneath the layer of peritoneum forming floor of the epiploic foramen (of Winslow). It then runs between the two rs of the lesser omentum, and ascends along with the hepatic duct which lies s right, and with the portal vein which lies behind it (figs. 520, 521).

The branches of the hepatic artery are: (1) The right gastric; (2) the gastroduodenal; (3) the hepatic proper.

(1) The **right gastric** artery [a. gastrica dextra] arises from the hepatic as the er vessel enters the lesser omentum, and, descending to the pylorus, there ıs to the left, and, ascending from right to left, anastomoses along the lesser

curvature of the stomach, as already mentioned, with the left gastric artery, w descends from the opposite direction.

(2) The **gastroduodenal** artery [a. gastroduodenalis] arises from the hep a little beyond the right gastric. It descends behind the first part of duodenum to the lower border of the pylorus, where it divides into the ri **gastroepiploic** and the **superior pancreaticoduodenal.** It varies from 1.2 2.5 cm. (½ to 1 in.) in length.

(*a*) The **right gastroepiploic** artery [a. gastroepiploica dextra] passes from right to along the greater curvature of the stomach between the layers of the great omentum, anastomoses with the left gastroepiploic branch of the splenic. From this anastomotic are given off: (i) **Ascending** or **gastric** branches, which supply the anterior and poste surfaces of the stomach, and anastomose with the descending gastric branches of the arte along the lesser curvature. (ii) **Epiploic** [rami epiploici] or **omental branches**—long slen vessels which descend between the two anterior layers of the great omentum, and then, loop upward, anastomose with similar slender branches given off from the middle and left p and passing down in like manner between the posterior layers of the great omentum.

(*b*) The **superior pancreaticoduodenal** [a. pancreaticoduodenalis superior]—the sma division of the gastroduodenal—arises from that vessel as it passes behind the first portion the duodenum, and courses downward behind the peritoneum, in the anterior groove betw the second portion of the duodenum and the pancreas, to anastomose with the inferior p creaticoduodenal, a branch of the superior mesenteric. Both the inferior and superior p creaticoduodenal give off **duodenal** [rami duodenales] and **pancreatic** branches [rami pancrea to supply these organs.

(3) The **hepatic artery proper** [a. hepatica propria] is the continuation of hepatic after the gastroduodenal has arisen. It ascends between the layer the lesser omentum, preserving the relations of the main artery to the portal and common bile (and hepatic) duct, and divides, near the porta hepatis, **right** and **left** branches.

(*a*) The **right branch** [r. dexter], given off at the porta (portal fissure) of the liver, runs t right either behind the hepatic and cystic ducts, or between these structures. At the righ of the porta it divides into branches, which again subdivide as they enter the liver subs for the supply of the right lobe. As it crosses the cystic duct it gives off the cystic artery.

The **cystic** artery [a. cystica] courses forward and downward through the angle fo by the union of the hepatic and cystic ducts, and just before it reaches the gall-bladder di into a superficial and deep branch. The former breaks up into a number of small vessels, ramify over the free surface of the gall-bladder beneath the peritoneal covering, and fu branches to the muscular and mucous coats. The deep branch ramifies between the bladder and the liver-substance, supplying each, and anastomosing with the superficial br

(*b*) The **left** branch [r. sinister], the smaller division of the hepatic artery, runs towar left end of the porta hepatis, and, after giving off a distinct branch to the caudate (Spig lobe, enters the left lobe of the liver.

3. The Splenic Artery

The **splenic** artery [a. lienalis]—the largest branch of the celiac art arises from the left side of the termination of that vessel below the left ga and passes along the upper border of the pancreas in a tortuous manner t spleen. It at first lies behind the posterior wall of the bursa omentalis, b nearing the spleen enters the phrenolienal (lienorenal) ligament, and there b up into numerous branches, which enter the hilus and supply the organ crosses in front of the left crus of the diaphragm and the upper end of th kidney and is placed above the splenic vein.

The **branches of the splenic artery** are: (*a*) The pancreatic; (*b*) th gastroepiploic; (*c*) the vasa brevia; and (*d*) the terminal.

(*a*) The **pancreatic** branches (rami pancreatici) come off from the splenic at varying in as that vessel courses along the upper margin of the pancreas. They enter and supp organ. One larger branch usually arises from the splenic about the junction of its with its left third. Entering the pancreas obliquely, it runs from left to right, commonly and a little behind, the pancreatic duct, which it supplies together with the substance organ.

(*b*) The **left gastroepiploic** [a. gastroepiploica sinistra] arises from the splenic n greater curvature and below the fundus of the stomach, and, passing between the s layers of the great omentum, descends along the greater curvature of the stomach fr to right, and anastomoses with the right gastroepiploic. Like that vessel, it gives off asc or **gastric** branches to the anterior and posterior surfaces of the stomach respectivel long slender **descending epiploic** or **omental** branches to the great omentum which anas with like branches from the right and left colic arteries.

(*c*) The **vasa brevia** [aa. gastricæ breves] come off from the splenic just before it divid its terminal branches, or from some of the terminal branches themselves. Passing from b

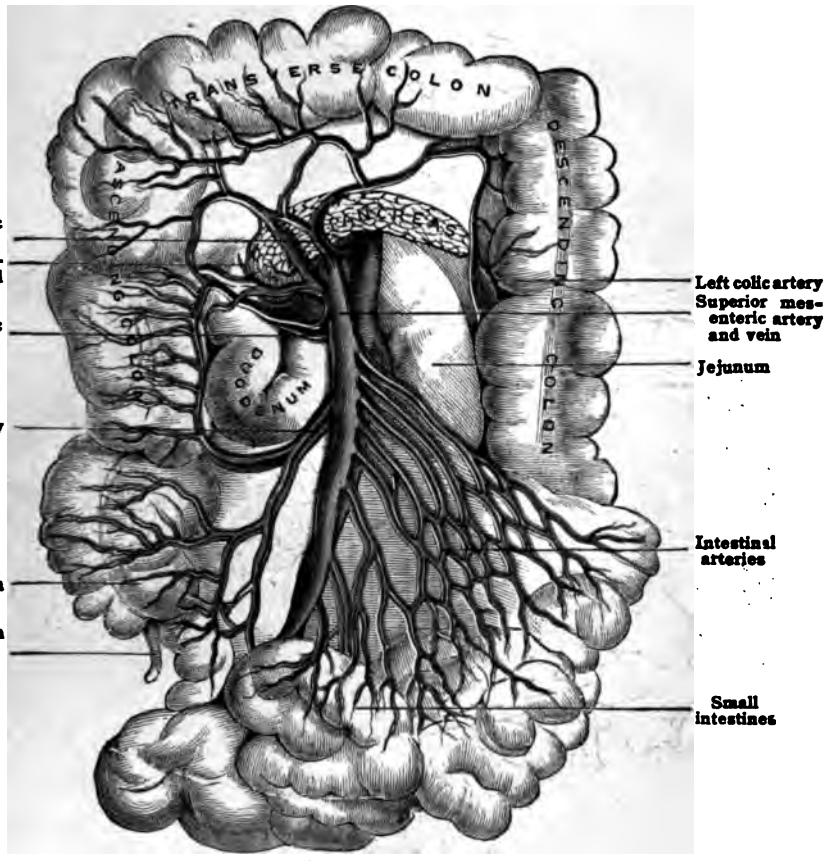
the phrenolienal ligament into those of the gastrolienal, they reach the fundus of the here, ramifying over its anterior and posterior surfaces, they anastomose with the and left gastroepiploic arteries.

splenic or terminal branches, five to eight or more in number, are given off from the it lies in the lienorenal ligament, and, entering the spleen at the hilum, are distributed the description of that organ.

THE SUPERIOR MESENTERIC ARTERY

superior mesenteric artery [a. mesenterica superior] arises from the the aorta a little below the celiac, which it nearly equals in size; some- two vessels arise by a common trunk. Lying at first behind the pan- splenic vein, it soon passes forward between the lower border of the and the upper border of the inferior portion of the duodenum. Now in front of the duodenum, it enters the mesentery, in which it runs

FIG. 522.—THE SUPERIOR MESENTERIC ARTERY AND VEIN.
e colon is turned up, and the small intestines are drawn over to the left side.)



rm of a curve with its convexity to the left, to the cecum, where it ses with its ileocolic branch. Its vein lies to its right side above, having y crossed obliquely in front of the artery from the left. It is sur- by the mesenteric plexus of nerves. The uncinate process of the head ncreas dips in behind the vessel.

branches of the superior mesenteric are: (1) the inferior pancreatico- ; (2) the intestinal arteries; (3) the ileocolic; (4) the right colic; and iddle colic.

inferior pancreaticoduodenal [a. pancreaticoduodenalis inferior] arises either from or mesenteric as that vessel emerges from the contiguous margins of the pancreas or part of the duodenum or from its first intestinal branch. Crossing behind the esenteric vein, it courses upward and to the right between the head of the pancreas uodenum, and beneath the ascending layer of the transverse mesocolon, to anas- h the superior pancreaticoduodenal.

FIG. 523.—THE BLOOD-VESSELS OF THE ILEOCECAL REGION. (From Kelly.)

Arteries red, veins blue.) The peritoneal covering is removed so as to show the vessels more clearly. Above and to the right are seen the cut ends of the ileocolic artery and vein. The artery gives off a branch to the ascending colon and a posterior and anterior cecal artery, the latter descending through the ileocolic fold. A short anastomosis connects the ileocolic with the mesenteric. The artery of the vermiform process (appendix) is seen to arise from the posterior cecal artery, 2 cm. above the ileum. It passes behind the ileum in the free border of the mesoappendix and gives off five branches (long appendices have 8–12, short appendices, 2–3), which traverse the mesoappendix at fairly regular intervals in the direction of the hilus of the appendix, where they divide into anterior and posterior branches. The branches in the mesoappendix are sometimes seen to anastomose, forming loops of varying size. The terminal branch curves around the tip. The cecoappendicular junction is supplied by a separate branch arising likewise from the posterior ileocecal trunk. This branch may or may not anastomose with the proximal appendicular twig and while in some cases it supplies only the cecum, in others, as in the present case, it sends a few delicate branches into the appendix. At the place where this cecoappendicular artery crosses the ileocecal fold it is seen to give off a delicate recurrent twig to this structure. Throughout their entire course the arteries are accompanied by veins.

) **The intestinal** arteries [aa. intestinales] arise from the convex side of the superior mesen- **and**, varying from twelve to sixteen in number, radiate in the mesentery, where each **s** into two branches, which inosculate with similar branches given off from the branch **and** below. From the primary loops thus formed, secondary loops are derived in like **er**, and from these tertiary, and at times quaternary, or even quinary loops. From **ltimate** loops terminal **jejunal and iliac** branches [aa. jejunales et ileæ] pass on to the mus- **coat** of the gut. These terminal vessels bifurcate, the two branches encircling the intes- **and** thus forming with those above and below a series of vascular rings surrounding the intestine throughout its whole length. The first intestinal artery anastomoses with the **reaticoduodenal** artery, and the last (the continuation of the main artery) with the ileo-

The branches of the superior mesenteric in their course to the intestine also supply the **ntery** and the mesenteric glands.

) **The ileocolic** [a. ileocolica] descends behind the peritoneum toward the cecum, where **ides** into a colic branch which tracks upward beneath the peritoneum to anastomose with **lescending** branch of the right colic; and into an iliac branch which passes between the **s** of the mesentery and anastomoses with the termination of the superior mesenteric **y**. Near the site of division the ileocolic gives off anterior and posterior cecal branches. **h** the latter of these arises a cecoappendicular artery, to the cecum and root of the vermi- process, and a main **appendicular** artery [a. appendicularis] (fig. 523).

) **The right colic** [a. colica dextra]—sometimes given off as a common trunk either with **iddle colic** or with the ileocolic—passes to the right behind the peritoneum to the back **ascending** colon, where it divides into an ascending branch, which anastomoses with the **nding branch** of the middle colic, and a descending branch which anastomoses with the **ding** or colic branch of the ileocolic.

) **The middle colic** [a. colica media], arising from the concavity of the superior mesenteric **e** below the pancreas, enters the transverse mesocolon, and divides into two branches— **f which passes** to the left and anastomoses with the ascending branch of the left colic; **ther, winding** downward and to the right, anastomoses with the ascending branch of the **colic**.

THE RENAL ARTERIES

he renal arteries [aa. renales] come off one on each side of the abdominal **, a little below** the superior mesenteric and first lumbar arteries, on a level **the first lumbar** vertebra. They pass laterally across the crura of the **iragm** to the kidneys, the right being on a slightly lower plane and somewhat **r than** the left, and passing behind the vena cava inferior. In front of each **corresponding renal** vein, and behind, at the hilus of the kidney, is the com- **ement** of the ureter. Each artery as it enters the hilus usually divides into **main stems, one** of which passes toward the upper part of the pelvis, a second **middle portion, and** a third to its lower. Each of these primary stems then **es so that** there result from seven to nine secondary branches, the majority **hich pass anteriorly** to the pelvis, while the remainder are posterior to it (fig.

No anastomoses take place between the branches of the anterior and **rior secondary** stems and hence a longitudinal incision into the kidney along **rved border**, half way between the anterior and posterior calices, will cut **terminal** arteries.

he branches of the renal arteries are:

) **The inferior suprarenal** [a. suprarenalis inferior] which ascends to the suprarenal body.
) **The capsular** or **perirenal** branches to the capsule of the kidney and perirenal fat.
) **The ureteral** branch to the upper end of the ureter.

THE MIDDLE SUPRARENAL ARTERIES

The middle suprarenal artery [a. suprarenalis media] comes off, one on each **from the aorta**, just above the first lumbar artery, and passes laterally to the **rarenal body**, across the crura of the diaphragm a little above the renal **eries**. In the fetus they equal the renals in size, but in the adult they are **ch** smaller. They anastomose with the superior and inferior suprarenal **eries** from the inferior phrenic and renal arteries respectively. For the **ribution** of the suprarenal vessels within the suprarenal bodies, see Section II.

THE INTERNAL SPERMATIC ARTERIES

The **internal spermatic** arteries [a. spermatica interna], (figs. 519, 582), right left, come off from the front of the abdominal aorta. They diverge from **i** other as they descend over the aorta and psoas muscle to the abdominal **inal** (internal abdominal) ring, where they are joined by the ductus deferens, passing with it through the inguinal canal and out of the subcutaneous

inguinal (external abdominal) ring, run downward into the scrotum in a t
course to the testes. They terminate in branches to the epididymis an
Within the abdomen they lie beneath the peritoneum, and cross in their
over the ureters and distal ends of the external iliac arteries; the right be

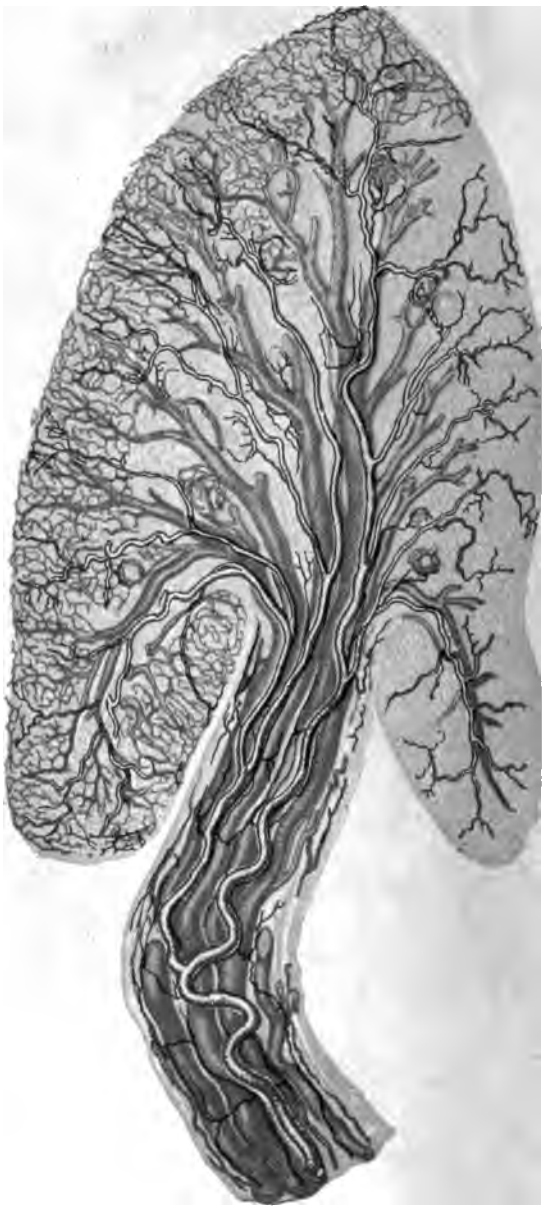
-THE VASCULAR TRUNKS OF THE LOWER ABDOMEN. (From Kelly, by Brödel.)

The **branches of the internal spermatic artery** are: (1) Ureteral; masteric; (3) epididymal; and (4) testicular.

(1) The **ureteral** are small branches given off to the ureter as the spermatic arter it. They anastomose with the other ureteral branches derived from the renal, comm and vesical arteries.

(2) The **cremasteric** are small branches given off to the cremaster muscle; they an with the cremasteric branch of the inferior epigastric.

FIG. 526.—THE OVARIAN VESSELS. (After Clark.)



(3) The **epididymal** are distributed to the epididymis, and **anastomose with the d** artery.

(4) The **testicular** arteries [aa. testiculares] are the **terminal branches of the s** they perforate the tunica albuginea posteriorly, and are distributed to the body of th described in the section on the TESTIS.

The external spermatic artery is a branch of the inferior **epigastric artery** (p. 651

THE OVARIAN ARTERIES

varian arteries [aa. ovaricæ] (figs. 525, 526, 531) are the homologs of **ıal** spermatic arteries in the male, and correspond in their relations in **r** part of their course. They diverge somewhat less, however, and, on **the** level of the common iliac artery, turn medialward over that vessel **end** tortuously into the pelvis between the folds of the broad ligament **aries.** In the broad ligament the ovarian artery lies below the Fallopian **l** on reaching the ovary turns backward and supplies that organ. In **s** shown how the artery enters the hilus of the ovary and breaks up into which correspond to the lobules of the organ.

ıranches of the ovarian arteries are: (1) Ureteral; (2) tubal; (3) uterine; **igamentous.**

e ureteral is distributed, as in the male, to the ureter.
e tubal supplies the isthmus and ampulla of the tuba uterina (Fallopian tube) and **ted extremity.**
e uterine runs beneath the tuba uterina (Fallopian tube) to the uterus, supplying **part of the fundus, and anastomosing with the uterine arteries from the hypogastric.**

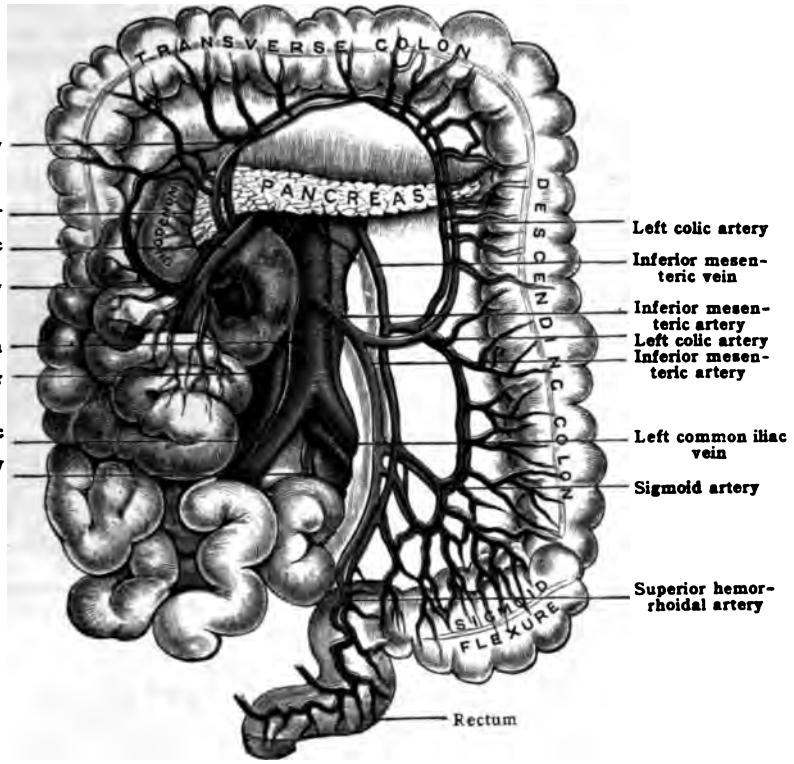
he colon is turned up, and the small intestines are drawn to the right side.)



ıe ligamentous is distributed to the round ligament, passing with that structure **ıe inguinal canal, and anastomosing with the superficial external pudendal artery.**
ıe spermatic, the ovarian arteries in the fetus come off at right angles to the aorta, transversely lateralward to the ovaries, which are formed, as are the testes, in the eft loin in front of the kidneys. They elongate as the ovaries descend into the pelvis. egnancy these arteries undergo great enlargement.

THE INFERIOR MESENTERIC ARTERY

inferior mesenteric artery [a. mesenterica inferior], smaller than the **arises from the front of the abdominal aorta about 3.7 cm. ($1\frac{1}{2}$ in.)** **ıe bifurcation of that vessel. It runs obliquely downward and to the nd the peritoneum, across the lower part of the abdominal aorta and then left psoas muscle and left common iliac artery. It descends into the tween the layers of the sigmoid mesocolon, and terminates on the rectum**

in the superior hemorrhoidal artery. It supplies the lower half of the large testine. Its vein lies at first close to the left side, but soon passes upward on psoas, away from the artery, to end in the splenic vein (fig. 527).

The **branches of the inferior mesenteric** are: (1) The left colic; (2) sigmoid; and (3) the superior hemorrhoidal.

(1) The **left colic** artery [a. colica sinistra] runs transversely to the left, beneath the toneum, and divides into two branches, one of which, entering the transverse mesocolon cends upward and to the right, to anastomose with the middle colic. The other descends, entering the sigmoid mesocolon anastomoses with the ascending branch of the sigmoid a

The distribution of the branches of the left colic and of the sigmoid artery to the co similar to that of the colic branches of the superior mesenteric, and does not require a rate description.

(2) The **sigmoid artery** [a. sigmoidea] runs downward and to the left over the psoas cle and, entering the sigmoid mesocolon, divides into two branches; the upper anastom with the left colic, the lower with the superior hemorrhoidal. The distribution of the bra of the left colic and of the sigmoid artery to the colon is similar to that of the colic branch the superior mesenteric, and does not require a separate description. (See p. 635.)

(3) The **superior hemorrhoidal** artery [a. hæmorrhoidalis superior] (fig. 525) is the cont trunk of the inferior mesenteric. It descends into the pelvis, behind the rectum, betwee layers of the sigmoid mesocolon. On reaching the wall of the bowel it bifurcates, one b proceeding on either side of the gut, to within 10 or 12 cm. (4 or 5 in.) of the anus. Here again divides, and the branches, piercing the muscular coat, descend between that coa the mucous membrane, forming with each other, and with the middle hemorrhoidal arte derived from the hypogastric (internal iliac)—a series of small vessels, running longitudina the rectum, and parallel to each other as far as the level of the internal sphincter, where, by anastomosis, they form a series of loops around the lower part of the rectum.

C. The Terminal Branches of the Abdominal Aorta

THE MIDDLE SACRAL ARTERY

The **middle sacral** artery [a. sacralis media] extends from the bifurcati the aorta to the tip of the coccyx. As it passes downward into the pelv runs behind the left common iliac vein, the hypogastric plexus of the sympat nerve, and the peritoneum. It lies successively upon the intervertebral between the fourth and fifth lumbar vertebræ, the fifth lumbar vertebra intervertebral disk between that vertebra and the sacrum, and lower down the anterior surface of the sacrum and coccyx.

(1) The **lowest lumbar** artery [a. lumbalis ima] runs laterally beneath the common iliac and vein; and, after giving off a dorsal branch, ramifies over the lateral part of the sacrum ends in the iliacus muscle by anastomosing with the circumflex iliac artery. The dorsal b passes to the back between the last lumbar vertebra and the sacrum and ramifies in the g maximus, anastomosing with the lumbar arteries above, and the superior gluteal artery

(2) **Lateral sacral** branches, are usually four in number. They are serially homologou the intercostal and lumbar arteries given off by the aorta. They run laterally, and anas with the lateral sacral branches of the hypogastric (internal iliac) artery. They give of spinal branches, which pass through the sacral foramina, and supply the sacral canal an of the sacrum.

(3) **Rectal** or **hemorrhoidal** branches pass forward beneath the peritoneum or in t moid mesocolon to the rectum, which they help to supply, and anastomose with the hemorrhoidal or rectal arteries.

THE COMMON ILIAC ARTERIES

The **common iliac** arteries [aa. iliacæ communes] arise opposite the le of the middle of the body of the fourth lumbar vertebra, at the bifurcation abdominal aorta, and, diverging from each other in the male at about an of 60°, and in the female at an angle of 68°, terminate opposite the lumbo articulation by bifurcating into the external iliac, which is continued alo brim of the pelvis to the lower limb, and into the hypogastric (internal which descends into the pelvis minor (fig. 528). The relations differ slig the two sides, which may be considered separately.

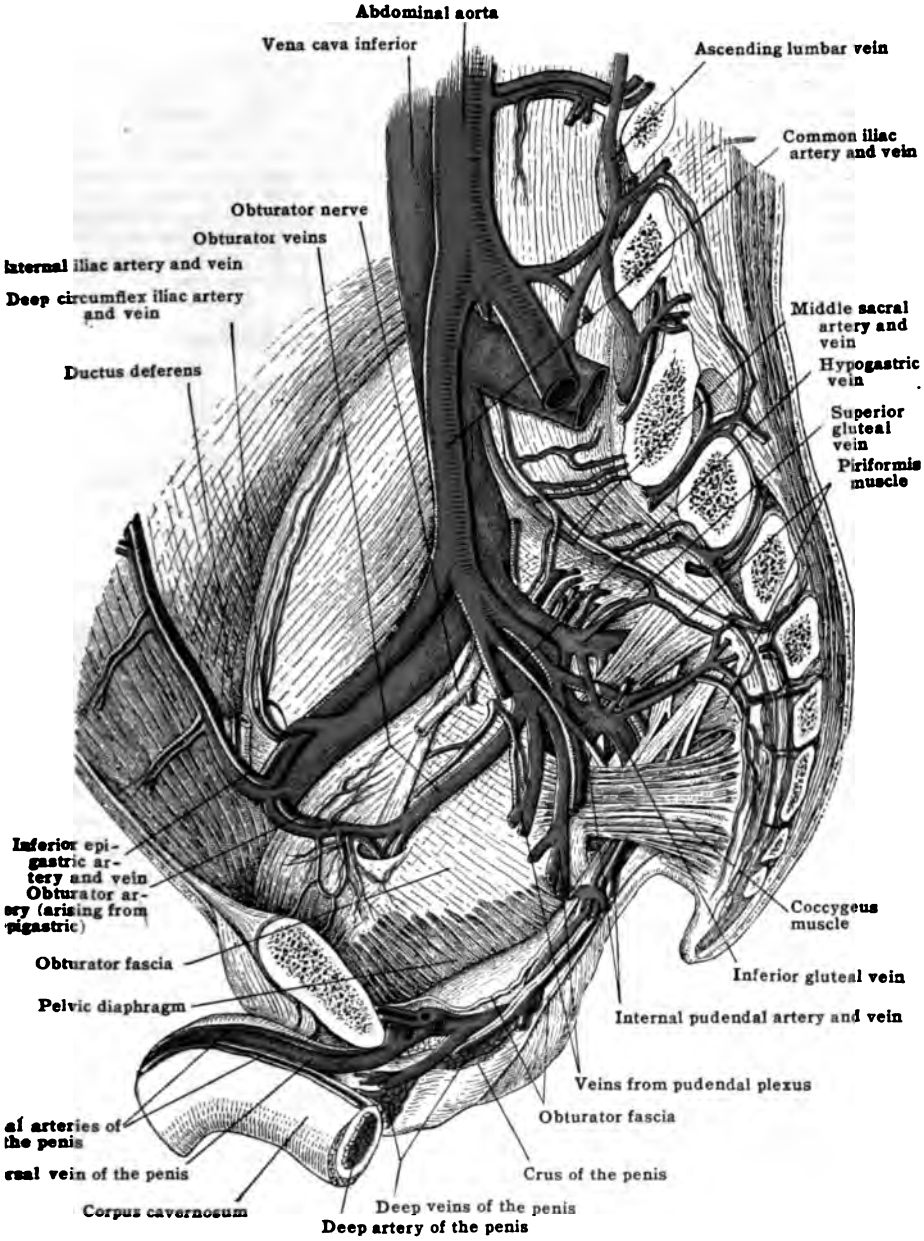
The Right Common Iliac Artery

The **right common iliac** (fig. 528) measures about 5 cm. (2 in.) in lengt is rather longer than the left, in consequence of the aorta bifurcating to the left of the median line.

Relations.—In front it is covered by the peritoneum, and is crossed by the right little before its bifurcation, by the ovarian artery in the female, by the termination of th

he terminal branches of the superior mesenteric artery, and by branches of the sympathetic e descending to the hypogastric plexus.
Behind, it lies on the right common iliac vein, the end of the left common iliac vein, and the mencement of the vena cava inferior which separate it from the fourth and fifth lumbar ebræ and their intervening disks, the psoas muscle, and the sympathetic nerve trunk. deeper in the groove between the fifth vertebra and the psoas are the lumbosacral trunk obturator nerve, and the iliolumbar artery.

528.—Blood-vessels of the Male Pelvis. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



To the **right side** are the beginning of the vena cava inferior, the end of the right common vein, and the psoas muscle. The muscle, however, is separated from the upper part of the y by the vena cava inferior.
To the **left side** are the right common iliac vein, the termination of the left common iliac vein, the hypogastric plexus.

The Left Common Iliac Artery

The left common iliac artery, 4 cm. (1.4 in.) in length, is a little shorter and **ker than the right.**

Relations.—In front it is covered by the peritoneum and is crossed by the ureter, the ova artery in the female, branches of the sympathetic nerve descending to the hypogastric ple the termination of the inferior mesenteric artery, the sigmoid colon, and the sigmoid mesoc

Behind are the lower border of the body of the fourth lumbar vertebra, the disk betwee fourth and fifth lumbar vertebra, the body of the fifth lumbar vertebra, and the disk betwe and the sacrum. Crossing deeply behind the artery between the fifth lumbar vertebra and psoas, are the obturator nerve, the lumbosacral trunk, and the iliolumbar artery.

To the **left side** is the psoas muscle.

To the **right side** are the left common iliac vein, the hypogastric plexus, and the mi sacral artery.

Collateral Circulation

The **collateral circulation** after obstruction or ligature of the common iliac artery is ca on chiefly (fig. 537) by the anastomosis of the middle sacral with the lateral sacral; the inte mammary with the epigastric; the lumbar arteries of the aorta with the iliolumbar and c circumflex iliac; the pubic branch of the epigastric with the pubic branch of the obturator; posterior branches of the sacral arteries with the superior gluteal (gluteal); the superior h orrhoidal from the inferior mesenteric, with the hemorrhoidal branches of the hypogastric ternal iliac) and pudic; the ovarian arteries from the aorta with the uterine branches of hypogastric (internal iliac); and by the anastomosis across the middle line of the pubic br of the obturator with the like vessel of the opposite side; the lateral sacral with the opp lateral sacral; and the vesical, hemorrhoidal, uterine, and vaginal branches of the hypoga with the corresponding branches of the opposite hypogastric (internal iliac).

Branches of the Common Iliac Artery

The **branches of the common iliac artery** (fig. 528) are:—(1) The hypogas (internal iliac); and (2) the external iliac.

A few small, unimportant branches are distributed to the peritoneum and subperito fat. They anastomose with vessels given off from the lumbar, inferior phrenic, and r arteries, forming a subperitoneal arterial anastomosis. The ureter as it crosses the ar receives small twigs which anastomose with the ureteral arteries given off from the inte spermatic above, and with those derived from the vesical arteries below.

THE HYPOGASTRIC ARTERY

The **hypogastric** or **internal iliac** artery [a. hypogastrica] (figs. 528, 5 arises at the bifurcation of the common iliac opposite the lumbosacral articulat It descends into the pelvis minor for about 3 cm. ($1\frac{1}{4}$ in.) and opposite the u margin of the great sciatic foramen, gives off the so-called posterior divis which forms the common stem of origin for the iliolumbar, lateral sacral superior gluteal arteries. The remainder of the artery, known as the ant division of the hypogastric, forms the common stem of origin for the obtur inferior gluteal, umbilical, inferior vesical, deferential, middle hemorrho uterine (in the female), and internal pudendal arteries.

In the fetus the hypogastric artery is larger than the external iliac; for through it the blood is returned to the placenta. The common iliac-hypogastric trunk replaces the pro part of the umbilical artery, which disappears at an early stage of development. The l part of the remainder of the intraabdominal portion of the umbilical artery is reduced, af after birth, to an impervious cord, the lateral umbilical ligament. The small part remains functional is represented by the section of the hypogastric artery giving origin t ceral branches and by the proximal part of the superior vesical artery.

Relations.—Behind, the hypogastric artery rests on the termination of the external vein, the hypogastric vein, the medial margin of the psoas muscle, the lumbosacral trunk obturator nerve, and the sacrum.

In front, it is covered by the peritoneum, and is crossed by the ureter.

The **branches of the hypogastric artery** may be divided into parietal visceral sets. The **parietal** branches are:—(1) The iliolumbar; (2) the la sacral; (3) the obturator; and (4) the gluteal arteries.

The **visceral** branches are:—(1) The umbilical; (2) the inferior vesical the middle hemorrhoidal; (4) the uterine; and (5) the internal pudendal.

Parietal Branches of the Hypogastric Artery

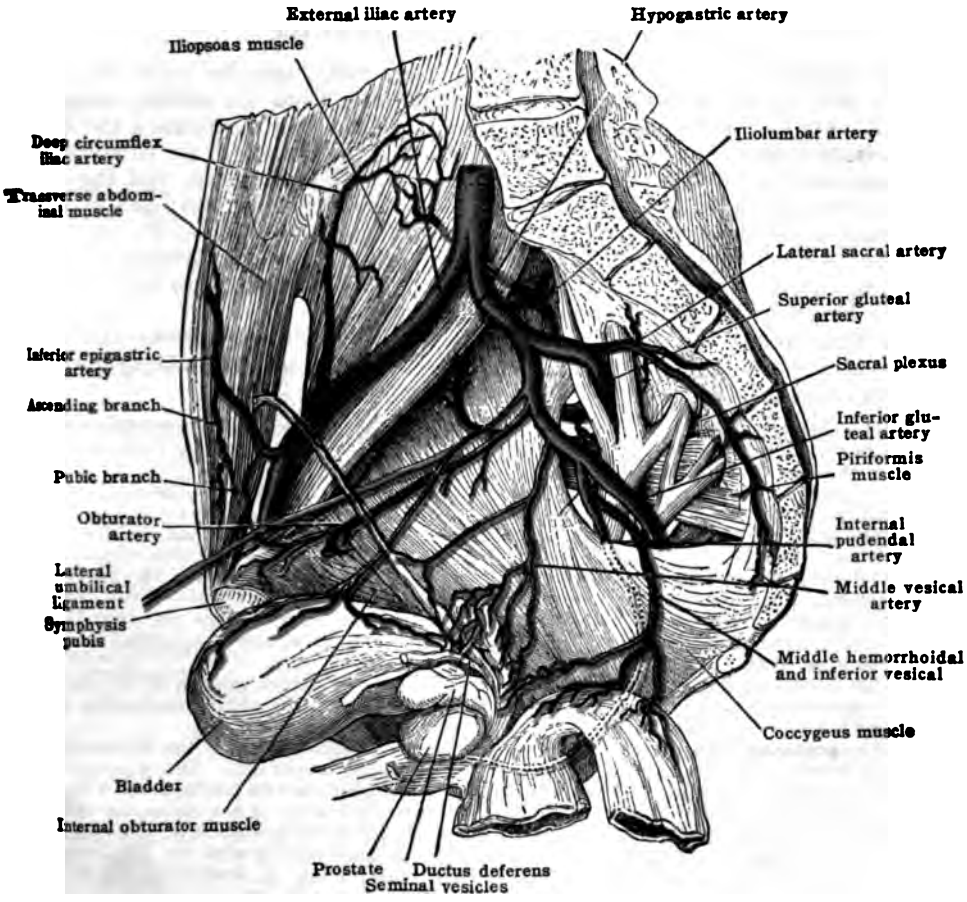
1. THE ILIOLUMBAR ARTERY

The **iliolumbar** artery [a. iliolumbalis]—a short vessel arising from the terior division of the hypogastric artery—runs upward and laterally beneath common iliac artery, first between the lumbosacral trunk and obturator n

and then between the psoas muscle and the vertebral column. On reaching the superior aperture of the pelvis minor it divides into two branches, an iliac and a lumbar (fig. 529).

The **iliac branch** [ramus iliacus] passes laterally beneath the psoas and the femoral (anterior crural) nerve and, perforating the iliacus, ramifies in the iliac fossa between that muscle and the bone. It supplies a nutrient artery to the bone, and then breaks up into several branches which radiate from the parent trunk, upward toward the sacroiliac synchondrosis, laterally toward the crest of the ilium, downward toward the anterior superior spine, and medially toward the pelvis minor. The first anastomoses with the last lumbar; the second with the lateral circumflex and gluteal; the third with the deep circumflex iliac from the external iliac; the fourth with

FIG. 529.—THE HYPOGASTRIC ARTERY. (After Henle.)



the iliac branch of the obturator. The **lumbar** branch [ramus lumbalis] ascends beneath the psoas, and, supplying that muscle and the quadratus lumborum, anastomoses with the last lumbar artery. It sends a **spinal** branch (ramus spinalis) into the vertebral canal through the intervertebral foramen between the last lumbar vertebra and the sacrum; this branch anastomoses with the other spinal arteries. The iliolumbar artery is serially homologous with the lumbar arteries. Hence the similarity in its course and distribution.

2. THE LATERAL SACRAL ARTERIES

The **lateral sacral artery** [a. sacralis lateralis], commonly arises as two vessels from the posterior division of the hypogastric. The **superior** artery (or branch, in cases in which two branches arise from a common stem), runs downward and medially to the first anterior sacral foramen, through which it passes. After supplying the spinal membranes and anastomosing with the other spinal arteries, it passes through the first posterior sacral foramen, and is distributed to the skin over the back of the sacrum, there anastomosing with branches of the superior and inferior gluteal arteries. The **inferior lateral sacral** descends on the side of the sacrum, on the lateral side of the sacral sympathetic trunk, and medially to the anterior sacral foramina, crossing in its course the slips of origin

of the piriformis muscle and the first anterior sacral nerve. On reaching the coccyx it anastomoses in front of that bone with the middle sacral artery, and with the inferior lateral sacral of the opposite side (fig. 529).

In this course it gives off:—**Spinal** branches [rami spinales], which enter the second, third and fourth anterior sacral foramina, and, after supplying the spinal membranes and anastomosing with each other, leave the spinal canal by the corresponding posterior sacral foramina, and are distributed to the muscle and skin over the back of the sacrum; and **rectal** branches which run forward to the rectum.

At times the lateral sacral arteries are exceedingly small, the spinal branches then coming chiefly from the middle sacral. The anastomosing branches between the lateral sacral and middle sacral are usually regarded as sacral segmental arteries serialy homologous with the lumbar and intercostal arteries.

3. THE OBTURATOR ARTERY

The **obturator** artery [a. obturatoria] (fig. 529), usually arises from the anterior division of the hypogastric, but sometimes from the inferior epigastric (fig. 488) or from the external iliac artery (see p. 652). It runs forward and downward a little below the brim of the pelvis, having the obturator nerve above and the obturator vein below. It here lies between the peritoneum and the endopelvic fascia, but later it passes through the obturator canal, the aperture in the upper part of the obturator membrane. In this course it is crossed by the ductus deferens. On emerging from the obturator canal the artery divides into two branches, anterior and posterior, which wind around the margin of the obturator foramen beneath the obturator externus muscle.

The **branches of the obturator artery** are:—(1) The iliac or nutrient branch; (2) a vesical branch; (3) the pubic branch; (4) the anterior, and (5) posterior terminal branches.

(1) The **iliac or nutrient** branch ascends to the iliac fossa, passing between the iliacus muscle and the bone. It supplies a nutrient vessel to the ilium, and **anastomoses** with the medial branch of the iliac division of the iliolumbar artery.

(2) The **vesical** branch or branches are small vessels which run beneath the peritoneum to the bladder, where they anastomose with the other vesical arteries.

(3) The **pubic** branch [ramus pubicus] comes off from the obturator as that vessel is leaving the pelvis by the obturator canal. It runs upward and medially behind the pubis, anastomosing with its fellow of the opposite side of the body, and with the pubic branch of the inferior epigastric artery. One of the anastomosing channels between the pubic branch of the obturator and pubic branch of the inferior epigastric arteries is sometimes of large size (fig. 1110), a fact of surgical interest in that the enlarged vessel may then run around the medial side of the femoral ring (p. 652).

(4) The **anterior** branch [ramus anterior] runs around the medial margin of the obturator foramen, and anastomoses with the posterior branch and with the medial circumflex artery. It supplies branches to the obturator and adductor muscles.

(5) The **posterior** branch [ramus posterior] skirts the lateral margin of the obturator foramen, lying between the obturator externus and the obturator membrane. At the lower margin of the foramen it divides into two branches. One branch continues its course around the lower margin of the foramen, and anastomoses with the anterior branch of the obturator and with the medial circumflex. The other branch turns laterally below the acetabulum, and ends in the muscles arising from the tuberosity of the ischium. It anastomoses with the inferior gluteal artery. This branch gives off a small twig, the **acetabular** artery [a. acetabuli], which passes under the transverse ligament into the hip-joint, where it supplies the synovial membrane, the ligamentum teres, and the fat in the fossa at the bottom of the acetabulum.

4. THE GLUTEAL ARTERIES

There are two gluteal arteries, the **superior** and **inferior** (fig. 530). The **superior gluteal** artery [a. glutea superior], the largest branch of the posterior division of the hypogastric, comes off as a short trunk from the lateral and back part of that vessel, of which indeed it may be regarded as the continuation. Passing backward between the first sacral nerve and the lumbosacral trunk through an osseo-tendinous arch formed by the margin of the bone and the upper edge of the endopelvic fascia, it leaves the pelvis through the great sciatic foramen above the piriformis muscle in company with its vein and the superior gluteal nerve. At its exit posteriorly from the great sciatic foramen it lies under cover of the gluteus maximus and beneath the superior gluteal vein, and in front of the superior gluteal nerve. It here breaks up into two chief branches, superior and inferior. Its emergence from the pelvis is indicated on the surface by a point situated at the junction of the posterior with the middle third of a line drawn from the anterior superior to the posterior superior spine of the ilium.

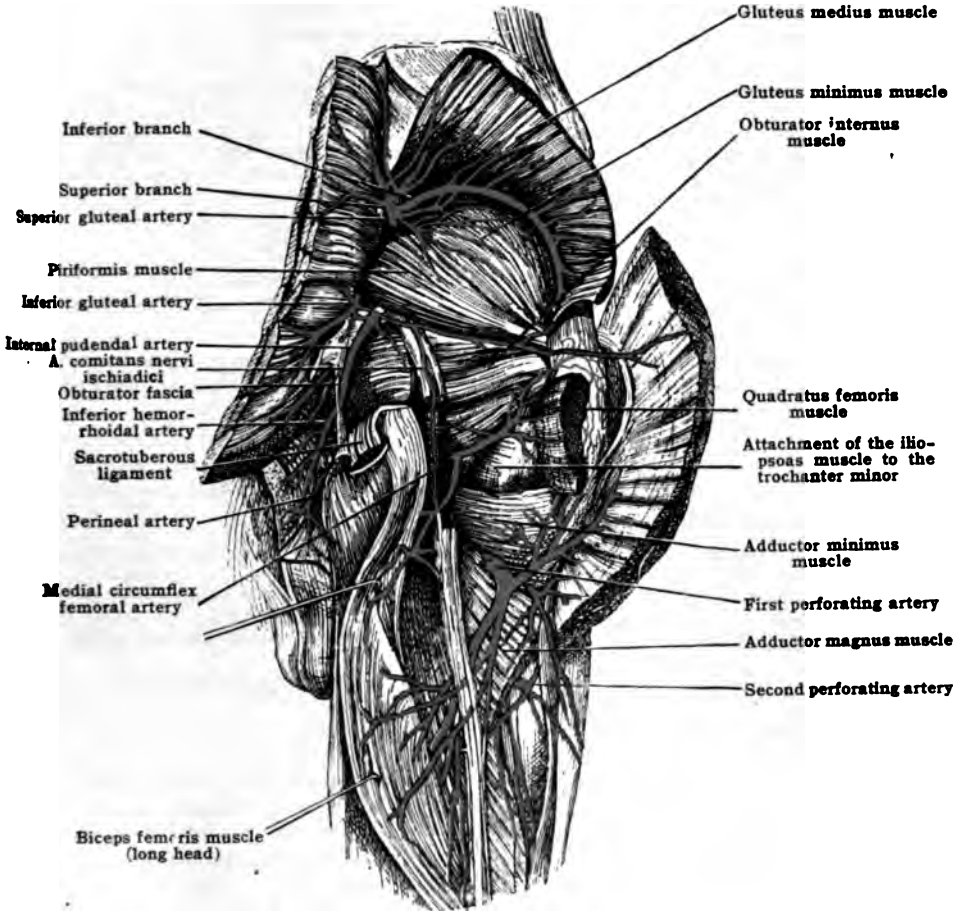
The branches of the superior gluteal artery are:—

(*a*) **Within the pelvis,** branches are distributed to the obturator internus, the piriformis, the levator ani, the coccygeus, and the pelvic bones.

(*b*) **External to the pelvis,** the artery divides into a superior and an inferior branch.

(i) The **superior** branch [ramus superior] breaks up into a number of large vessels for the supply of the upper portion of the gluteus maximus, some of them piercing the muscle and supplying the skin over it, and anastomosing with the posterior branches of the lateral sacral arteries; one of larger size, emerging from the muscle near the iliac crest, anastomoses with the deep circumflex iliac artery. The lower branches to the muscle anastomose with branches of the inferior gluteal (sciatic).

FIG. 530.—THE GLUTEAL ARTERIES. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



(ii) The **inferior** branch [ramus inferior] subdivides into two branches. One skirts along the line of origin of the gluteus minimus (fig. 530), between the gluteus medius and the bone, and, emerging in front from beneath these muscles under cover of the tensor fasciæ latæ, anastomoses with the ascending branch of the lateral circumflex and the deep circumflex iliac arteries. The other passes forward between the gluteus medius and minimus, accompanied by the branch to the tensor fasciæ latæ of the inferior division of the superior gluteal nerve, toward the greater trochanter, where it anastomoses with the ascending branch of the lateral circumflex. It supplies branches to the contiguous muscles and to the hip-joint. The inferior branch before its division gives off the external nutrient artery of the ilium.

The inferior gluteal [a. glutea inferior], is one of the terminal branches of the anterior division of the hypogastric artery. It leaves the pelvis below the piriformis muscle, and immediately breaks up into a number of diverging branches. The largest enter the gluteus maximus muscle, where they anastomose with the superior gluteal branches. Others pass to the hip-joint, and the deep muscles around it; a third group passes downward to the hamstring muscles and anastomoses with the medial and lateral circumflex and first perforating; a fourth

slender branch, the **sciatic** artery [a. comitans n. ischiadici], accompanies the sciatic nerve (fig. 530).

Visceral Branches of the Hypogastric Artery

1. THE UMBILICAL ARTERY

The **umbilical** artery in the fetus is the continuation of the hypogastric. Passing forward along the side of the pelvis, it runs beneath the lateral reflection of peritoneum from the bladder, where, after giving off one or more vesical branches, it ceases to be pervious and passes on to the side and upper part of the bladder. Thence it ascends in the lateral umbilical fold, as a fibrous cord [ligamentum umbilicale laterale], to the umbilicus, where it is joined by its fellow of the opposite side. As it lies upon the bladder it is crossed by the ductus deferens.

The **branches of the umbilical artery** are:—(1) Superior vesical arteries, the lowest of which is sometimes called (2) the middle vesical artery (fig. 529).

The **superior vesical** arteries [aa. vesicales superiores] ramify over the upper surface of the bladder, anastomosing with the artery of the opposite side and with the middle and inferior vesical below. They give off the following branches:—(*a*) The **urachal** branches which pass upward along the urachus. (*b*) The **ureteric** branches pass to the lower end of the ureter, and anastomose with the other ureteric arteries. (*c*) The **middle vesical** may come off from one of the superior vesicals or from the umbilical. It is distributed to the sides and base of the bladder, and anastomoses with the other vesical arteries.

2. THE INFERIOR VESICAL ARTERY

The **inferior vesical** artery [a. vesicalis inferior] arises from the anterior division of the hypogastric, frequently in common with the middle hemorrhoidal (fig. 529), and passes downward and medially to the fundus of the bladder, where it breaks up into branches which ramify over the lower part of the viscus. It gives off branches to the prostate, which supply that organ and anastomose with the arteries of the opposite side by passing through the prostatic plexus of veins and with the inferior hemorrhoidal branches of the internal pudendal. At times one of these prostatic branches is of large size, and supplies certain of the parts normally supplied by the internal pudendal. It is then known as the accessory **pudendal** and most commonly terminates as the dorsal artery of the penis.

The inferior vesical usually gives off the **deferential artery.** This vessel, which may come off from the superior or the middle vesical (as in fig. 529), divides, on the ductus deferens, into an ascending and a descending branch. The ascending branch follows the ductus through the inguinal canal to the testis, where it anastomoses with the internal spermatic artery. The descending branch passes downward to the dilated portion of the ductus and to the vesiculæ seminales.

3. THE MIDDLE HEMORRHOIDAL ARTERY

The **middle hemorrhoidal** artery [a. hemorrhoidalis media] (fig. 529), variable in origin, perhaps most commonly arises from the anterior division of the hypogastric along with the inferior vesical. It runs medially to the side of the middle portion of the rectum, dividing into branches which anastomose above with the superior hemorrhoidal derived from the inferior mesenteric, and below with the inferior hemorrhoidal derived from branches of the internal pudendal. Its corresponding vein terminates in the inferior mesenteric vein. In the female it also sends branches to the vagina.

4. THE UTERINE ARTERY

The **uterine** artery [a. uterina] (fig. 531), arises from the anterior division of the hypogastric close to or in conjunction with the middle hemorrhoidal or inferior vesical. It runs downward and medially through the pelvic connective tissue, crossing the ureter about 12 mm. ($^1/_2$ in.) from the cervix uteri. It then ascends in the parametrium between the layers of the broad ligament at the side of the uterus in a coiled and tortuous manner, and, after giving off a number of tortuous branches which ramify horizontally over the front and back of the uterus, supplying its substance, anastomoses with the uterine branch of the ovarian artery.

The **branches of the uterine artery** are:—(1) **Cervical.**—This branch comes off from the uterine as the latter artery crosses the ureter to turn upward on to the uterus. It is directed medially, and divides into three or four branches which pass on to the cervix at right angles to it; one branch anastomosing with its fellow of the opposite side in front and behind the neck,

ɛ **the so-called** coronary artery of the cervix. (2) **Tubal** [ramus tubarius]. This courses he lower surface of the tuba uterina (Fallopian tube) as far as fimbriated extremity, and so send a branch to the ligamentum teres. (3) **Ovarian** [ramus ovarii]. This runs along arched border of the ovary, sending branches to that structure, and terminates by anas- ng widely with the ovarian artery. Usually the vaginal artery also arises from the uter- i) **The vaginal** artery [a. vaginalis] corresponds to the inferior vesical artery of the male,

FIG. 531.—OVARIAN AND UTERINE AND VAGINAL ARTERIES. (From Kelly, by Brödel).

ay arise directly from the hypogastric artery, close to the origin of the uterine, or from the or vesical. It passes medially, behind the ureter, to the upper part of the vagina, and numerous branches to that structure and also some to the posterior part of the fundus of adder.

ie branches to the vagina tend to anastomose with one another and with the cervical h of the uterine, to form a more or less perfect vertical stem in the median line of the a, both back and front. This stem is sometimes termed the **azygos artery of the vagina.** hes also pass to the vagina from the middle hemorrhoidal artery.

5. THE INTERNAL PUDENDAL ARTERY

he internal pudendal (pudic) artery [a. pudenda interna] (figs. 532, 533, 629) e of the terminal branches of the anterior division of the hypogastric artery

FIG. 532.—THE INTERNAL PUDENDAL ARTERY. (From Kelly, by Brödel.)

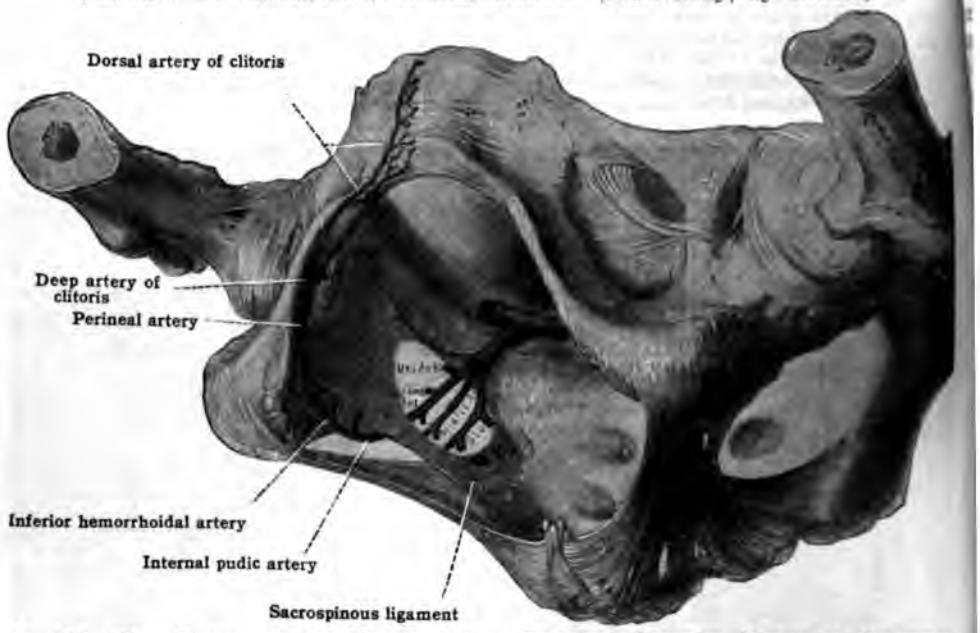


FIG. 533.—THE PERINEAL AND HEMORRHOIDAL BRANCHES OF THE INTERNAL PUDENDAL ARTERIES. (From Kelly, by Brödel.)

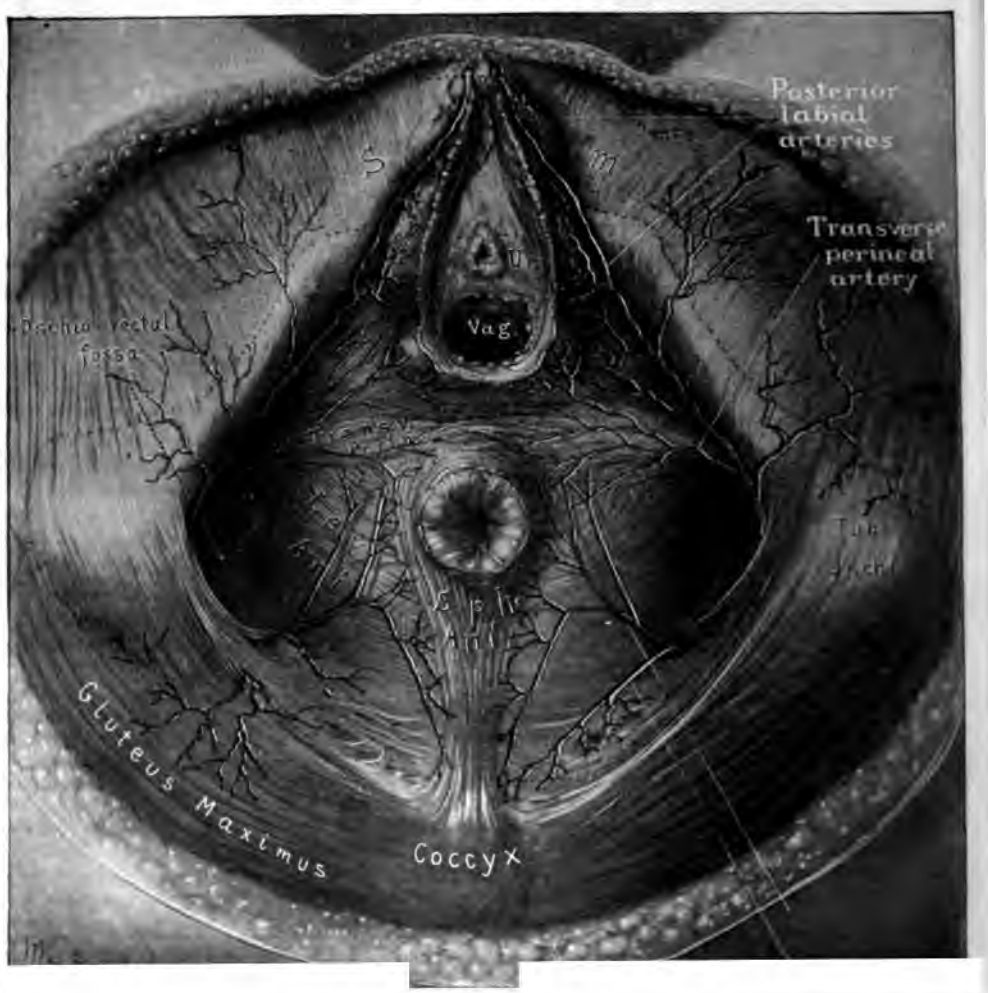
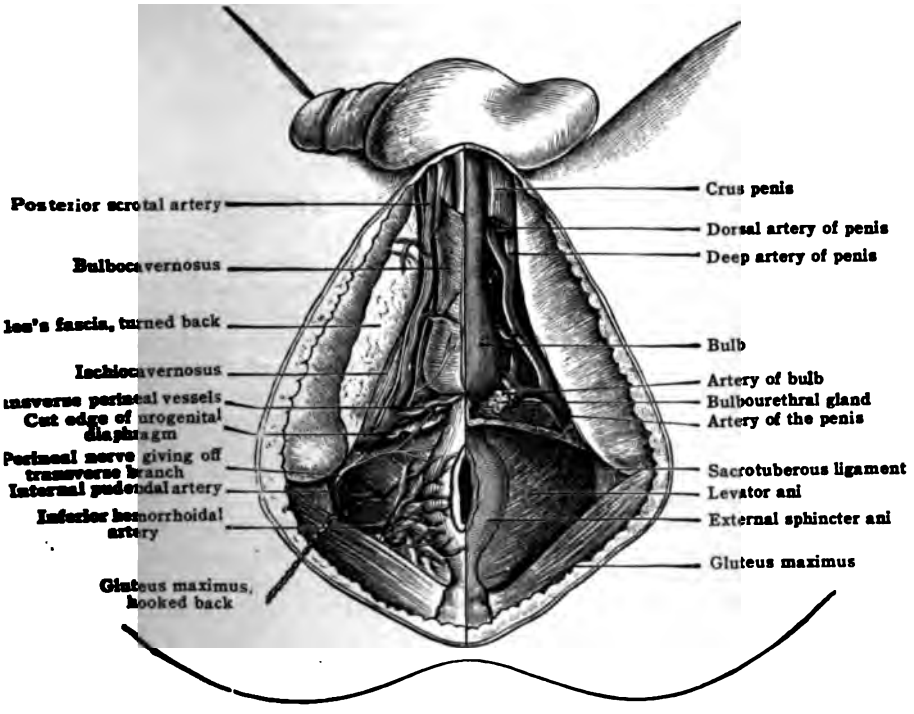


e inferior gluteal being the other). It arises opposite the piriformis muscle and ompanies the inferior gluteal downward to the lower border of the great ıtic foramen. It leaves the pelvis between the piriformis and coccygeus and ds over the ischial spine to enter the ischiorectal fossa through the small ıtic foramen. Running forward in the ischiorectal fossa medial to the lower ŧ of the obturator internus it ends by dividing into the **perineal artery** and the ry of the penis (or clitoris).

Relations.—*Within the pelvis*, the artery lies anteriorly to the piriformis muscle and the sacral us of nerves, and laterally to the inferior gluteal artery. It passes between the piriformis coccygeus, with the gluteal artery and pudendal nerve on the medial side, and the nerve to obturator internus upon the lateral. The sciatic and posterior femoral cutaneous (lesser ic) nerves lie still more laterally. *On the ischial spine* the artery retains its relations to pudendal nerve (which often divides in this situation into its two terminal branches and the e to the obturator internus. It is accompanied by venæ comitantes and covered by the eus maximus muscle. *In the ischiorectal fossa* the artery is placed on the lateral wall about mm. (1¼ in.) above the tuberosity of the ischium. It is accompanied in a canal in the ob- .tor fascia (Alcock's canal) by the dorsal nerve of the penis and the perineal nerve, which respectively above and below the artery.

FIG. 534.—THE ARTERIES OF THE MALE PERINEUM.



The branches of the internal pudendal artery are:—(1) Small branches to the uteal region; (2) the inferior hemorrhoidal arteries; and the terminal branches,) perineal; and (4) artery of the penis or clitoris.

(1) **The branches of the gluteal region** are:—(*a*) twigs to the gluteus maximus; (*b*) branches companying the nerve to the obturator internus; (*c*) a sacral branch which pierces the sacro- berous ligament and anastomoses with the inferior gluteal artery.

(2) **The inferior hemorrhoidal** artery [a. hæmorrhoidalis inferior] (figs. 533, 534) arises at e posterior part of the ischiorectal fossa and, perforating the obturator fascia, at once breaks into several branches. These, running medially toward the anus, traverse the ischiorectal ; and supply the fascia, skin and the levator ani and external sphincter muscles. The in- ior hemorrhoidal branches anastomose with those from the middle and superior hemor- oidal, and from the gluteal and perineal arteries.

(3) **The perineal artery** [a. perinei] (figs. 533, 534), one of the terminal arteries of the in- nal pudendal, arises at the anterior part of the ischiorectal fossa. It pierces the base of the ogenital diaphragm (triangular ligament), and enters the space deep to Colles's fascia. Here runs forward between the ischiocavernosus and bulbocavernosus muscles to the scrotum or ium majus and divides into numerous terminal branches. Immediately after piercing the phragm, the perineal artery gives off a constant transverse perineal branch which runs toward e median line along the superficial transverse perineal muscle. The terminal branches of the

perineal are the **posterior scrotal or labial** arteries [aa. scrotales, or labiales posteriores] which ramify on the scrotum or labia majora (according to sex) and anastomose with external pudendal arteries.

(4) The **artery of the penis, or clitoris** [a. penis or clitoridis] (figs. 533, 534) pierces the posterior border of the urogenital diaphragm and runs forward between the layers of the diaphragm with the dorsal nerve of the penis along the inferior ramus of the pubis. It traverses the fibers of the deep transverse perineal muscle and of the sphincter of the membranous urethra and ends by dividing into deep and dorsal arteries of the penis, or clitoris, according to sex.

On the right side Colles's fascia has been turned back to show the perineal artery. On the left side the perineal vessels have been cut away with the inferior layer of the urogenital diaphragm to show the artery of the penis.

The **branches of the artery of the penis (or clitoris)** are:—(*a*) The artery to the bulb; (*b*) the urethral artery; and (*c*) the terminal, deep artery of the penis or clitoris.

(*a*) The **artery of the bulb** [a. bulbi urethræ or vestibuli vaginæ] takes a medial direction through the fibers of the m. transversus perinei profundus. It then pierces the inferior fascia of the urogenital diaphragm to reach the bulb, the erectile tissue of which it supplies, in either sex. This vessel also supplies branches to the bulbourethral gland (Cowperi) or the gland of the vestibule (Bartholini).

(*b*) The **urethral** artery [a. urethralis] is a small branch which passes into the corpus spongiosum (corpus cavernosum urethræ) and anastomoses with branches from the artery of the bulb.

(*c*) The **deep artery of the penis or clitoris** [a. profunda penis or clitoridis], larger in the male sex, pierces the inferior layer of the urogenital diaphragm near the inferior ramus of the pubis. It enters the crus of the penis (fig. 534) or clitoris, and is distributed in the corpus cavernosum urethræ.

(*d*) The **dorsal artery of the penis or clitoris** [a. dorsalis penis or clitoridis] (figs. 532, 534), perforates the inferior fascia of the urogenital diaphragm near its apex. The dorsal nerve lies on the lateral side of the artery and joins the dorsal vein (which lies between the arteries of either side) on the dorsum of the penis or clitoris. The artery is much larger in the male than the female; in either sex it supplies the glans, corona, and prepuce and anastomoses with the external pudendal artery.

THE EXTERNAL ILIAC ARTERY

The **external iliac** artery [a. iliaca externa]—the larger in the adult of the two vessels into which the common iliac divides opposite the lumbosacral articulation—extends along the superior aperture of the pelvis minor, lying upon the medial border of the psoas muscle, to the lower margin of the inguinal ligament, where, midway between the anterior superior spine of the ilium and the symphysis pubis, it passes into the thigh, and takes the name of the femoral.

It measures 8.5 to 10 cm. (3½ to 4 in.) in length. The course of the vessel is indicated by a line drawn from 2.5 cm. (1 in.) below and a little to the left of the umbilicus to a point midway between the symphysis pubis and the anterior superior spine of the ilium. If this line is divided into thirds, the lower two-thirds of it will indicate the situation of the external iliac, and the upper third that of the common iliac. The external iliac vein, the continuation upward of the femoral vein from the thigh, lies to the medial side of the artery but on a slightly deeper plane, and, just before its termination, extends a little behind the artery on the right side.

Relations.—In front, the artery together with the vein is covered by the parietal peritoneum descending from the abdomen into the pelvis, and by a layer of condensed subperitoneal tissue (Abernethy's fascia). It is crossed by the termination of the ileum on the right side, and by the sigmoid colon on the left. The external spermatic (genital) branch of the genital femoral (genitocrural) nerve runs obliquely over its lower third, and just before its termination it is crossed transversely by the deep circumflex iliac vein. The internal spermatic or ovarian vessels lie for a short distance on the lower part of the artery, and the ductus deferens in the male curves over it to descend to the pelvis. It is sometimes crossed at its origin by the ureter. The external iliac lymphatic nodes lie along the course of the artery. The commencement of its inferior epigastric branch is also in front.

Behind.—The artery at first lies partly upon its own vein; lower down upon the medial border of the psoas; just before it passes through the lacuna vasorum, beneath the inguinal ligament, it lies upon the tendon of the psoas. The iliac fascia is also behind it.

To its **medial, side** are the external iliac vein, the peritoneum, and the ductus deferens in the male, or the ovarian vessels in the female.

To its **lateral side** are the psoas muscle and the iliac fascia.

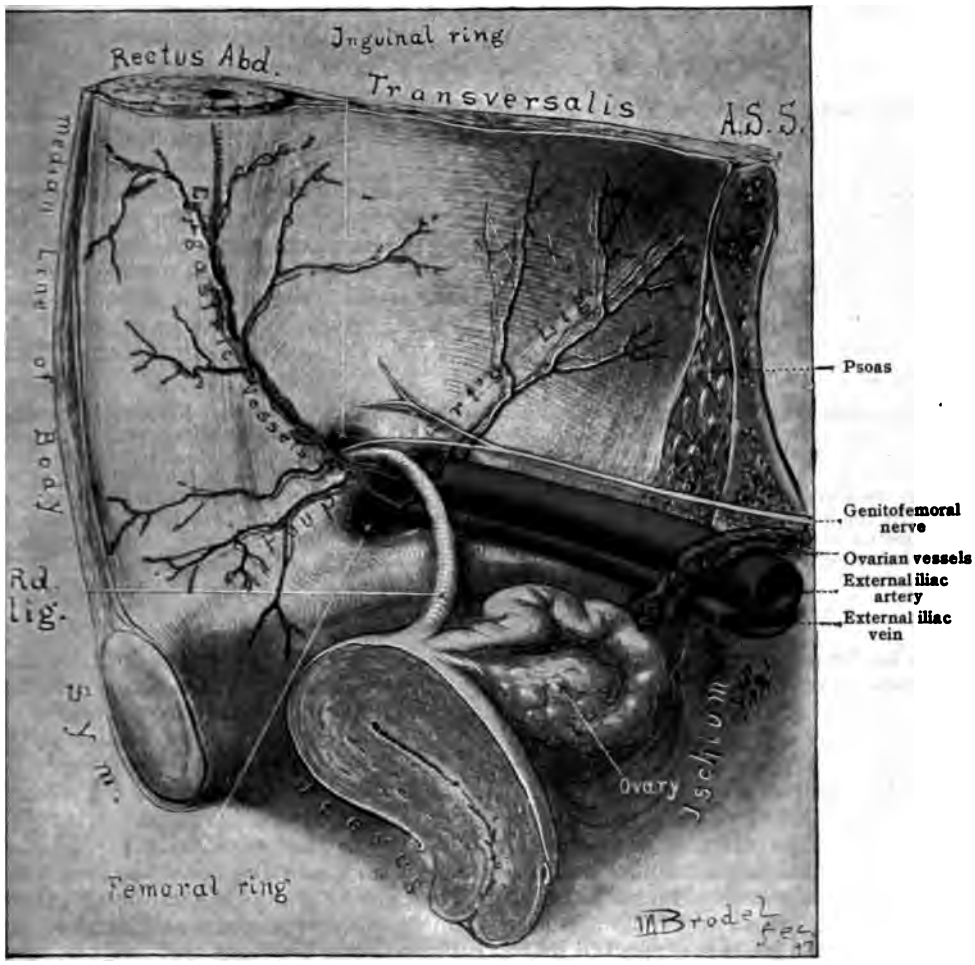
The **collateral circulation** is carried on (fig. 537) when the external iliac is tied, by the anastomosis of the iliolumbar and lumbar arteries with the circumflex iliac; the internal mammary with the inferior epigastric; the obturator with the medial circumflex; the inferior gluteal with the medial circumflex and superior perforating; the gluteal with the lateral circumflex; the arteria comitans nervi ischiadici from the inferior gluteal, with the perforating branches of the profunda; the external pudenal with the internal pudendal; the pubic branch of the obturator with the pubic branch of the epigastric.

The branches of the external iliac artery are:—(1) The inferior epigastric; (2) the deep circumflex iliac; and (3) several small and insignificant twigs to the neighboring psoas muscle and lymphatic glands.

(1) The Inferior Epigastric Artery

The inferior or deep epigastric artery [a. epigastrica inferior] (fig. 535) usually comes off from the external iliac just above the inguinal (Poupart's) ligament. Immediately after its origin, the ductus deferens in the male, or the round ligament in the female, loops around it where it lies medially to the abdominal inguinal (internal abdominal) ring, behind the inguinal canal, and a little above and laterally to the femoral ring. Thence it ascends with a slightly medial direction passing above and to the lateral side of the subcutaneous inguinal

Fig. 535.—The Inferior (Deep) Epigastric Artery. (From Kelly, by Brödel.)



(external abdominal) ring, lying between the fascia transversalis and the peritoneum. Having pierced the fascia transversalis, it passes in front of the linea semicircularis (Douglas' fold) and turns upward between the rectus and its sheath. Finally, it enters the substance of the rectus muscle, and anastomoses with the superior epigastric artery from the internal mammary.

The situation of the artery between the two inguinal rings should be borne in mind in the operation for strangulated inguinal hernia, and its near proximity to the upper and lateral side of the femoral ring should not be forgotten in the operation for femoral hernia. The artery is accompanied by two veins which end in a single trunk before opening into the external iliac vein.

The branches of the inferior epigastric are small and include:—(*a*) The **external spermatic**

[a. spermatica externa], which runs with the ductus through the inguinal canal, supplies the cremaster muscle, and anastomoses with the internal spermatic, external pudendal, and perineal arteries. In the female a corresponding artery [a. lig. teretis uteri] accompanies the round ligament of the uterus through the inguinal canal and anastomoses in a similar manner. (*b*) The **pubic** [ramus pubicus], which passes below, or sometimes above, the femoral ring to the back of the pubis, where it anastomoses with the pubic branch of the obturator. This branch, though usually small, is occasionally considerably enlarged (fig. 1110), when its exact course becomes of great interest to the surgeon. Thus it may descend on the medial side of the external iliac vein, and therefore lateral to the side of the femoral ring, or it may course medially in front of the femoral ring and turn downward either behind the os pubis or immediately behind the free edge of the lacunar (Gimbernat's) ligament, in which situation it would be exposed to injury in the operation for the relief of a strangulated femoral hernia. In such cases the obturator may not be connected with the hypogastric artery at all, but may take origin entirely from the external iliac or from the inferior epigastric. This abnormal origin of the obturator is said to occur once in every three and a half subjects but the abnormal artery courses around the medial side of the ring—in which situation it is liable to injury in operation for femoral hernia—in exceptional cases only. According to Langton (Holden's 'Anatomy'), the chances are about seventy to one against this occurrence. But even when it takes the abnormal course it lies 3 mm. or so from the margin of the ring, and will probably escape injury in the division of the stricture if several short notches are made in place of a single and longer incision.

(2) The Deep Circumflex Iliac Artery

The **deep circumflex iliac** artery [a. circumflexa ilium profunda], (fig. 535) arises from the lateral side of the external iliac artery either opposite the epigastric or a little below the origin of that vessel. It courses laterally just above the lower margin of the inguinal (Poupart's) ligament, lying between the fascia transversalis and the peritoneum, or at times in a fibrous canal formed by the union of the fascia transversalis with the iliac fascia. Near the anterior superior spine of the ilium, it perforates the transversus, and then courses between that muscle and the internal oblique, along and a little above the crest of the ilium. It finally runs backward to anastomose with the iliolumbar artery. It is accompanied by two veins. These unite into one trunk, which then crosses the external iliac artery to join the external iliac vein.

The **branches of the deep circumflex iliac artery** are as follows:—(*a*) **Muscular** branches which supply the psoas, iliacus, sartorius, tensor fasciæ latæ, and the oblique and transverse muscles of the abdomen. One of these branches, larger than the rest, usually arises about 2.5 cm. (1 in.) behind the anterior superior spine of the ilium and ascends perpendicularly between the transversus muscle and the internal oblique. It has received no name but is important to the surgeon, as it indicates the intermuscular plane between the two muscles. (*b*) **Cutaneous** branches, which supply the skin over the course of the vessel, and anastomose with the superficial circumflex iliac, the superior gluteal, and the ascending branch of the lateral circumflex.

THE FEMORAL ARTERY

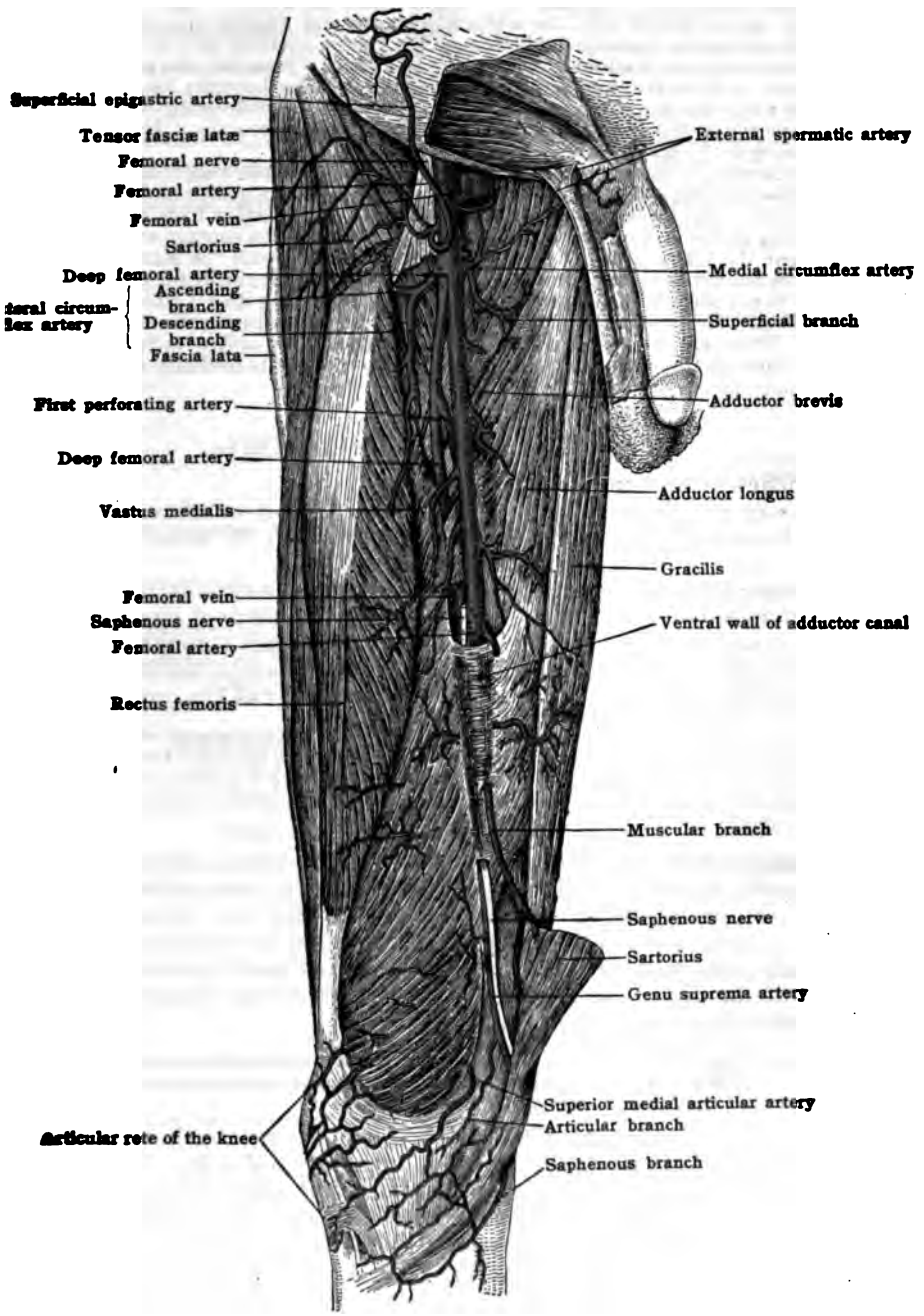
The **femoral** artery (fig. 536) is the continuation of the external iliac, and extends from the lower border of the inguinal (Poupart's) ligament, down the anterior and medial aspect of the thigh, to the tendinous opening in the adductor magnus, through which it passes into the popliteal space, and is then known as the popliteal. The femoral artery is at first quite superficial, being merely covered by the skin, and superficial and deep fascia; but after passing about 13 cm. (5 in.) downward through the space known as the femoral trigone (Scarpa's triangle), it sinks at the apex of that triangle beneath the sartorius muscle. Thence to its termination it continues beneath the sartorius, coursing deeply between the vastus medialis and adductor muscles in the space known as the adductor (Hunter's) canal. It at first rests upon the brim of the pelvis minor and head of the femur from which it is separated by the capsule of the hip-joint and the tendon of the psoas. Owing to the obliquity of the neck of the femur and the direct course taken by the artery, the latter lies lower down on muscles only, at some distance from the bone. At its termination, in consequence of the shaft of the femur inclining toward the middle line of the body, the artery lies close to the medial side of the femur.

The *course of the vessel* when the thigh is slightly flexed and abducted is indicated by a line drawn from a spot midway between the anterior superior spine of the ilium and the symphysis pubis to the adductor tubercle. When the thigh is in the extended position and parallel with its fellow, the course of the artery will correspond to a line drawn from the spot above mentioned to the medial border of the patella. Its *anastomoses* are shown in figs. 537 and 1140.

The relations of the femoral artery in the femoral trigone.—In front, the femoral artery (fig. 536) is covered by the skin, the superficial fascia, the iliac portion of the fascia lata, and the

boinguinal (crural) branch of the genitofemoral nerve. The superficial circumflex iliac a descends over the artery from the lateral to the medial side. Just proximally to the orius, the artery is crossed by the most medial of the anterior cutaneous branches of the oral nerve. The fascia transversalis, which is continued into the thigh beneath the in- nal ligament, is also in anterior relation, but it soon becomes indistinguishable from the ath of the vessel.

. 536.—THE FEMORAL ARTERY. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



Behind, the artery rests in turn upon the tendon of the psoas muscle, which separates rom the brim of the pelvis and capsule of the hip-joint; the pectineus, and adductor longus. artery is partially separated from the pectineus by the femoral vein and the profunda vein artery, and from the adductor longus by the femoral vein which is almost directly behind artery near the apex of the femoral trigone. The small nerve to the pectineus crosses ind the artery to reach its medial side.

A prolongation similar to that derived from the fascia transversalis in front, descends behind the vessel from the iliac fascia; but this, like the anterior prolongation or fascia, soon blends with the sheath of the vessels.

To the **medial side** is the femoral vein. This is separated from the artery, where the two vessels lie in the femoral sheath, by a thin fascial septum. More distally, the vein gradually reaches the posterior aspect of the artery.

To the **lateral side.**—Proximally, the common stem of the femoral (anterior crural) nerve is about 1 cm. (⅓ in.) lateral to the artery. When the femoral nerve gives off its branches, the saphenous nerve and the nerve to the vastus medialis accompany the artery on the lateral side.

The **adductor (Hunter's) canal** (fig. 536) is the somewhat trihedral space bounded by the vastus medialis on the lateral side, the adductors longus and magnus posteriorly, and by an aponeurosis thrown across from the adductors to the vastus medially and in front. Distally, the canal terminates at the tendinous opening in the adductor magnus; proximally, its limit is less well defined, as here the aponeurosis between the muscles becomes less tendinous, and gradually fades away into the perimuscular fascia. The transverse direction of the fibers of the aponeurotic covering at the distal two-thirds of the canal is characteristic. Lying superficially to the aponeurosis is the sartorius muscle.

The femoral artery, in the adductor (Hunter's) canal, has the **following relations:**—**In front,** in addition to the skin, superficial and deep fascia, are the sartorius muscle and the aponeurotic fibers of the canal. The saphenous nerve crosses in front of the artery from the lateral to the medial side, lying in the wall of the canal. **Behind,** the artery is in contact with the adductor longus, and near the opening in the adductor magnus, usually with the latter muscle. The femoral vein lies behind the artery, but gets a little lateral to it at the distal part of the canal. It is here very firmly and closely attached to the artery, embracing it as it were on its posterior and lateral aspect. Hence it is very liable to be punctured on ligaturing the artery in this part of its course. There are sometimes two veins, which then more or less surround the artery. To the **lateral side** are the vastus medialis, the nerve to the vastus medialis, and at the distal part of the canal, the femoral vein.

Branches of the Femoral Artery

The **branches of the femoral artery** are:—

(1) The superficial epigastric; (2) the superficial circumflex iliac; (3) the external pudendal; (4) the inguinal; (5) the profunda; (6) muscular branches; and (7) the suprema genu (anastomotica magna).

(1) The **superficial epigastric** artery [a. epigastricas uperficialis] (fig. 536) comes off from the femoral about 1.2 cm. (½ in.) beyond the inguinal ligament. At its origin it is beneath the fascia lata, but almost at once passes through this fascia, or else through the fossa ovalis, and courses in an upward and slightly medial direction in front of the external oblique muscle almost as far as the umbilicus.

It ends in numerous small twigs, which anastomose with the cutaneous branches from the inferior epigastric and internal mammary. In its course it gives off small branches to the inguinal glands and to the skin and superficial fascia. Running with it is the superficial epigastric vein, which ends in the great saphenous just before the latter passes through the fossa ovalis (saphenous opening).

(2) The **superficial circumflex iliac** artery [a. circumflexa ilium superficialis], (fig. 536), usually smaller than the superficial epigastric, arises either in common with that vessel, or as a separate branch from the femoral. It passes laterally over the iliacus, and, soon perforating the fascia lata a little to the lateral side of the fossa ovalis, runs more or less parallel with the inguinal ligament about as far as the crest of the ilium, where it ends in branches which anastomose with the deep circumflex iliac artery.

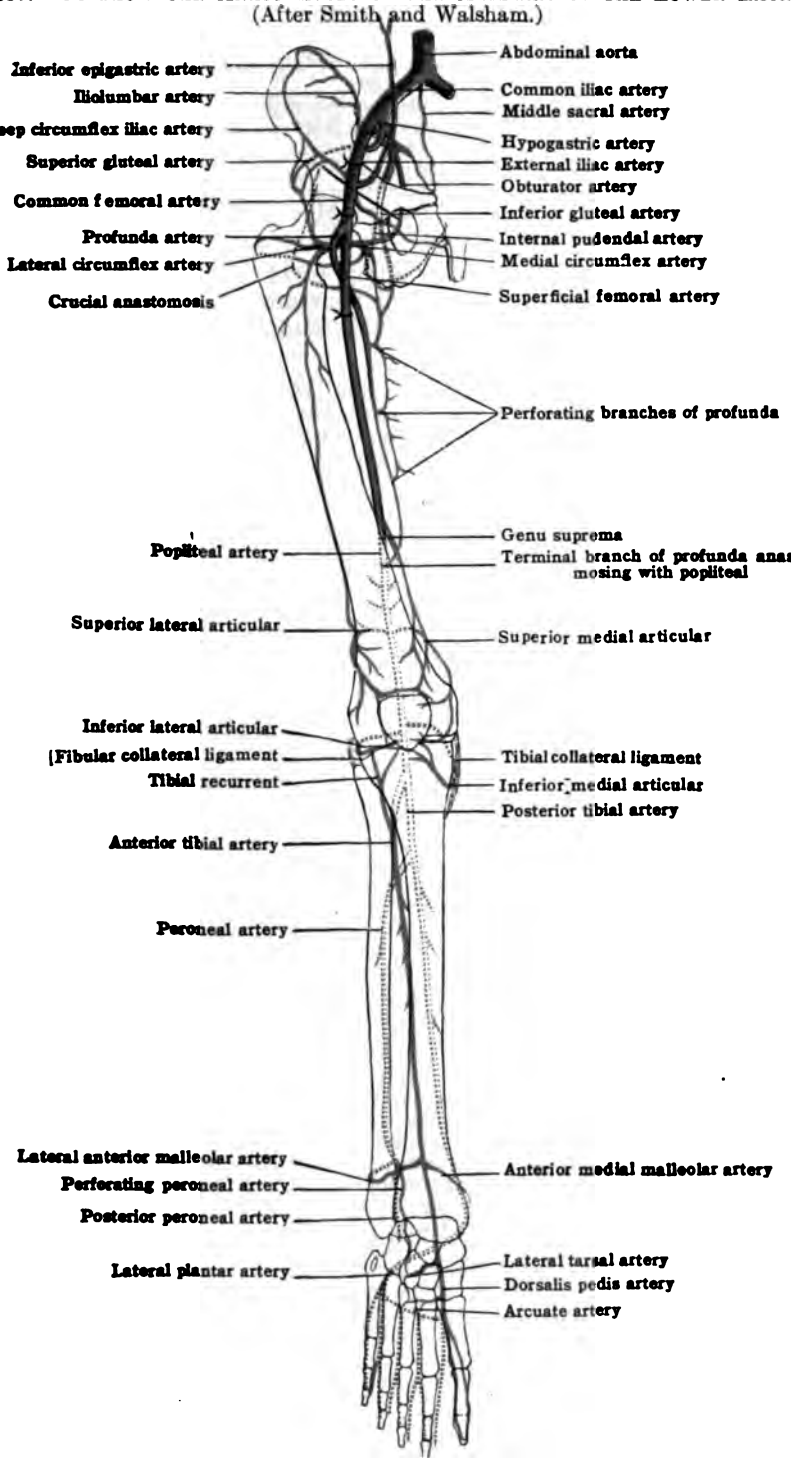
In its course it gives off branches to the iliacus and sartorious muscles to the inguinal glands, and to the fascia and skin. Its companion vein ends in the great saphenous vein just before the latter passes through the fossa ovalis (saphenous opening).

(3) The **external pudendal** arteries [aa. pudendæ externæ], arise from the medial side of the femoral or, occasionally, from the profunda. Some of them pass either through the fascia lata or through the fascia covering the fossa ovalis (saphenous opening) and cross the spermatic cord in the male, or round ligament in the female, to reach and supply the integument above the pubes.

One branch descends along the penis and anastomoses at the corona with the dorsal artery, and with the corresponding artery of the opposite side. In the female, this branch terminates in the preputium clitoridis, anastomosing with the dorsal artery of the clitoris. Other branches run medially beneath the deep fascia, across the pectineus and adductor longus muscles, and, perforating the fascia close to the ramus of the pubis, supply the skin of the scrotum or the *labium majus* in the female [aa. scrotales or labiales anteriores] anastomosing with the posterior scrotal or labial branches of the perineal artery. The external pudendal supplies small twigs to the pectineus and adductor muscle. Its companion veins terminate as a single trunk in the great saphenous.

(4) The **inguinal** branches [rami inguinales], a series of five or six small nches arise a short distance below the inguinal ligament. They supply the nguinal lymph-nodes, and the skin and muscles in this region.

G. 537.—To show the Anastomoses of the Arteries of the Lower Extremity. (After Smith and Walsham.)



(5) The **profunda** artery [a. profunda femoris] (figs. 536, 537), is the chief ient vessel of the thigh. It is usually given off from the back and lateral of the common femoral, about 4 cm. (1½ in.) beyond the inguinal (Poupart's)

ligament. At first it is a little lateral to the femoral, but as it runs distally and backward it gets behind that artery and closer to the bone. On reaching the proximal border of the adductor longus muscle, it leaves the femoral, and, passing beneath the muscle, pierces the adductor magnus. Finally, much reduced in size, it ends in the hamstring muscles, anastomosing with the third perforating and muscular and articular branches of the popliteal.

The profunda in some cases arises 5 cm. or more distally to the inguinal ligament; or, more rarely, proximally to it, from the external iliac artery.

Relations.—**Behind**, the profunda artery lies successively upon the iliacus, the pectineus, the adductor brevis, and adductor magnus muscles. **In front**, at first it is superficial, being merely covered by the skin, superficial and deep fasciæ, and branches of the femoral (anterior crural) nerve; but as it sinks behind the femoral artery, it has in front of it both the femoral and the profunda veins and, more distally, the adductor longus muscle. **Laterally** is the femur at the angle of union of the adductors longus and brevis. **Medially** is the pectineus in the proximal part of its course.

Branches of the profunda.—The profunda gives off the following branches:—(*a*) The lateral circumflex; (*b*) the medial circumflex; and (*c*) the three perforating. The termination of the artery is sometimes called the fourth perforating branch.

(*a*) The **lateral circumflex** [a circumflexa femoris lateralis] a short trunk, but the largest in diameter of the branches of the artery, arises from the lateral side of the profunda as it lies on the iliacus muscle, about 2 cm. (¾ in.) beyond the origin of that vessel from the femoral. It passes in a transversely lateral direction over the iliacus, under the sartorius and rectus, and between the branches of the femoral (anterior crural) nerve. In this course it gives off branches to the rectus and vastus intermedius (crureus), and then divides into two chief sets of branches—ascending and descending.

The **ascending** branch [ramus ascendens] either breaks up at once into numerous branches or it may arise as several vessels some of which are apt to come from the profunda itself or even from the femoral. These run upward under the sartorius and tensor faciæ latæ or laterally under the rectus femoris. The highest branches reach the gluteus medius and minimus and anastomose with the gluteal and deep circumflex iliac arteries; one branch runs beneath the rectus femoris to the hip-joint, and the others cross the vastus intermedius and pierce the vastus lateralis to anastomose with the first perforating and the medial circumflex.

The **descending** branches [rami descendentes] run distally along with the nerve to the vastus lateralis muscle. They lie beneath the rectus muscle and on the vastus intermedius (crureus) or vastus lateralis, some of them being just under cover of the anterior edge of the latter muscle. They are distributed to the vastus lateralis, vastus intermedius, and rectus, one branch usually running along the anterior border of the vastus lateralis as far as the knee-joint, where it anastomoses with the superior lateral genicular branch of the popliteal (fig. 538); another, entering the vastus intermedius, anastomoses with the termination of the profunda and with the genu suprema (anastomotica magna).

(*b*) The **medial circumflex** artery [a. circumflexa femoris medialis] comes off from the back and medial aspect of the profunda artery on about the same level as the lateral circumflex; sometimes as a common trunk with that vessel. As it winds around the medial side of the femur to reach the region of the trochanters, it lies successively, first, between the psoas and pectineus, then between the obturator externus and adductor brevis; finally, between the adductor magnus and quadratus femoris, where it anastomoses with the lateral circumflex, with the inferior gluteal (sciatic), and with the superior perforating, forming the so-called **crucial anastomosis**. While still in the femoral trigone it gives off a *superficial* branch [r. superficialis] which runs in a transversely medial direction to supply the pectineus, adductor longus and brevis, and the gracilis. The remainder of the artery is designated as the *deep* branch ([r. profundus]. An acetabular branch [r. acetabuli] courses upward beneath the tendon of the psoas, and enters the hip-joint beneath the transverse ligament, and, together with the articular branch of the obturator, supplies the fatty tissue in the acetabulum, and sends branches to the synovial membrane. The medial circumflex veins join the profunda vein.

(*c*) The **perforating arteries of the profunda** are so called because they perforate, in a more or less regular proximodistal order certain of the adductor muscles. They form a series of loops by anastomosing with one another (fig. 537), and with the superior gluteal, medial circumflex, and inferior gluteal arteries, and with the muscular and genicular branches of the popliteal. They are distributed chiefly to the hamstring muscles, but send twigs along the lateral intermuscular septum to supply the integuments at the back and lateral parts of the thigh. Other branches perforate the lateral intermuscular septum and the short head of the biceps, and, entering the vastus intermedius (crureus) and vastus lateralis, anastomose with the descending branch of the lateral circumflex. All the perforating arteries, moreover, contribute to reinforce the artery of the sciatic nerve, a branch of the inferior gluteal (sciatic) artery. They are each accompanied by two veins which terminate in the profunda vein.

The **first perforating** artery [a. perforans prima] is given off from the profunda as that vessel sinks beneath the adductor longus. It either pierces the adductor brevis, or runs between the pectineus and adductor brevis, and then passes through a small aponeurotic opening in the adductor magnus close to the medial lip of the linea aspera. In this course it supplies branches to the adductors, and, after perforating the adductor magnus, is distributed to the lower part of the gluteus maximus and the hamstring muscles, a recurrent branch commonly running beneath the gluteus maximus to anastomose with the lateral circumflex, medial circumflex, and inferior

uteal (sciatic) arteries, forming the **crucial anastomosis** at the junction of the neck of the mur with the great trochanter (fig. 537). A second branch anastomoses with a recurrent anch of the second perforating.

The second perforating artery [a. perforans secunda] which is given off from the profunda as it lies behind the adductor longus, pierces the adductor brevis, and then passes through a second aponeurotic opening in the adductor magnus a little distally to that of the first perforating artery, and also close to the linea aspera. It supplies the hamstring muscles, sends a branch to anastomose with the first perforating, and another branch to anastomose in like manner with a recurrent branch of the third perforating.

The third perforating artery [a. perforans tertia] also arises from the profunda as it lies under the adductor longus, usually about the level of the distal border of the adductor brevis. It turns beneath this border, and then, like the first and second perforating, passes through an aponeurotic opening in the adductor magnus close to the linea aspera. It also supplies the hamstring muscles, and divides into two branches, which anastomose above the second perforating, and with the termination of the profunda.

Two nutrient arteries to the femur (aa. nutritiæ femoris superior et inferior] arise from the perforating arteries. The superior generally arises from the first perforating, the inferior usually from the third, but there is some variation in this regard.

(6) The **muscular** branches [rami musculares], of the femoral artery supply the sartorius, the rectus, the vastus medialis, the vastus intermedius (crureus), and the adductor muscles.

(7) The arteria **genu suprema** (or anastomotica magna) arises from the front and medial side of the femoral just before the latter perforates the adductor magnus muscle, and almost immediately divides into branches, (*a*) saphenous, (*b*) muscular, and (*c*) articular. These branches may sometimes come off separately from the femoral.

(*a*) **The saphenous** branch [a. saphena] pierces the aponeurotic covering of the adductor canal, passes between the sartorius and gracilis muscles along with the saphenous nerve, and, perforating the deep fascia, supplies the skin of the proximal and medial side of the leg and anastomoses with the inferior medial genicular branch of the popliteal and the other vessels forming the plexus or rete at the medial side of the knee. In its course it gives twigs to the distal part of the sartorius and gracilis muscles.

(*b*) **The muscular** branches [rr. musculares] run distally in front of the adductor magnus tendon, burrowing amongst the fibers of the vastus medialis as far as the medial condyle. They break up into numerous twigs which supply the distal ends of the vasti muscles and adductor magnus. One branch runs laterally across the distal end of the femur to end in the vastus lateralis.

(*c*) **The articular** branches [rr. articulares] come off from the saphenous and muscular branches and enter the arterial rete on the medial and lateral sides of the knee. They anastomose with the medial and lateral superior genicular branches of the popliteal and the anterior tibial recurrent and supply branches to the joint.

THE POPLITEAL ARTERY

The popliteal artery [a. poplitea] (fig. 539) runs through the popliteal fossa. It is a continuation of the femoral, and extends from the aponeurotic opening in the adductor magnus at the junction of the middle with the distal third of the thigh to the distal border of the popliteus muscle, where it terminates by dividing into the anterior and posterior tibial arteries. This division is on a level with the distal border of the tuberosity of the tibia. The proximal part of the artery is accompanied by the branch of the obturator nerve to the knee-joint. The vein is behind the artery throughout; it lies at first a little laterally, but as the vessels pass through the popliteal fossa the vein crosses obliquely over the artery, and at the termination of the artery lies a little to its medial side. The tibial (internal popliteal) nerve is superficial to both artery and vein. At the proximal part of the fossa it is well to the lateral side of the vessels, but as it descends it crosses behind them, and reaches their medial side. The artery in the whole of its course is deeply placed and covered by a considerable amount of fat and areolar tissue.

Relations (fig. 539).—**In front,** the artery lies successively on the popliteal surface of the femur (from which it is separated by a little fat and sometimes one or two small glands); on the popliteal ligament of the knee; on the hinder edge of the articular surface of the head of the tibia; and on the popliteus muscle. From the latter muscle it is separated by the expansion from the semimembranosus which covers the muscle, and is attached to the popliteal line on the tibia.

Behind, the artery is covered, proximally by the semimembranosus; in the center of the popliteal fossa by the skin, superficial and deep fascia; and distally, by the gastrocnemius. The popliteal vein is behind it in the whole of its course. The tibial (internal popliteal) nerve crosses behind it obliquely, from the lateral to the medial side, about the center of the fossa.

As the artery divides into the anterior and posterior tibial, it is crossed by the aponeurotic a of the soleus which stretches between the tibial and fibular origins of that muscle.

To the **medial side** are the semimembranosus proximally, and the medial head of the g trocnemius and the tibial (internal popliteal) nerve distally.

To the **lateral side** are the biceps and the tibial (internal popliteal) nerve proximally, and lateral head of the gastrocnemius and the plantaris distally.

Branches of the Popliteal Artery

The **branches of the popliteal** include the following:—(1) the sural; (2) genicular; and (3) the terminal.

(1) The **sural** arteries [aa. surales] arise irregularly from the popliteal; supply the muscles of the calf, sending branches to the muscles bounding proximal part of the popliteal fossa. From the sural arteries also arise

superficial sural or cutaneous branches which pass distally between the heads of the gastrocnemius, and, perforating the deep fascia, supply the and fascia of the calf. A branch, usually of moderate size, accompanies the saphenous vein.

(2) The **genicular** arteries, five in number, are divided into two su (medial and lateral), two inferior (medial and lateral), and the middle or a (figs. 538, 539). The superior and inferior come off transversely in pairs either side of the popliteal, the superior above, the inferior below the Winding round the bones to the front of the knee, they form—by anastom with one another and with the genu suprema (anastomotica magna), the ter tion of the profunda, the descending branch of the lateral circumflex, ar tibial recurrent arteries—a superficial and deep arterial rete (fig. 538). superficial anastomosis or rete lies between the skin and fascia round the patella (**patellar rete**), which it supplies, the larger branches entering i above. The deep anastomosis or **articular rete** [rete articularis genu] lies surface of the bones around the articular surfaces of the femur and tibia, sup branches to the contiguous bones and to the joints. The middle genicul

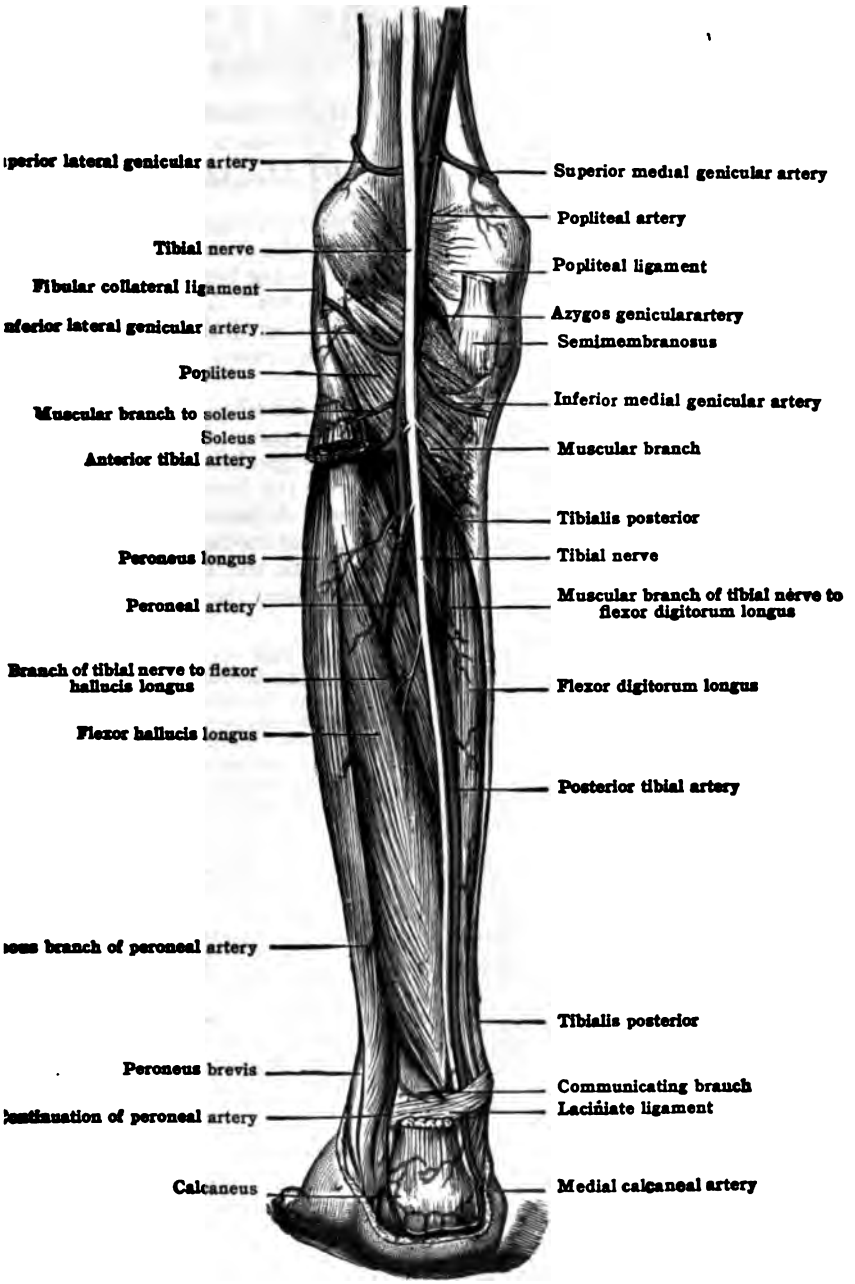
ıort trunk coming off from the deep surface of the popliteal artery. It at ıses through the popliteal ligament into the joint.

he **superior lateral genicular** artery [a. genu superior lateralis], the larger of the two genicular branches, runs in a lateral direction above the lateral head of the gastrocnemius, passing beneath the biceps and through the lateral intermuscular septum and vastus enters the substance of the vastus intermedius (crureus), and anastomoses, proximally

G. 539.—THE ANASTOMOSIS ABOUT THE LEFT KNEE-JOINT. (Walsham.)
(Semi-diagrammatic.)

descending branch of the lateral circumflex, distally with the inferior lateral genicular, s the front of the femur with the superior medial genicular, the genu suprema (anas-magna), and termination of the profunda, forming with them, as already described, the ular rete. Branches are given off to the patella, to the upper and lateral part of the the bone, and to the contiguous muscles.

e **superior medial genicular** artery [a. genu superior medialis] runs medially just above al head of the gastrocnemius, beneath the semimembranosus, and, after perforating the f the adductor magnus, enters the substance of the vastus medialis. Here it anasto-



moses with the deep branch of the genu suprema (anastomotica magna) and termination of profunda above, with the inferior medial genicular below, and with the superior lateral genicular across the front of the femur. It supplies small branches to the contiguous muscles, to the femur, to the patella, and to the joint.

(*c*) The **inferior medial genicular** artery [a. genu inferior medialis], the larger of the two inferior genicular arteries, passes in an obliquely medial direction across the popliteus, below the medial condyle (tuberosity) of the tibia and beneath the tibial collateral ligament to the front and medial side of the knee-joint. Here it anastomoses (fig. 538), proximally with the superior medial genicular and the superficial branch of the genu suprema (anastomotica magna), and across the front of the tibia with the inferior lateral genicular. It supplies branches to the lower and medial part of the joint.

(*d*) The **inferior lateral genicular** artery [a. genu inferior lateralis] passes laterally above the head of the fibula, along the tendon of the popliteus muscle, beneath the lateral head of the gastrocnemius, and then under the tendon of the biceps, and between the long and short fibular collateral ligaments. Then winding to the front of the joint, it anastomoses proximally with the superior lateral genicular, distally with the anterior tibial recurrent, and across the front of the tibia with the inferior medial genicular. It also supplies branches to the lateral and lower part of the joint.

(*e*) The **middle or azygos genicular** artery [a. genu media] arises from the deep surface of the popliteal artery, and passes, with the articular branch of the obturator nerve, through the popliteal ligament, directly into the knee-joint, where it supplies the crucial ligaments and the patellar synovial and alar folds. It anastomoses with the intrinsic branches of the other genicular arteries.

(3) The **terminal branches** of the popliteal are the posterior and the anterior tibial arteries.

THE POSTERIOR TIBIAL ARTERY

The **posterior tibial** artery [a. tibialis posterior] (fig. 540), the larger of the two branches into which the popliteal divides at the distal border of the popliteus muscle, runs distally on the flexor aspect of the leg between the superficial and deep muscles to the back of the medial malleolus. Midway between the tip of the malleolus and the calcaneus, and under cover of the origin of the abductor hallucis as it arises from the laciniate (internal annular) ligament, it divides into the medial and lateral plantar arteries.

The artery is first situated midway between the tibia and fibula, and is deeply placed beneath the muscles of the calf. As it passes distally it inclines to the medial side and at the distal third of the leg is superficial, being covered only by the skin and fasciæ. At the ankle it lies beneath the laciniate ligament, and at its bifurcation also beneath the abductor hallucis. A line drawn from the center of the popliteal fossa to a spot midway between the medial malleolus and point of the heel will indicate its course. In addition to the branches named below it supplies the muscles between which it passes, and the integument of the lower medial region of the leg.

Relations.—Anteriorly, it is in relation successively with the tibialis posterior, the flexor digitorum longus, the posterior surface of the tibia, and the deltoid ligament of the ankle-joint.

Posteriorly, it is covered by the skin and fascia, the gastrocneumius and soleus, and the deep or intermuscular fascia of the leg, by which it is tightly bound down to the underlying muscles. It is crossed by tibial nerve about 4 cm. (1¾ in.) beyond its origin, after it has given off its peroneal branch; the nerve first lies on the medial, and for the rest of its course on the lateral side of the vessel. It is accompanied by two veins, which send numerous anastomosing branches across it. In the distal third of the leg the artery is superficial, being covered only by the skin and by the superficial and deep fasciæ.

At the **medial malleolus** it lies beneath the laciniate (internal annular) ligament and abductor hallucis, upon the deltoid ligament of the ankle-joint. Here it has the tibialis posterior and flexor digitorum longus in front of it, and the tibial nerve and the flexor hallucis longus behind and to its lateral side. At times the tibial nerve divides higher than usual, when one branch lies on the medial side of the artery and the other branch on the lateral side.

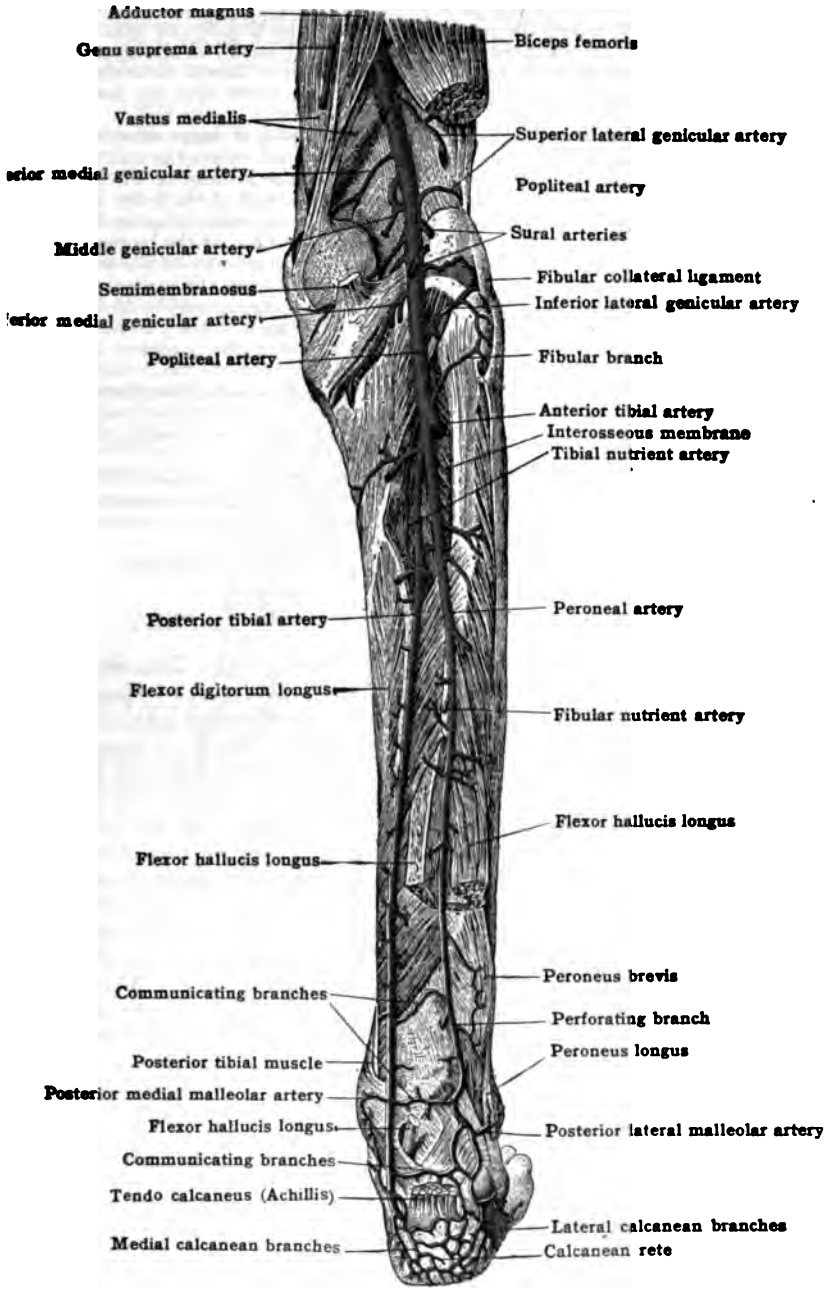
The **branches of the posterior tibial artery** (figs. 539, 540) are:—(1) The fibular; (2) the peroneal; (3) the tibial nutrient; (4) the communicating; (5) the posterior medial malleolar; (6) the medial calcanean; and (7) the terminal, medial and lateral plantar. The anastomoses of the posterior tibial branches are shown in fig. 1152.

(1) The **fibular** or superior fibular branch [ramus fibularis], usually arises from the beginning of the anterior tibial or from the posterior tibial recurrent (see fig. 540). It runs laterally toward the head of the fibula. It is small and gives twigs to the soleus, peroneus longus, and extensor digitorum longus, and anastomoses with the inferior lateral genicular and the lateral sural arteries.

(2) The **peroneal** artery [a. peronea] is a large vessel which (figs. 539, 540) arises from the posterior tibial about 2.5 cm. (1 in.) below the distal border of the

s muscle. It first curves laterally beneath the soleus muscle and reaches
la at the proximal margin of the flexor hallucis longus muscle. It then
eath that muscle and enters a canal bounded by the fibula and the flexor
allucis and tibialis posterior muscles. At the distal margin of the latter
t lies upon the interosseous membrane where it gives off a large perforat-

540.—The Popliteal, the Posterior Tibial, and the Peroneal Arteries. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



terior peroneal) branch. It now passes over the tibiofibular syndesmosis under the name of the posterior lateral malleolar (posterior peroneal) upon the posterior aspect of the lateral malleolus. It terminates upon ral surface of the tuber calcanei by breaking up into lateral calcaneal s.

The **branches of the peroneal** artery (fig. 540) are:—(*a*) The fibular nutrient; (*b*) the communicating; (*c*) the perforating; (*d*) the lateral malleolar; and (*e*) the lateral calcaneal.

(*a*) The *fibular nutrient* artery [a. nutritia fibulæ] enters the nutrient canal of the fibula.

(*b*) The *communicating* branch [r. communicans] passes between the interosseous membrane and the tendon of the flexor hallucis longus in the supramalleolar region and joins the communicating branch of the posterior tibial artery.

(*c*) The *perforating* (or anterior peroneal) branch [r. perforans] arises usually a short distance below, but sometimes above, the communicating branch, and passes through the interosseous membrane (fig. 543). It supplies the tibiofibular syndesmosis and anastomoses with the lateral tarsal, arcuate and anterior lateral malleolar arteries.

(*d*) The *lateral posterior malleolar* artery [a. malleolaris posterior lateralis] is the terminal part of the peroneal. It crosses the posterior aspect of the tibiofibular syndesmosis and lateral malleolus to reach the lateral aspect of the tuber calcanei. It gives off branches on the malleolus which anastomose with branches of the anterior *lateral malleolar rete;* also (*e*) the *lateral calcaneal* branches [rr. calcanei laterales] which enter into the formation of the *rete calcaneum.*

(3) The **tibial nutrient** artery [a. nutritia tibiæ], a vessel of large size, leaves the posterior tibial at its proximal part, pierces the tibialis posterior, and enters the nutrient foramen in the proximal third of the posterior surface of the tibia. In the interior of the bone it divides into two branches: a smaller branch, which runs toward the head of the bone; and a larger, which courses toward the distal end. It gives off two or three muscular twigs to the tibialis posterior before it enters the foramen. The nutrient artery of the tibia is the largest artery of its kind in the body, and is accompanied by a nerve given off by the nerve to the popliteus.

(4) The **communicating** branch [r. communicans] arises from the posterior tibial about 5 cm. (2 in.) above the medial malleolus, and, passing transversely across the tibia beneath the flexor hallucis longus, anastomoses with the communicating branch of the peroneal.

Frequently another branch of communication between the posterior tibial and peroneal arteries is likewise present in the loose connective tissue behind the flexor hallucis longus tendon.

(5) The **posterior medial malleolar** branch [ramus malleolaris posterior medialis] divides for distribution over the medial malleolus, anastomosing with the anterior medial malleolar artery in the *medial malleolar rete* [rete malleolare mediale]. It runs beneath the flexor digitorum longus and tibialis posterior muscles.

(6) The **medial calcanean** branches [rami calcanei mediales] are distributed to the soft parts over the medial side of the calcaneus. These branches come off more frequently from the lateral plantar artery than from the posterior tibial; they enter the rete calcaneum and anastomose with the lateral calcaneal and posterior medial malleolar arteries.

(7) The **terminal branches** are the lateral and medial plantar arteries.

THE LATERAL PLANTAR ARTERY

The **lateral plantar** artery [a. plantaris lateralis] (figs. 541, 542)—the larger of the two branches into which the posterior tibial divides beneath the laciniate (internal annular) ligament—passes at first laterally and forward across the sole of the foot to the base of the fifth metatarsal bone, where it bends medially, and still running forward sinks deeply into the foot and terminates at the proximal end of the first interosseous space by anastomosing with the deep plantar (communicating) branch of the dorsal artery of the foot. In its course to the fifth metatarsal bone the artery runs in a more or less straight line obliquely across the foot; while its deep portion, extending from the fifth metatarsal bone to the proximal end of the first interosseous space, forms a slight curve with the convexity forward, and is known as the **plantar arch.** The plantar arch is comparable to the deep volar arch formed by the deep branch of the ulnar anastomosing with the radial through the first interosseous space. The lateral plantar artery is accompanied by two veins. The course of the artery is indicated by a line drawn across the sole of the foot from a point midway between the tip of the medial malleolus and the medial tubercle of the calcaneus to the base of the fifth metatarsal bone, and thence to the lateral side of the base of the first metatarsal.

The lateral plantar artery, besides the branches named below, gives twigs to supply the muscles between which it passes, and the tarsal joints. It almost invariably also gives off a number of medial calcaneal branches. These branches occasionally arise from the posterior tibial artery, and are described with the other branches of that vessel.

Relations.—In the first part of its course from the medial malleolus to the base of the fifth metatarsal bone, the artery is covered successively by the abductor hallucis and the flexor digitorum brevis, by which it is separated from the plantar aponeurosis, and may be slightly overlapped in muscular subjects by the abductor quinti digiti. As it approaches the base of the fifth metatarsal bone it lies, as it turns medially before sinking into the foot, in the interspace between the flexor digitorum brevis and the abductor quinti digiti, and is here covered only by the skin and superficial fascia and the plantar aponeurosis. It lies upon the calcaneus, the quadratus plantæ (flexor accessorius), and the flexor digiti quinti brevis. It is accompanied by the lateral plantar nerve, the smaller of the two divisions into which the tibial nerve divides. In this part of its course it gives off small branches to the contiguous muscles and to the heel.

the second part of its course the artery, which is here known as the **plantar arch** [arcus [illegible]aris], sinks into the sole, and is covered, in addition to the skin, superficial fascia, plantar [illegible]urosis, and flexor digitorum brevis, by the tendons of the flexor digitorum longus, the [illegible]icales, branches of the medial plantar nerve, and the abductor hallucis. It lies upon the [illegible]imal ends of the second, third, and fourth metatarsal bones and the corresponding interos[illegible] muscles.

The **branches of the lateral plantar artery** are:—(1) Perforating; and (2) [illegible]ntar metatarsal (digital).

(1) The **perforating** branches [rr. perforantes], three in number, ascend through the [illegible]imal end of the second, third, and fourth spaces, between the two heads of the correspond[illegible]y named dorsal interosseous muscles, and communicate with the proximal ends of the [illegible], second, and third dorsal metatarsal (interosseous) arteries (fig. 542).

Anastomosis of plantar digital arteries around matrix of nail and pulp of toe

(2) The **plantar metatarsal** arteries [aa. metatarseæ plantares] are usually four in number and pass forward in the four intermetatarsal spaces, which are numbered from the medial side They rest upon the interosseous muscles of their spaces, and are at first under cover of the lumbricals, but as they approach the clefts of the toes each divides into two branches, the **plantar digital arteries** [aa. digitales plantares], which supply the contiguous sides of the toes. The plantar digital branch for the medial side of the great toe is usually given off by the first plantar metatarsal; that for the lateral side of the little toe is usually a separate branch from the lateral end of the plantar arch.

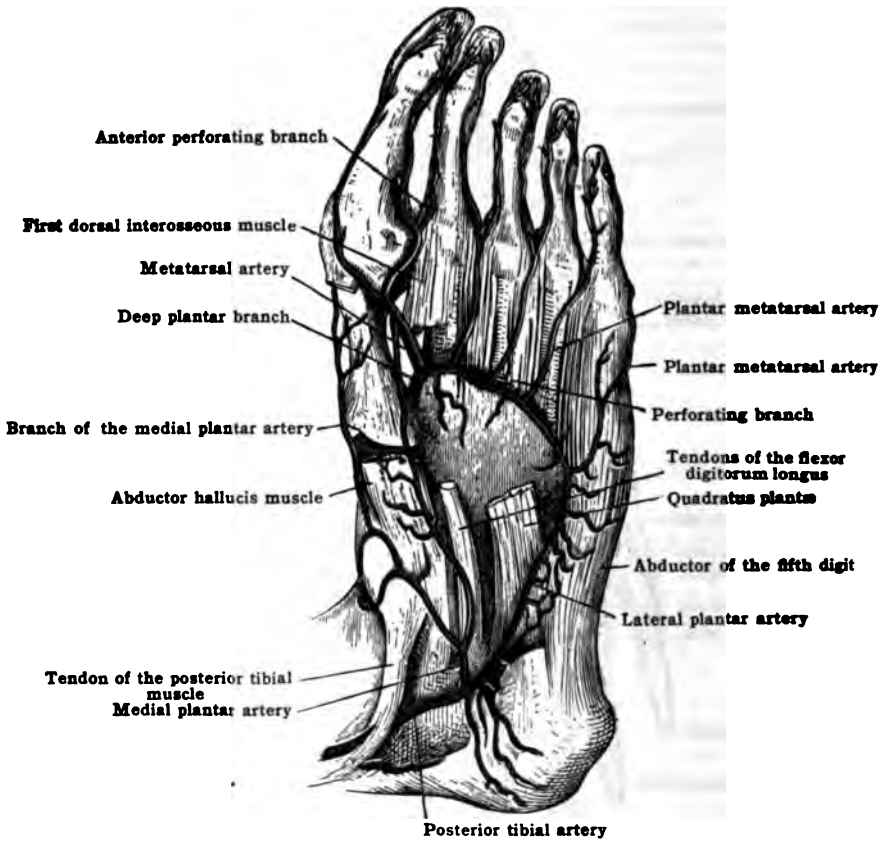
The plantar metatarsal arteries, immediately before they bifurcate, send to the dorsum of the foot a perforating branch each to the corresponding dorsal metatarsal arteries. They anastomose by many small twigs with the dorsal metatarsal arteries, which also run along the sides of the metatarsal bones, but more toward the dorsal aspect. Immediately below each phalangeal joint the plantar digital vessels communicate by cross branches, forming a rete for the supply of the articular end of the phalanges and the contiguous joints. At the distal end of the toes they also freely anastomose with each other, forming a rete beneath the pulp and around the matrix of the nail. The metatarsal and digital arteries are each accompanied by two small veins.

THE MEDIAL PLANTAR ARTERY

The **medial plantar** artery [a. plantaris medialis] (figs. 541, 542)—much smaller of the two divisions into which the posterior tibial divides—passes forw along the medial side of the sole of the foot usually to the first interosseous spa Here it ends by anastomosing either with the first plantar metatarsal arte derived from the plantar arch, or with the branch given off by the first plant metatarsal to the medial side of the great toe.

Relations.—The artery is at first under cover of the abductor hallucis, but afterward li in the interval between that muscle and the flexor digitorum brevis. It is covered by the sk and superficial fascia, but not by the plantar aponeurosis, since it lies between the central a medial portions of that structure.

FIG. 542.—DEEP PLANTAR ARTERIES. (After Henle.)



The **branches of the medial plantar** are:—(1) The deep and (2) the superfic

(1) The **deep** branch [ramus profundus], which at once divides—or it may come of several branches—to supply the muscles, articulations, and integument of the medial side o sole. Some of these branches form an anastomosis around the medial margin of the foot, branches of the dorsalis pedis.

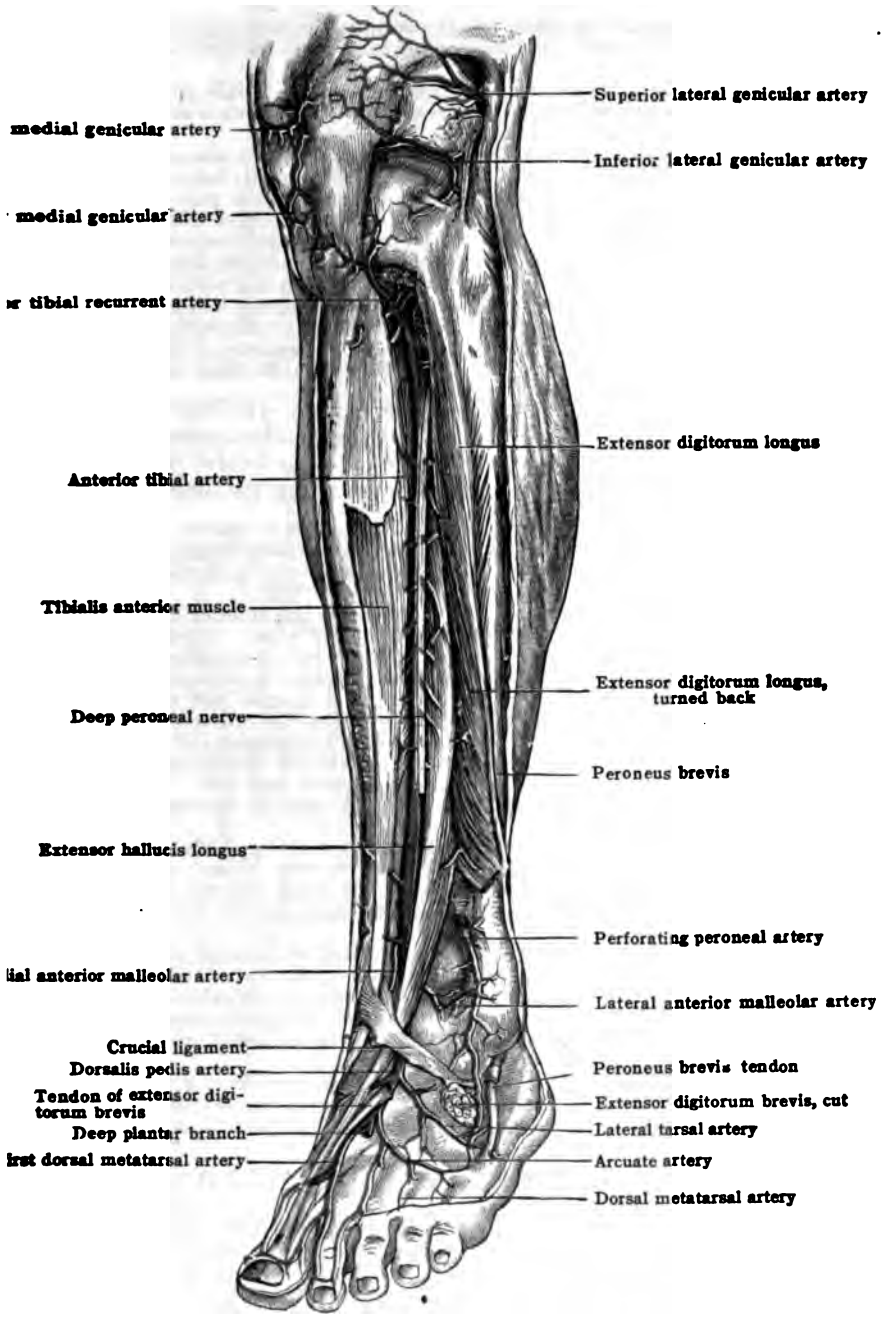
(2) The **superficial** branch [ramus superficialis] breaks up into very small twigs whic company the digital branches of the medial plantar nerves, and anastomose with the pl metatarsal arteries in the first, second, and third spaces. At times a twig from one of branches joins the lateral plantar artery to form a superficial plantar arch.

THE ANTERIOR TIBIAL ARTERY

The **anterior tibial** artery [a. tibialis anterior] (fig. 543)—the smaller of two branches into which the popliteal artery divides at the distal border of popliteus muscle—at first courses forward between the two heads of origi the tibialis posterior, and, after passing between the tibia and fibula abov proximal part of the interosseous membrane, runs on the front and lateral as

g, between the anterior muscles, as far as the front of the ankle-joint. the joint the artery is known as the dorsalis pedis. The course of the indicated by a line drawn from the front of the head of the fibula to a dway between the two malleoli.

—THE ANTERIOR TIBIAL, DORSALIS PEDIS AND PERFORATING (ANTERIOR) PERONEAL ARTERIES.



artery is accompanied by two veins which communicate with each other ient intervals across it. It is also accompanied in the distal three-fourths ourse by the deep peroneal nerve. The nerve, which winds round the head ibula, and pierces the extensor digitorum longus, first comes into contact e lateral side of the artery about the proximal third of the leg; in the middle

On its lateral side it is in contact in its proximal third with the extensor digitorum muscle; in its middle third with the extensor hallucis longus; but, as this muscle cro the medial side of the artery, the vessel usually for a very short part of its course come into contact with the extensor digitorum longus. At the proximal and distal thirds of its on the front of the leg the artery has the deep peroneal (anterior tibial) nerve to its later

In front the artery is covered by the skin, superficial and deep fascia. In its proxim thirds it is deeply placed in the cellular interval between the tibialis anterior on the side and the extensor digitorum longus and extensor hallucis longus on its lateral sid in its distal third it is crossed in the lateromedial direction by the tendon of the extensor l longus, and lies beneath the cruciate (anterior annular) ligament of the ankle-joint. Th peroneal nerve is usually in front of the artery in the middle third of the leg.

The **branches of the anterior tibial artery** are:—(1) The posterior tibial rent; (2) the anterior tibial recurrent; (3) the medial anterior malleolar; a the lateral anterior malleolar. In addition, ten or twelve muscular branch given off irregularly to the adjacent muscles along the artery.

(1) The **posterior tibial recurrent** artery is occasionally absent. It passes betwe popliteus muscle and the popliteal ligament of the knee-joint, supplying these structu the tibiofibular joint. It anastomoses with the inferior lateral genicular branch of the po and to a less extent with the inferior medial genicular branch.

(2) The **anterior tibial recurrent** is given off from the anterior tibial artery imm after that vessel has passed above the interosseous membrane. It winds tortuously t the substance of the tibialis anterior muscle, over the lateral condyle (tuberosity) of th close to the bone; and, perforating the deep fascia, ramifies on the lower and lateral par capsule of the knee-joint. It anastomoses with the inferior and superior lateral g branches of the popliteal, with the descending branch of the lateral circumflex, and so less freely with the medial genicular branches of the popliteal and with the genu s (anastomotica magna). It gives off small branches to the tibialis anterior, the extens torum longus, the knee-joint, and the contiguous fascia and skin. It forms one of lateral channels by which the blood is carried to the part of the limb beyond an ob popliteal artery (fig. 543).

(3) The **medial anterior malleolar**, the smaller of the two malleolar branches, arises f distal part of the anterior tibial artery, usually near the place at which the tendon of the e hallucis longus crosses the anterior tibial artery. It winds over the medial malleolus, beneath the tibialis anterior, and joins the **medial malleolar rete anastomosing with t** from the posterior tibial artery.

(4) The **lateral anterior malleolar** artery, larger than the medial, arises from the lat of the anterior tibial artery, usually beyond the level of the medial malleolar. It winds and laterally round the lateral malleolus, passing beneath the extensor digitorum lon peroneus tertius, and joins the **lateral malleolar rete** by anastomosing with the per peroneal, the termination of the peroneal, and the lateral tarsal branch of the dorsa (figs. 543, 544).

The anastomosis between the lateral malleolar and perforating peroneal is some considerable size, supplying the blood to the dorsal artery of the foot; the anterior tib much reduced in size, usually ends at the place of origin of the lateral malleolar.

the dorsal ligaments uniting the second cuneiform to the first cuneiform. It is more o bound down to the bones by aponeurotic fibers derived from the deep fascia.

Above, the artery is covered by the crucial (anterior annular) ligament, sometimes b extensor hallucis longus, by the skin, the superficial and deep fascia, and, just before its t nation, by the tendon of the extensor hallucis brevis. The angle formed by this tendon wi extensor hallucis longus is the best guide to finding the artery in the process of ligature (fig.

To its **lateral side** is the most medial tendon of the extensor digitorum longus, and distally the tendon of the extensor hallucis brevis. The deep peroneal (anterior tibial) is also to its lateral side.

To its **medial side** is the extensor hallucis longus, except at times for the distal hal where the tendon of the extensor hallucis brevis, having crossed the artery, may lie betw and this tendon.

The **branches of the dorsalis pedis artery** (figs. 543, 544) are:—(1) The ti (2) the arcuate; and (3) the deep plantar.

(1) The **tarsal branches** may be divided into (*a*) the lateral and (*b*) the medial. (*a*) **lateral tarsal** artery [a. tarsea lateralis] runs laterally over the navicular and cuboid bon neath the extensor digitorum brevis. It supplies branches to that muscle, and to the bon the articulations between them, and anastomoses with the lateral malleolar and perfo (anterior) peroneal, with the arcuate (metatarsal) and, over the lateral border of the with the anastomotic branches of the lateral plantar artery. (*b*) The **medial tarsal a** [aa. tarseæ mediales] consist of a few small branches which run over the medial side of the supplying the skin and articulations, and anastomose with the medial malleolar arteries with branches of the medial plantar.

(2) The **arcuate (metatarsal)** artery [a. arcuata] (figs. 543, 544) runs laterally acro foot, in a slight curve with the convexity forward, over the bases of the metatarsal bone beneath the extensor tendons and the extensor digitorum brevis. At the lateral border foot it anastomoses, with the lateral tarsal artery, and with branches of the lateral planta

From the convexity of the arch it gives off four **dorsal metatarsal** (interosseous) ar which run forward on the dorsal interosseous muscles in the center of the four interosseous s to the cleft of the toes, where they bifurcate for the supply of the contiguous sides of th The artery to the first space is large, and gives off the digital artery to the medial side of the toe. This vessel continues the direction of the dorsalis pedis and is commonly known a **dorsalis hallucis** artery. The most lateral of the interosseous branches gives off a small for the supply of the lateral side of the little toe. At the proximal end of the second, thi fourth interosseous spaces each artery receives a perforating branch from the lateral p artery, and, immediately before they bifurcate, a second perforating artery through the end of the interosseous space from the corresponding digital.

The **dorsal digital** arteries [aa. digitales dorsales], into which the dorsal metatarsal a divide at the cleft of the toes, run along the side of each toe toward the dorsal aspect, tomosing with each other across the dorsum of the toes and by frequent branches wi digital branches of the plantar metatarsal arteries, which also run along the sides of th but nearer the plantar surface. At the end of the toes they anastomose with each other a the quick of the nail.

(3) The **deep plantar** branch [ramus plantaris profundus] comes off from the dorsali with the first dorsal metatarsal (into which arteries indeed the dorsalis pedis may be s divide). At the proximal end of the first interosseous space it dips into the sole between t heads of the first dorsal interosseous muscle, and communicates with the termination lateral plantar artery, completing the plantar arch, in a manner similar to that in wh radial artery, passing through the first dorsal interosseous muscle in the hand, compl anastomosing with the ulnar the deep palmar arch.

MORPHOGENESIS AND VARIATIONS OF THE ARTEI

A. ARTERIES OF THE HEAD AND TRUNK

1. MORPHOGENESIS

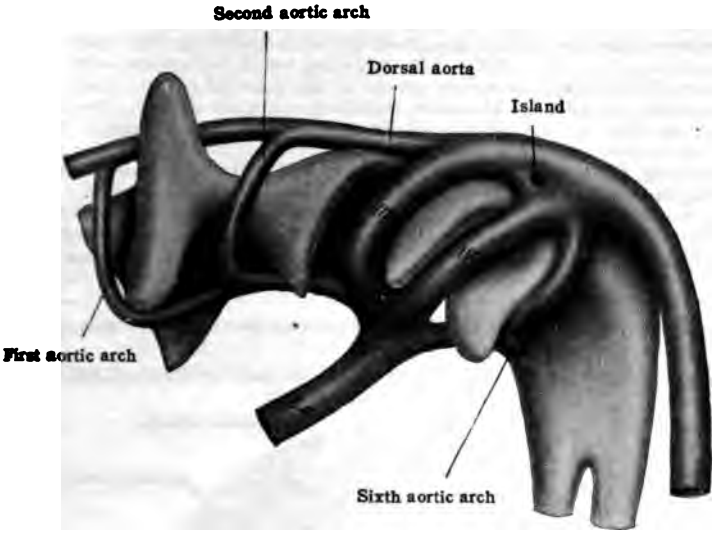
In conformity with the branchiomeric and metameric development of th and trunk (see p. 13) the arteries are developed in two sets, the branchi (aortic arches) and metameric (segmental arteries).

(1) **The system of aortic arches** consists of five pairs of arteries which spring from tral aorta, or aortæ, and pass around the pharynx in the branchial arches to join th dorsal aortæ. Some of the arches are very transitory, but all of those that give rise to nent vessels are present in embryos about five millimeters in length. Fig. 545 shows t tribution and relations to the pharyngeal pouches at this stage. The fifth pair in the usually regarded as representing the sixth of the lower vertebrates. The true fifth ar probably not always developed, but may occur as imperfect and transitory structure dorsal aortæ, originally paired throughout, later become united in the median line near forward as the last pair of aortic arches.

During the separation of the heart into right and left halves (p. 558), the primitive aorta is divided by the aortic septum into two vessels, the *main pulmonary artery* and *ending aorta* of the adult. The pulmonary trunk becomes connected with the sixth arches only; the other arches then communicate, by means of the ventral aorta, with ventricle. The further changes which occur in the arches to bring about the condition

adult are shown diagrammatically in fig. 546. The right and left *pulmonary arteries* arise he corresponding sixth arches. The portion of the sixth arch between the pulmonary and the dorsal aorta disappears on the right side, while on the left it persists until birth *ductus arteriosus* (lig. arteriosum of the adult). The fourth arch, including the short l stem between the fourth and sixth arch, becomes the permanent *aortic arch* on the left nd the *innominate* and proximal portion of the subclavian upon the right. The dorsal

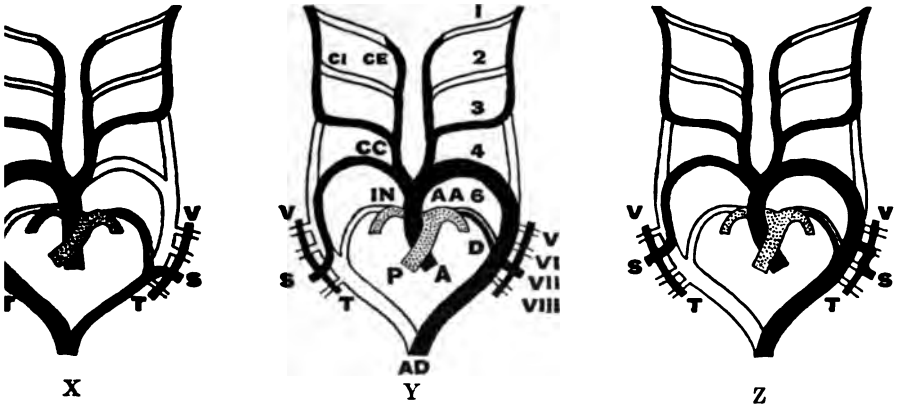
15.—Model of the Pharynx and Aortic Arches of a Human Embryo 5 mm. Long. (Tandler, ×75.)



lisappears on both sides between the third and fourth arches. The part of the left dorsal between the fourth and sixth arches enters into the composition of the aortic arch, while rresponding part of the right dorsal aorta forms part of the right subclavian artery. The ıder of the dorsal aorta of the left side forms part of the descending thoracic aorta of the while that of the right side usually disappears entirely. A trace of the latter vessel ınally persists in the adult as a small vessel (*a. aberrans*) connecting the dorsal aorta,

46.—Diagrams showing the Method of Normal Development of the Aortic Arches, and Indicating the Mechanism of some Variations.

imitive aortic arches (1–6), and some of the cervical dorsal segmental arteries are shown all the diagrams but numbered in Y only. Y., normal; X., abnormal: the aortic arch is ı the right; the left subclavian takes the dorsal course; the right vertebral arises directly ɔm the aortic arch. *Z.*, abnormal: the right subclavian arises from the sixth cervical ırsal segmental; the left from the sixth in part only. A, ascending aorta; AA, aortic ch; AD, dorsal aorta; CC, common carotid; CE, external carotid; CI, internal carotid; , ductus arteriosus; IN, innominate; S, subclavian; T, costocervical; V, vertebral.



r or indirectly, with the right subclavian artery (p. 609). The ventral stems between the and third arches form the *common carotids;* those between the third and first become the l *carotids*. The *internal carotid* arteries are formed by the third arches and by the parts lorsal aortæ between the third and first arches. The distal part of the internal carotid ı, the circulus arteriosus and the cerebral arteries are developed from the primitive vascu- uses of the forebrain and midbrain.

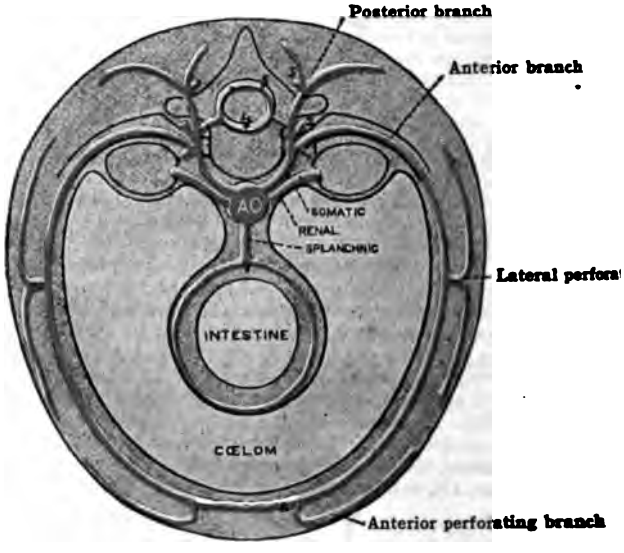
In early development the segmental arteries are caudally placed with regard to arch vessels. The latter, however, become shifted as the heart migrates from the ne thorax.

Little is known of the share taken by the first and second aortic arches in the forma branches of the internal and external carotid arteries. It has been shown by Tandl *internal maxillary* is primarily a branch of the internal carotid (the first and sec taking a share in its formation). The primitive vessel is known as the *stapedial* sinc between the crura of the developing stapes. It gives off supraorbital, infraorbital, and lar branches; the latter two arising from the main artery by a common trunk. Th trunk is later joined by a branch from the external carotid and, together with the su becomes the *middle meningeal*. An anastomosis between the supraorbital and the o persists so that in the adult the anterior branch of the meningeal frequently takes a co share in the blood-supply of the orbit. The stapedial trunk undergoes retrogress represented in the adult by the *caroticotympanic* of the internal carotid and by th *tympanic* of the middle meningeal. The infraorbital branch of the stapedial becomes t and third parts of the internal maxillary and gives off branches accordingly. The m branch becomes the *inferior alveolar* of the adult.

(2) The **segmental system** (figs. 547, 548) consists of arteries primarily arising aorta in three longitudinal series, dorsal, lateral, and ventral on either side. The arrangement is much less perfect in the ventral and lateral groups than in the dorsal so, in fact, that the term segmental is used for the ventral and lateral groups rather a of convenience than as indicating a strict numerical correspondence between segm vessels.

FIG. 547.—SCHEME OF THE TYPICAL ARRANGEMENT OF THE BRANCHES OF THE AORTA Quain.)

Longitudinal anastomoses: 1, precostal; 2, postcostal; 3, postvertebral; 4, preneura neural; 6, mammary.



The **dorsal segmental arteries** primarily supply the central nervous system bu off two sets of vessels to the body wall: these persist in the adult as the *anterior* a *main branches of the intercostal and lumbar arteries*. The termination of the orig segmental arteries is represented in the adult by the *spinal ramus* which accor corresponding nerve root through the intervertebral foramen. The tendency to for mental anastomoses between these vessels (and their branches) gives rise to many o tant longitudinal stems of adult anatomy. Thus, the spinal ramus gives rise to postneural anastomosing channel on either side, the (primarily paired) *anterior a spinal arteries*. The anterior branches have each a longitudinal precostal anasto as they grow forward with the developing body wall, their ends are connected to for mary anastomosis. Between the posterior rami, a postcostal and a postvertebral may be formed (fig. 547).

Two dorsal segmental arteries have been recognized in the occipital region; t appears and the second, the *hypoglossus artery*, follows the hypoglossal nerve to the face of the brain where it is connected with a longitudinal anastomosis out of which *artery* is formed.

In the *cervical region*, the spinal ramus of segmental cervical I forms the third, o tal, part of the *vertebral artery*. Cervical segmentals I to VI lose their connection wi and a postcostal anastomosis between them forms the second part of the same ve first part of the vertebral is formed by the posterior ramus of cervical VI and by th anastomosis of that artery with the subclavian (fig. 548).

The *subclavian artery* does not seem to belong to the dorsal segmental series. T part of the right subclavian originates from the aortic arch system. The distal po

nd the entire vessel of the left side, represents the only persistent artery out of the e number originally entering the primitive arm-bud. It usually comes to occupy etween cervical arteries VI and VIII of the dorsal segmental series.
anterior ramus of cervical VIII is connected with the subclavian artery by a pre- nosis which becomes the *costocervical* trunk. The posterior ramus becomes the *ep cervical*, and, by a postvertebral anastomosis with the other posterior cervical the occipital, forms the remainder of the deep cervical and the *descending branch artery.*
acic and lumbar regions, the embryonic conditions very largely persist (fig. 548). rami of thoracic segmentals I and II, however, lose their connection with the y a precostal anastomosis with cervical VIII, become secondarily connected costocervical trunk) with the subclavian. The *superior intercostal* of the adult is

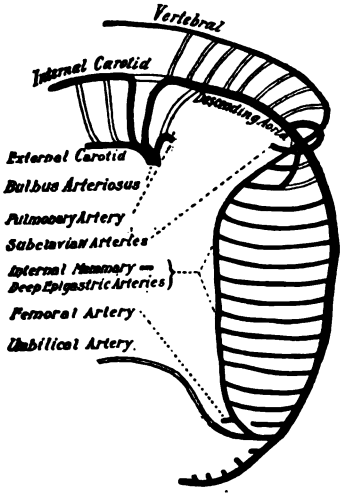
vhich persist are black; those which degenerate are in outline; those newly formed are shaded. (After Mall.)



ral region, the arteries of the dorsal segmental series arise from the middle sacral to the anterior vertebral foramina, but before doing so are connected with one precostal anastomosis. This anastomosis forms part of the *lateral sacral artery;* e greater part of its blood from the hypogastric.
l segmental arteries take origin from the aorta in series, intermediate in position lorsal and ventral segmentals. They reach their fullest development in embryos n., when they extend from the seventh cervical to the twelth thoracic segment and esonephros. At this stage Broman found twenty arteries on each side, many of on-segmental. As the suprarenals and gonads develop, they each receive branches mesonephric arteries. The latter arteries now undergo rapid retrogression and l and gonadic branches are shifted caudally through the mesonephric series to l (non-segmental) arteries opposite the upper lumbar segments. Finally there suprarenal arteries opposite the twelfth thoracic and first and second lumbar l a gonadic artery (*ovarian or internal spermatic* of the adult) opposite the third nt. All of these vessels now appear to be direct branches from the aorta. Of the nal branches, the upper and lower each gives a large branch to the diaphragm and tively and become the *inferior phrenic* and *renal arteries* of the adult. The middle *middle suprarenal* of the adult. Felix regards the lateral segmental arteries as from longitudinal anastomoses connecting the ventral segmental series. He rent interpretation upon the vessels which persist in the lumbar region after the e of the thoracic mesonephric arteries. He finds in an embryo of 18 mm. nine ther side, extending from the ninth thoracic to the third lumbar segment, all of s upon as mesonephric. These arteries he classifies into three groups: Cranial, he mesonephros by passing dorsally to the suprarenal; caudal which pass ventrally enal, and middle which pass through it. Inasmuch as the arteries anastomose

in the mesonephros there is great liability to variation in the number and position of the stems which persist in the adult. The suprarenal arteries are usually derived from the caudal group, the renals from the caudal or middle and the spermatics from the middle. When accessory renals or spermatics occur in the adult their place of origin and course indicate the group from which they have been derived.

The **ventral segmental arteries** appear very early. In an embryo of seven somites (1.5 mm.) described by Dandy there is a right and a left series of twelve arteries, each arising from the still ununited dorsal aortæ, the artery at the caudal end of each series being the umbilical, and the remainder vitelline arteries. In an embryo of 4.9 mm. (35 somites) described by Ingalls the originally paired vitelline arteries have united (as have the dorsal aortæ in part) to form unpaired vessels. There are unpaired ventral segmental arteries as follows: one opposite the seventh cervical segment (celiac); five opposite the first four thoracic (omphalomesenterics, united by a longitudinal anastomosis), and one vessel of doubtful significance opposite the fifth and sixth thoracic segments. The paired umbilical arteries are opposite the first lumbar segment.

It has been found from more fully developed stages that the inferior mesenteric artery is distinguishable at a stage of 8 mm. opposite the second lumbar segment. Also that the ventral segmental vessels undergo a process of apparent migration until they reach their definite positions, the *celiac* opposite the twelfth thoracic segment; the *superior mesenteric* opposite the first, the *inferior mesenteric* opposite the third, and the umbilicals opposite the fourth lumbar segments, respectively. The esophageal arteries of the adult do not belong to this series: but seem to be vessels of later formation.

The *umbilical arteries* become connected by anastomosis with the common iliac-hypogastric trunks. The original (or ventral) roots of the umbilical arteries soon disappear and the umbilical arteries are subsequently supplied through the common iliac-hypogastric trunks alone.

2. VARIATIONS

Aorta and pulmonary artery.—The variations met with in the arch of the aorta are usually to be explained as persistent fetal conditions, and are often associated with abnormalities of the heart. Many of the variations are due to different modes of transformation of the primitive system of aortic arches. Since the aorta and pulmonary artery develop from a common conus and truncus arteriosus, irregular and imperfect development of the aortic septum may also be productive of variations.

It has been seen that at one stage of development two fourth arches, a right and a left, are present, and such a condition is occasionally persistent in the adult. In such cases, the right arch passes from right to left behind the esophagus, which thus seems to perforate the aortic arch.

Another variation occasionally seen is the occurrence of an aortic arch curving to the right instead of the left. This may be due to a persistence of the lower portion of the right dorsal longitudinal stem and the disappearance of the left, as shown in fig. 546; or it may be associated with transposition of the viscera (*situs inversus*).

If the lower portion of the right dorsal longitudinal trunk should persist, and the part of it which normally forms the proximal part of the right subclavian should disappear, the right subclavian would arise from the descending portion of the aortic arch. It is to be noted that in such cases the subclavian passes behind the esophagus and below the right inferior laryngeal nerve. Partial persistence of the lower portion of the right dorsal longitudinal trunk is represented in the arteria aberrans (see p. 609).

Another group of variations is based on abnormal persistence of the ductus arteriosus, which is a derivative of the sixth aortic arch. With this group belong the cases in which the pulmonary artery arises from the aorta; that is, where the blood of the pulmonary arteries passes from the aorta through the ductus arteriosus.

Variations in the number and the position of the vessels arising from the aortic arch are numerous and important. Many of these conditions are found normally in other mammals or birds. There may be from one to six branches. The case of one branch is the normal in the horse. It involves the fusion of the two aortic stems and the shortening of the fourth arch so that the left subclavian joins with the common stem. The avian form with two innominate arteries is extremely rare. A more common form is the one found in most apes, in which the innominate and left carotid form one branch; in rare instances the three branches are the two subclavians with a single common carotid artery. When there are more than three branches the vertebral arteries are added, or the extra branch may be the thyroidea ima (fig. 487). The commonest form with four vessels is the one in which the left vertebral arises between the left carotid and subclavian. In a rarer form the order is right subclavian, right carotid, left carotid, and left subclavian. Where there are five arteries, the extra ones are the right subclavian and left vertebral. The case of six branches is due to the separate origin of both vertebrals and both subclavians. The manner in which the vertebral artery may arise from the adult aortic arch is indicated in fig. 546.

The **innominate artery** may be absent, or may give off additional branches (see AORTA). It may be longer than usual and, bending to the left, ascend in front of the trachea (or more rarely behind the trachea and esophagus) to turn again to the right. The *thyroidea ima* has been referred to (p. 573).

Carotid arteries.—The *common carotid* may be absent or bifurcate at a higher or a lower level than usual. It may not bifurcate at all, in which case the branches usually arising from the external carotid are derived from the common. The ascending pharyngeal and superior thyroid occasionally arise from an otherwise normal common carotid. Unusual origin of the common carotid arteries has been referred to (see AORTA).

Branches of the carotid arteries.—The superior thyroid, lingual and external maxillary

sometimes have a common stem of origin. The *superior thyroid* artery varies in size inversely with the inferior. The *external maxillary* occasionally terminates in its submental branch. In such cases the main supply of the face is taken over by an abnormally large dorsal nasal branch of the ophthalmic, or transverse facial branch of the temporal artery. The *occipital* sometimes arises from the internal carotid or from the ascending cervical. The *ascending pharyngeal* is very variable in its place of origin from the external carotid, it may arise from the common or internal.

Out of 447 arteries examined, the second portion of the *internal maxillary* passed laterally to the external pterygoid muscle in 55 per cent., and medially to it in 45 per cent. of cases. When it passes to the medial side of this muscle the internal maxillary sometimes passes medially to the inferior alveolar and lingual nerves and occasionally between them. The variability in the course of this artery appears to depend on a tendency to reduplication of the infraorbital branch of the *stapedial artery* (p. 670) in the neighborhood of the mandibular nerve. Such a condition was found by Thyng in a 17 mm. human embryo. When the internal maxillary passes medially to the external pterygoid there is often a parallel anastomosing channel between the posterior deep temporal and buccal branches.

The *ophthalmic artery* may arise, wholly or in part, from the middle meningeal, or *vice versa*. This is due to the anastomosis between the supraorbital branch of the stapedial and the ophthalmic in the embryo.

Subclavian artery.—Irregularities of origin have been referred to (see AORTA).

The branches of the subclavian artery are very variable in their place of origin (p. 597). The *vertebral* may arise directly from the arch of the aorta (p. 672) or take an unusual course in the neck. It may enter the foramen transversarium of the fourth or fifth cervical vertebra instead of the sixth; this arises from substitution of an embryonic precostal anastomosis in these segments for the usual postcostal. By a converse substitution it may enter the seventh; or the pre- and postcostal anastomoses may coexist. The *aa. transversa colli and scapulæ* vary inversely in size. The *arteria aberrans* connecting the right subclavian with the dorsal aorta has been referred to (p. 672).

The thoracic aorta.—Transposition, and the arteria aberrans have been referred to above.

Branches of the thoracic aorta.—The *intercostal arteries* are liable to numerical variation, evidently owing to the occurrence of precostal intersegmental anastomoses between the embryonic dorsal segmentals. A common longitudinal stem may even take over the vessels of both sides. The arrangement of the *bronchial arteries* is liable to much variation; this has not received adequate explanation.

The abdominal aorta sometimes divides as low as the fifth lumbar vertebra, occasionally a little higher than usual, depending usually upon the position of origin of the common iliac. (p. 671). Cases are on record of accessory pulmonary arteries arising by a single stem from the abdominal aorta, which passes into the thorax along the esophagus. The aorta and vena cava inferior may be transposed either as a part of *situs inversus* or as an abnormality of the venous system.

Branches of the abdominal aorta.—The *lumbar arteries* are subject to the same type of variation as occurs in the intercostals. There may be a loop connecting the *celiac* and *superior mesenteric* arteries. Any or all of the branches of the celiac may arise from the superior mesenteric (celiomesenteric in the latter case) or directly from the aorta. The instability of the celiac and superior mesenteric branches is favored by the rapid craniocaudal migration of the two trunks; intersegmental anastomosis, in some cases, may be a factor also. There is very great variation in the number of branches given off by the superior mesenteric and in the details of their arrangement. This is a natural result of the number of possible routes which may be taken by the blood, which resemble, in their variety, those which occur in an embryonic plexus. The region of supply of the *inferior mesenteric artery* is sometimes taken over entirely or in part (e.g., middle colic) by the superior mesenteric. An *omphalomesenteric* artery, in rare cases, arises from the superior mesenteric or one of its branches. It passes to the navel and anastomoses with inferior epigastric and with the small arteries accompanying the round ligament of the liver or the urachus.

Accessory renal arteries are very common; as many as six on a side have been recorded. These may arise from the aorta, middle sacral, inferior phrenic, middle suprarenal or internal spermatic. According to Felix, they are to be regarded as persistent mesonephric arteries. Those arising above the regular renal frequently enter the kidney on the dorsal side of the hilum. Those below it are more apt to be ventrally placed.

Nearly all possible variations of origin are met with in the *inferior phrenic, middle suprarenal, internal spermatic* and *accessory renal* arteries which find explanation in the caudal migration of, and anastomosis between, the embryonic representatives of these vessels. The occasional origin of the inferior phrenic from the celiac (or from one of its branches) or from the superior mesenteric; of the internal spermatic or the middle suprarenal from the lumbar arteries, or of an accessory renal from the inferior mesenteric must be taken as indicating embryonic anastomoses between the dorsal, lateral, or ventral segmental arteries, as the case may be.

The iliac and hypogastric arteries.—The length of the *common iliac* depends upon the site of aortic bifurcation (p. 674); also upon the site of division of the common iliac into external iliac and hypogastric. Many of the variations of the *common iliac* and *hypogastric* arteries are, in reality, anomalies of position of the *external iliac*. Failure in the separation of the common iliac from the hypogastric may be due to origin of the external iliac from the aorta (Cruveilhier, Walsham) or to its origin from the distal region of the hypogastric (Ellis, Ledwich, Luschka, Vonviller). In the latter case the hypogastric has been erroneously reported absent.

The *branches of the hypogastric artery* may not combine so as to form the typical anterior and posterior divisions. The marked tendency to variation in the branches of the a. hypogastrica does not appear to have been satisfactorily explained. The *obturator artery* may arise by the union of a stem from the hypogastric with another arising from the external iliac or from the inferior epigastric, or it may arise solely from any one of these arteries.

B. ARTERIES OF THE EXTREMITIES

1. MORPHOGENESIS

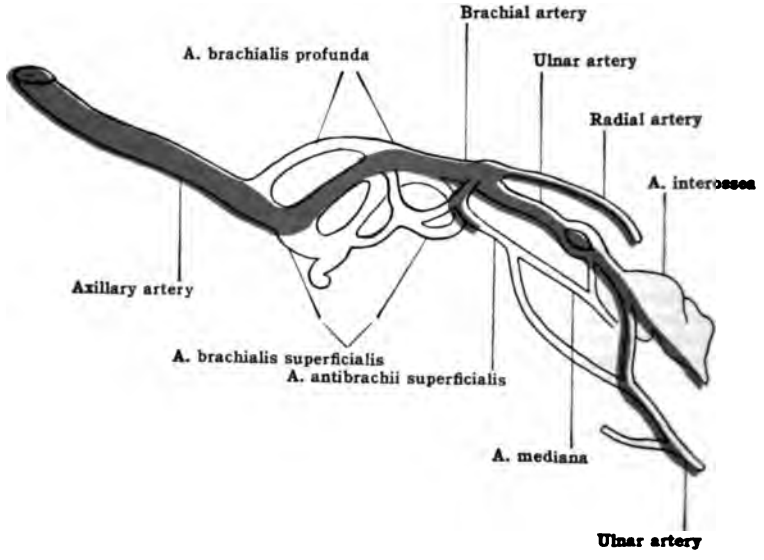
The developing extremities are at first supplied by lateral branches of the aorta and by branches of the neighboring dorsal segmental arteries, which form a plexus drained by the umbilical and postcardinal veins.

The further development of the *arteries of the upper extremity* has been described by both DeVriese (Arch. de Biol., T. 18, 1902), and Müller (Anat. Hefte, 1903). The accounts given by the two authors differ, however, very considerably in detail. According to DeVriese there is an axial artery of the embryonic extremity, which follows the median nerve in the arm and the volar interosseous nerve in the forearm. It breaks up to supply the volar surface of the hand, and sends a perforating carpal branch to supply the dorsum. Embryonic arteries of secondary formation follow the radial and the ulnar nerve in the arm and forearm and the median nerve in the forearm. For further details on the ensuing changes, see the original article.

Müller describes a plexus which traverses the axis of the limb at the stage of 8.3 mm. At the stage of 11.7 mm. the plexus reaches its full development and centers about a main trunk which corresponds to the axillary, the brachial and to the volar interosseous arteries of the adult. Some of the other elements of the plexus of the stage of 11.7 mm. are recognizable as the remaining arteries of the normal adult; others consist of anastomosing channels which would be instrumental, if they were to persist, in the production of various anomalies (fig. 549).

FIG. 549.—DIAGRAM INDICATING THE METHOD OF DEVELOPMENT OF THE ARTERIES OF THE LEFT UPPER EXTREMITY. (After E. Müller.)

(The embryonic arteries are outlined in black, and labelled in Latin. The normal adult arteries are colored red and labelled in English).



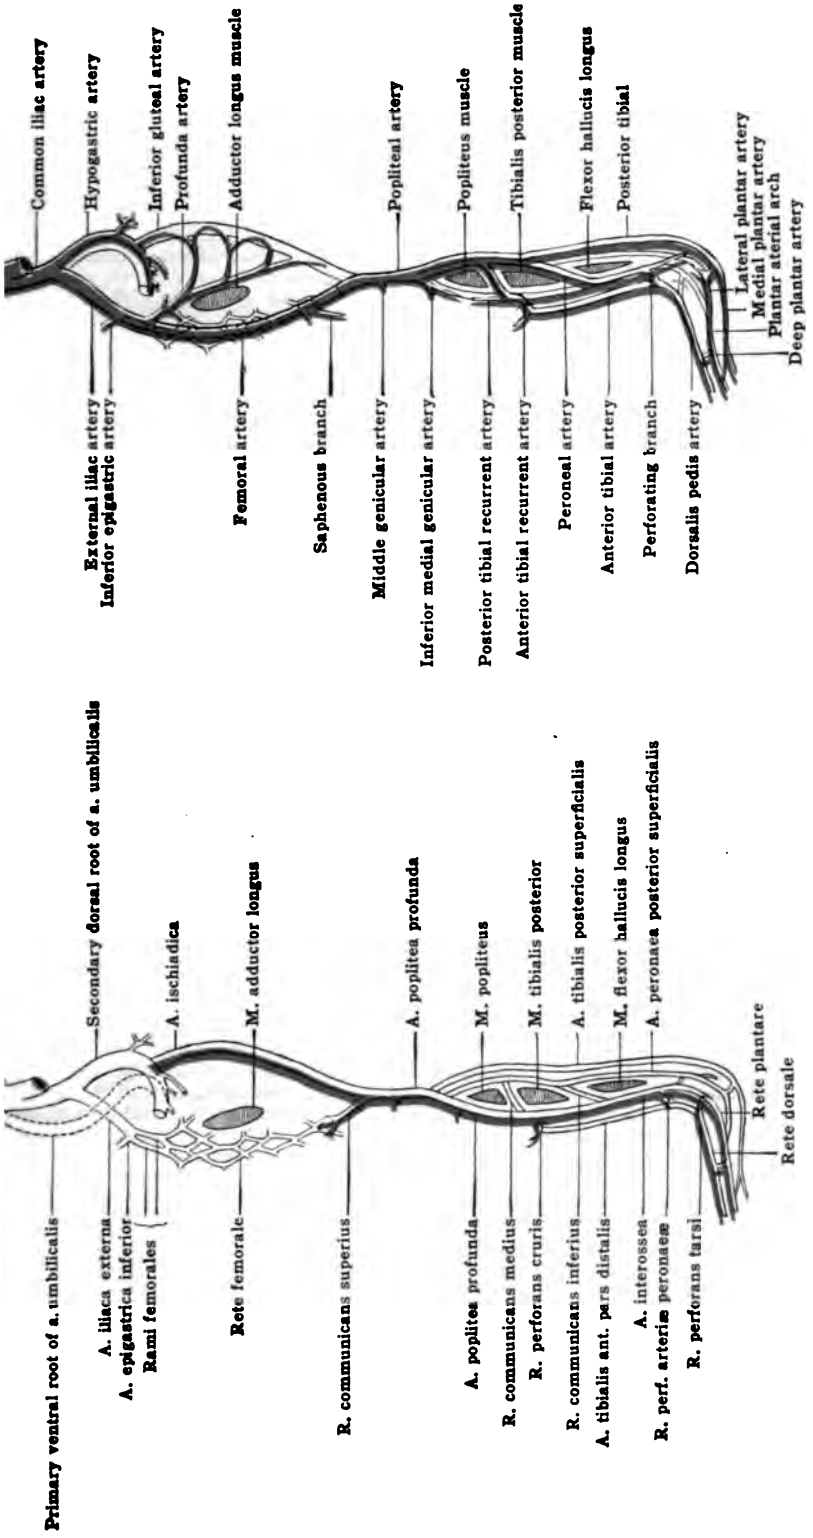
The further history of development consists in the loss of existing arterial channels which have no place in the normal upper extremity. By the stage of 20.2 mm. the definitive arrangement has been established.

In the *lower extremity* (fig. 550) the arterial part of the vascular plexus of the early limb-bud gives place to the common iliac-hypogastric trunk which replaces the original, or ventral, root of the umbilical artery, and to an artery which traverses the axis of the limb. In the thigh the axial artery accompanies the tibial nerve; and is called the a. ischiadica. In the proximal part of the leg it passes between the popliteus muscle and the tibia, on which account it takes the name of a. poplitea profunda; it then follows the posterior surface of the interosseous membrane, as the a. interossea, to the medial malleolus. Passing below the malleolus it breaks up into an arterial plexus (rete) for the supply of the sole and sends a branch, the r. perforans tarsi, through the sinus tarsi to the dorsum of the foot. The axial artery is represented in the adult by the inferior glutaeal artery and by the part of the popliteal artery above the popliteus muscle. Smaller parts of it persist in the postfemoral anastomosis; in the inferior medial genicular artery; in the posterior tibial recurrent and in the part of the anterior tibial artery from which the latter arises, also in the part of the peroneal artery which lies in contact with the interosseous membrane (fig. 550).

The external iliac is an artery of new formation which is connected, by means of the rete femorale, with a recurrent branch of the axial artery, the r. communicans superius; the femoral artery is developed from the rete femorale and ramus communicans, as are all of its branches. The distal part of the popliteal artery, and the part of the posterior tibial artery above the origin of the peroneal, are formed by the blending of two embryonic arteries. One of these, the superficial posterior tibial, still further persists in the distal part of the posterior tibial artery and in

-DIAGRAM INDICATING THE METHOD OF DEVELOPMENT OF THE ARTERIES OF THE RIGHT LOWER EXTREMITY. (After E. Müller.)

onic arteries are outlined in black, In *A*, the axial artery of the developing limb, and of its branches are colored red; the original, or ventral, root of the umbilical artery cated by a broken line. In *B*, the adult arteries are colored red.



the medial plantar. The other, the superficial posterior peroneal, is united with the axial artery by means of the r. communicans inferius to form a combination of which a part persists as the peroneal artery of the adult. The distal part of the anterior tibial artery arises as a communication between the rete dorsale of the foot and the ramus perforans cruris, which is a branch of the axial artery. The proximal part consists of the ramus communicans medius, a branch which connects the axial with the popliteal artery. The lateral plantar artery is derived from the terminal bifurcation of the embryonic superficial posterior peroneal artery which forms a connection between the superficial posterior tibial and the plantar rete of the foot. All the deeper arteries of the foot are developed from the embryonic retia.

2. VARIATIONS

Variations of the *arteries of the upper extremity* are very common. The most important group of major variations centers about persistence of the embryonic *superficial brachial* artery This vessel crosses in front of the median nerve instead of behind it; it may partly, or entirely, replace the normal, or deep, brachial, or both vessels may occur together. In the latter case the superficial brachial may end in, or communicate with, the deep brachial artery near the bend of the elbow, forming an *arteria aberrans;* or it may pass without communication, into the forearm. In the latter case it most commonly follows the course of the radial artery (high origin of radial); while the deep brachial is continued as the ulnar. The superficial brachial artery may, however, be continued into the forearm as the embryonic *superficial antibrachial* artery. This vessel may combine, with the distal part of the ulnar, or with the median artery, to form the *superficial ulnar* or *median*, as the case may be, or it may combine with both. When the persisting superficial antibrachial artery enters into combinations of this kind, the ulnar nerve is not accompanied by an artery in the middle of the forearm, and the radial artery, the continuation of the deep brachial, gives origin to the common interosseus and to the ulnar recurrent arteries. When the deep and superficial brachial arteries occur together the superficial brachial frequently arises in the distal third of the arm. It may arise from the proximal third, however, or from the axillary; it seldom arises in the middle third. In cases in which the superficial brachial artery altogether replaces the deep brachial and the distal portion of the axillary, the branches of the third part of the axillary artery arise by a common stem, the *a. profunda axillaris*. The latter vessel takes the same course, with regard to the medial root of the median nerve, as does the normal axillary artery. The deep axillary artery may give origin to the a. profunda brachii and the superior ulnar collateral in addition to the branches which usually arise from the third part of the axillary. The embryological basis for these variations, according to DeVriese and Müller is stated above (fig. 549).

Apart from the variations mentioned above, the radial or ulnar artery may be small or absent, compensation usually occurring through enlargement of the median. The volar interosseous artery may be sufficiently large to take part in the supply of the deep volar arch. Many variations less commonly encountered have been recorded by Barkow, Gruber, Quain, Tiedemann and others.

Arterial variations are much less common in the *lower extremity* than in the upper. In the absence of the embryonic r. communicans superius the *ischiadic artery* may persist in the adult. The femoral is small in such cases, and ends either as the a. genu suprema or as the a. profunda femoris. Partial *reduplication of the femoral artery* may result from the formation of a double channel, instead of the usual single one, through the elements of the rete femorale. The *profunda artery* is quite commonly represented by several branches of the femoral. This seems to result from the fact that the circumflex arteries, and the common stem of the aa. perforantes, make their appearance separately at different periods of development, and that their proximal ends may fail to combine in the formation of a single stem. The perforating arteries may even arise individually or in two or more groups from the femoral (Hepburn, Ruge, Young). In consequence of the failure of the proximal part of the embryonic a. peronaea posterior superficialis to unite with the corresponding part of the a. tibialis posterior superficialis, the *popliteal artery may divide at the upper border of the popliteus muscle* into the posterior tibial and a trunk which gives origin to the peroneal artery and to the anterior tibial. In the absence of the embryonic r. communicans medius, part of the a. poplitea profunda persists as the proximal portion of the *anterior tibial artery*, which crosses the anterior surface of the popliteus muscle. The *posterior tibial artery* is occasionally absent; in such cases the distal part of the embryonic a. peronaea posterior superficialis persists and the peroneal artery, through it, supplies the sole. The *peroneal artery* is constantly present; through the abnormal persistence of the embryonic a. interossea (Hyrtl) or of the a. peronaea posterior superficialis (Barkow, Hyrtl) it may appear to be reduplicated. The distal part of the anterior tibial artery is often small, and may be altogether absent. In such cases the *dorsal artery of the foot* receives its blood-supply through the perforating branch of the peroneal.

The *a. saphena magna* is occasionally present, also the *a. suralis magna*, and either of them may be large enough to take part in the arterial supply of the foot. These arteries do not appear regularly in the embryo; the occurrence of either of them, whether in the embryo or in the adult, appears to afford an example of individual variations.

3. THE SYSTEMIC VEINS

The systemic veins are naturally divided into three groups—(1) the veins of the heart; (2) the vena cava superior and its tributaries, namely the veins of the head, neck, upper extremity, and thorax; and (3) the vena cava inferior and its tributaries, namely, the portal system, and the veins of the abdomen, pelvis, and lower extremity.

I. THE VEINS OF THE HEART

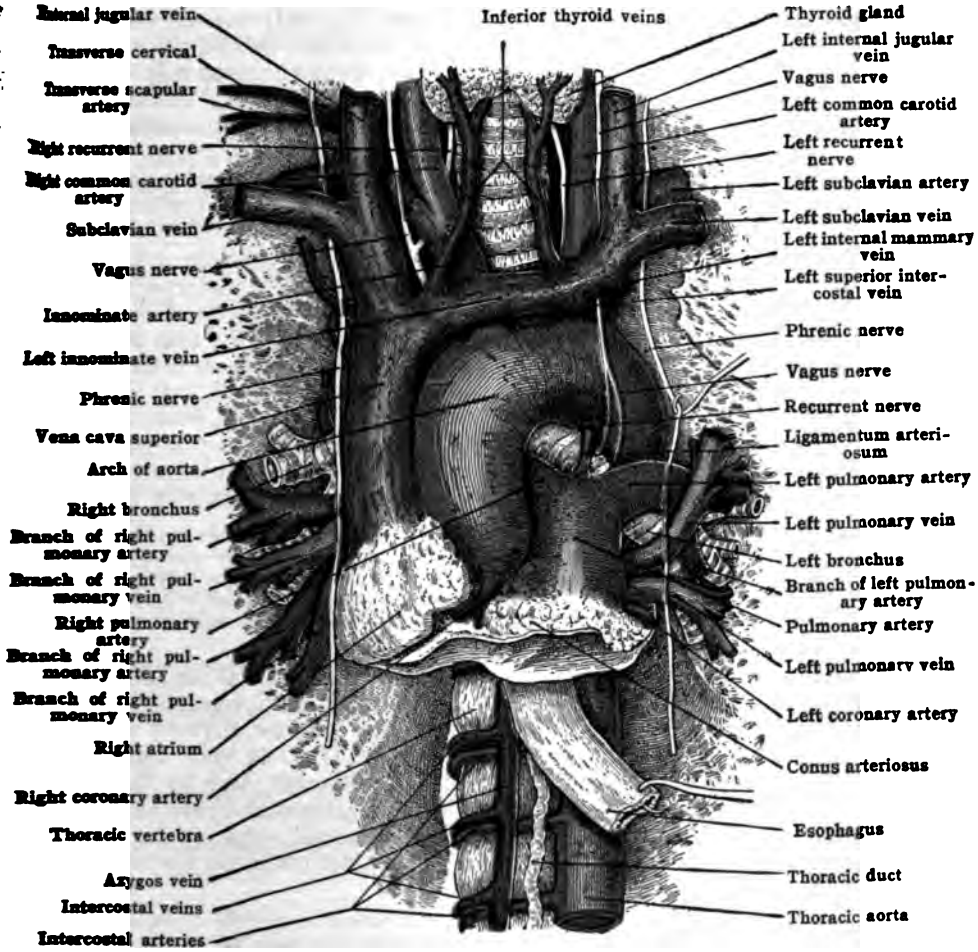
The veins of the heart have already been described (p. 561).

II. THE VENA CAVA SUPERIOR AND ITS TRIBUTARIES

THE VENA CAVA SUPERIOR

The **vena cava superior** (fig. 551) carries to the heart the blood returned from the head and neck and upper extremities through the right and left innominate veins, and from the walls of the thorax, either directly through the azygos vein, or indirectly through the innominate veins. It is formed by the confluence of the right and left innominate veins behind the first right sternochondral

FIG. 551.—THE VENA CAVA SUPERIOR AND THE INNOMINATE VEINS.
(Modified from a dissection in St. Bartholomew's Hospital Museum.)



articulation. Descending from its origin in a gentle curve with its convexity to the right and in a direction slightly backward behind the sternal end of the first and second intercostal spaces and second costal cartilage, it terminates in the right atrium of the heart on a level with the third right costal cartilage in front and the seventh thoracic vertebra behind. It measures about 7 to 8 cm. (3 in.) in length. A little more than its lower half (4 cm.) is contained within the pericardium, the serous layer of that membrane being reflected obliquely over it immediately below the spot where it is joined by the vena azygos, and on a lower level than the reflection of the pericardium on the aorta. The vena cava superior contains no valves.

Relations.—In front, in addition to the first and second intercostal spaces and the second costal cartilage, **it is covered by** the remains of the thymus gland, the intrathoracic fascia, and the pericardium, **and is overlapped** by the right pleura and lung.

Behind are the vena azygos (major), the right bronchus, the right pulmonary artery, and the superior right pulmonary vein; and below, the fibrous layer of the pericardium. The serous layer is reflected over the front and sides of the vessel, but not over its posterior part.

To the **right side** are the right lung and pleura and the phrenic nerve.

To the **left side** are the innominate artery and the ascending aorta.

Tributaries.—In addition to the right and left innominate veins and the vena azygos it receives small veins from the mediastinum and pericardium.

THE INNOMINATE VEINS

The **innominate** veins [vv. anonymæ] return the blood from the head and neck and upper extremity. They are formed on each side by the confluence of the internal jugular and subclavian veins behind the sternal end of the clavicle. They terminate behind the first costal cartilage on the right side by uniting to form the vena cava superior. The innominate veins have no valves.

The **right innominate** vein [v. anonyma dextra] (fig. 551) measures about 2 to 3 cm. (1 to 1½ in.) in length, and descends from its origin behind the sternal end of the clavicle, very slightly forward and medially, along the right side of the subclavian and innominate arteries, to its junction with the left vein behind the first costal cartilage close to the sternum. It is superficial to the innominate artery.

Relations.—**In front** are the origins of the sternohyoid and sternothyroid muscles, the clavicle, the first costal cartilage, and the remains of the thymus gland. **Behind** are the pleura and lung. To the **right** are the right pleura and lung and the phrenic nerve. To the **left** are the right subclavian artery, the innominate artery, the right vagus nerve, and the trachea.

The **left innominate** vein [v. anonyma sinistra] (fig. 551) measures 6 to 7.5 cm. (2½ to 3 in.) in length, and extends from its origin behind the sternal end of the left clavicle obliquely across the three main branches of the arch of the aorta to unite with the right innominate vein behind the cartilage of the first rib close to the sternum to form the vena cava superior. In this course it runs from left to right with an inclination downward and slightly backward. A line drawn obliquely across the upper half of the manubrium of the sternum, from the sternoclavicular articulation on the left side to the lower border of the first costal cartilage at its junction with the sternum on the right side, will indicate its course. The left innominate vein is on a level with the top of the sternum at birth.

Relations.—**In front,** in addition to the manubrium of the sternum, it has the origins of the sternohyoid and sternothyroid muscles, and the remains of the thymus gland, the sternal end of the left clavicle, and the sternoclavicular articulation. **Behind** are the three chief arteries arising from the arch of the aorta, the trachea, and the left phrenic and left vagus nerves. **Below** it is the arch of the aorta. **Above** it are the cervical fascia, the inferior thyroid, and thyroidea ima veins.

Tributaries.—In addition to the internal jugular and subclavian veins, by the confluence of which the innominate veins are formed, each vein receives on its upper aspect the vertebral, the deep cervical, and inferior thyroid veins; and on its lower aspect the internal mammary vein. The left vein, moreover, is joined by the thyroidea ima, the left superior intercostal, and by the thymic, tracheal, esophageal, superior phrenic, anterior mediastinal, and pericardiac veins. At the confluence of the internal jugular and subclavian veins on the right side the three lymphatic trunks or the right lymphatic duct open; on the left side the thoracic duct.

THE VEINS OF THE HEAD AND NECK

The **veins of the head and neck** may be divided for purposes of description into the **superficial,** which return the blood from the external parts of the head and neck; and the **deep,** which return the blood from the deeper structures. All the veins, whether superficial or deep, terminate in the internal jugular or subclavian, or open directly into the innominate veins at the root of the neck. Through the latter all the blood from the head and neck ultimately passes on its way to the heart.

THE SUPERFICIAL VEINS OF THE HEAD AND NECK

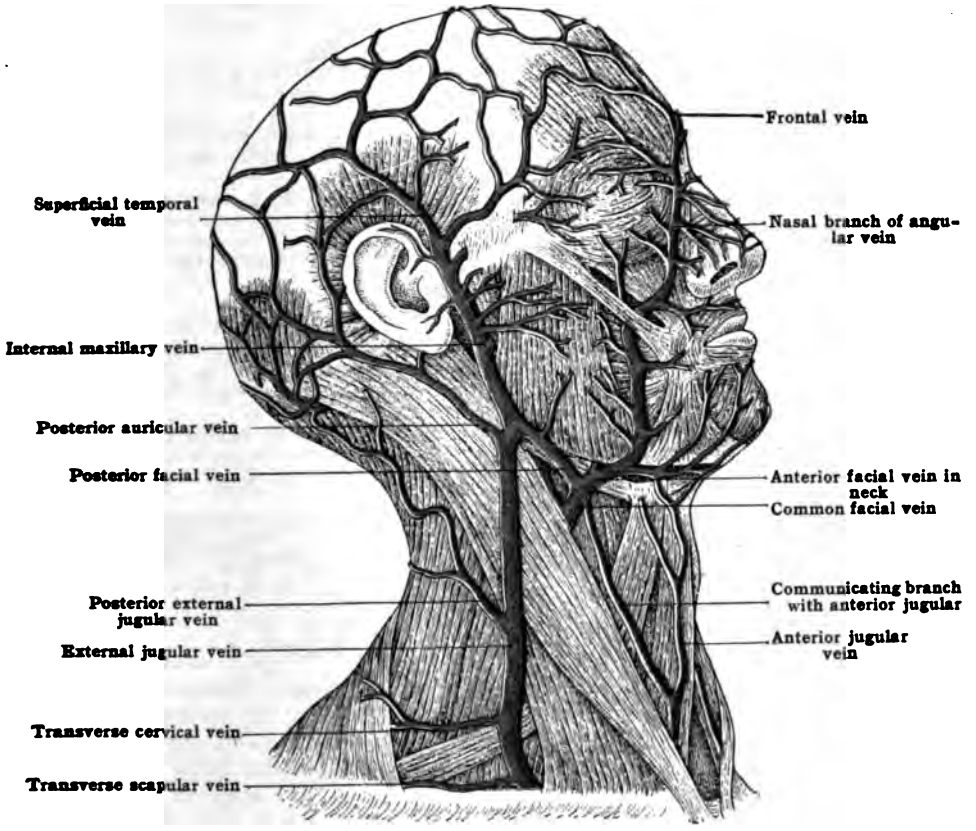
The venous blood from the anterior part of the scalp and integument of the face is returned, through the **anterior and posterior facial veins, to the common**

cial, a tributary of the internal jugular vein. From the posterior part of the **calp and from the integument of the neck venous blood is returned, through the external jugular** and its tributaries, to the subclavian vein.

A. The Anterior Facial Vein

The **anterior facial** vein [v. facialis anterior] (fig. 552) begins a little below the medial end of the eyebrow where it is formed by the union of the frontal and supraorbital veins. It descends near the medial angle of the orbit, and then by the side of the nose to the cheek, which it crosses obliquely, to the anterior edge of the masseter muscle. Thence it passes through the digastric triangle to the upper border of the hyoid bone, where it terminates in the common facial vein. In this course it is reinforced by numerous collateral veins, and gradually increases in size. It has, moreover, numerous communications with the deep veins.

Fig. 552.—The Superficial Veins of the Face and Scalp. (After Quain.)



The portion of this vein above the lower margin of the orbit is called the **angular** [v. angularis]. In the remainder of its course over the face and neck it is termed the **anterior facial** vein.

The angular vein skirts around the medial margin of the orbit, lying with the angular artery on the frontal (nasal) process of the maxillary bone slightly medial to the lacrimal sac. Branches pass from the posterior part of the angular vein into the orbit to join the ophthalmic.

The angular, the facial, and the ophthalmic veins contain no valves. The blood, therefore, can pass either forward from the ophthalmic into the angular, or backward through the facial and angular into the ophthalmic, and so on to the cavernous and other venous sinuses of the cranium.

The anterior facial vein runs in a more or less direct line behind its corresponding artery, the external maxillary (facial), which itself pursues a tortuous course. It usually passes deep to the zygomatic muscle, the zygomatic head of the quadratus labii superioris, and the risorius, but superficial to the other muscles At the anterior edge of the masseter it meets the external maxillary artery, lying

immediately posterior to it. In the neck it lies beneath the platysma and cervical fascia, and is usually separated from the external maxillary artery by the submaxillary gland and the stylohyoid and posterior belly of the digastric muscle, below which it is joined by the posterior facial, to form the **common facial vein**.

Tributaries.—It receives, from above downward:—(a) the frontal vein; (b) the supraorbital vein; (c) the superior palpebral veins; (d) the external nasal veins; (e) the inferior palpebral veins; (f) the superior labial vein (g) the inferior labial vein; (h) the masseteric veins; (i) the anterior parotid veins; (j) the palatine vein and (k) the submental vein.

(a) The **frontal** vein [v. frontalis] (figs. 552, 562) begins about the level of the coronal suture in a venous plexus which communicates with the anterior division of the temporal vein. Soon forming a single trunk, it passes vertically downward over the frontal bone, a short distance from the middle line and parallel with its fellow of the opposite side, to the medial end of the eyebrow where it terminates in the angular vein.

(b) The **supraorbital** vein [v. supraorbitalis] begins over the frontal eminence by intercommunication with the middle temporal vein. It receives tributaries from the forehead and eyebrow, and, running obliquely, medially and downward, opens into the termination of the frontal vein to form the angular. It communicates with the ophthalmic vein, and receives the frontal vein of the diploë as the latter vein issues from the bone at the bottom of the supraorbital notch.

(c) The **superior palpebral** veins [vv. palpebrales superiores] arise in the upper eyelid and open into the lateral side of the angular vein. They communicate with the middle temporal vein.

(d) The **external nasal** veins [vv. nasales externæ] form three or four stems on either side. The upper veins run upward into the angular and the lower, from the ala, pass more horizontally into the anterior facial vein.

(e) The **inferior palpebral** veins [vv. palpebrales inferiores] arise in the lower eyelid, and, passing medially and downward over the cheek from which they receive tributaries, open into the lateral side of the anterior facial vein. They communicate with the infraorbital vein.

(f) The **superior labial** vein [v. labialis superior] and (g) the **inferior labial** vein [v. labialis inferior] arise from venous plexuses in the upper and lower lips. They run laterally to open into the medial side of the facial vein.

(h) The **masseteric** veins [vv. massetericæ] and (i) the **anterior parotid** veins [vv. parotidæ anteriores], of small size, drain the cheek over the masseteric and parotid regions.

(j) The **palatine** vein [v. palatina] accompanies the ascending palatine or tonsillar artery from the venous plexus about the tonsil and soft palate, and joins the anterior facial vein just below the body of the mandible.

(k) The **submental** vein [v. submentalis] lies on the mylohyoid muscle superficial to the submental artery. Running back in the submental triangle, it joins the anterior facial vein just after the latter has passed over the body of the mandible. It communicates with the anterior jugular vein.

Communications.—The tributaries of the anterior facial vein communicate freely with the anterior and middle temporal, ophthalmic, infraorbital and anterior jugular veins. The main trunk has a large communicating branch with the pterygoid plexus. This vein, sometimes known as the deep facial, opens into the anterior facial below the zygomatic bone under cover of the zygomaticus muscle.

B. The Posterior Facial Vein

The **posterior facial** (temporomaxillary) vein [v. facialis posterior] (figs. 552, 562) is formed in the region of the root of the zygoma by the union of the superficial and middle temporal veins. It passes downward behind the ramus of the mandible through the substance of the parotid gland—here lying lateral to the superficial temporal and external carotid arteries. At the angle of the mandible it runs medially and somewhat forward, and, passing either deep or superficial to the stylohyoid and digastric muscles, joins the anterior facial to form the common facial vein.

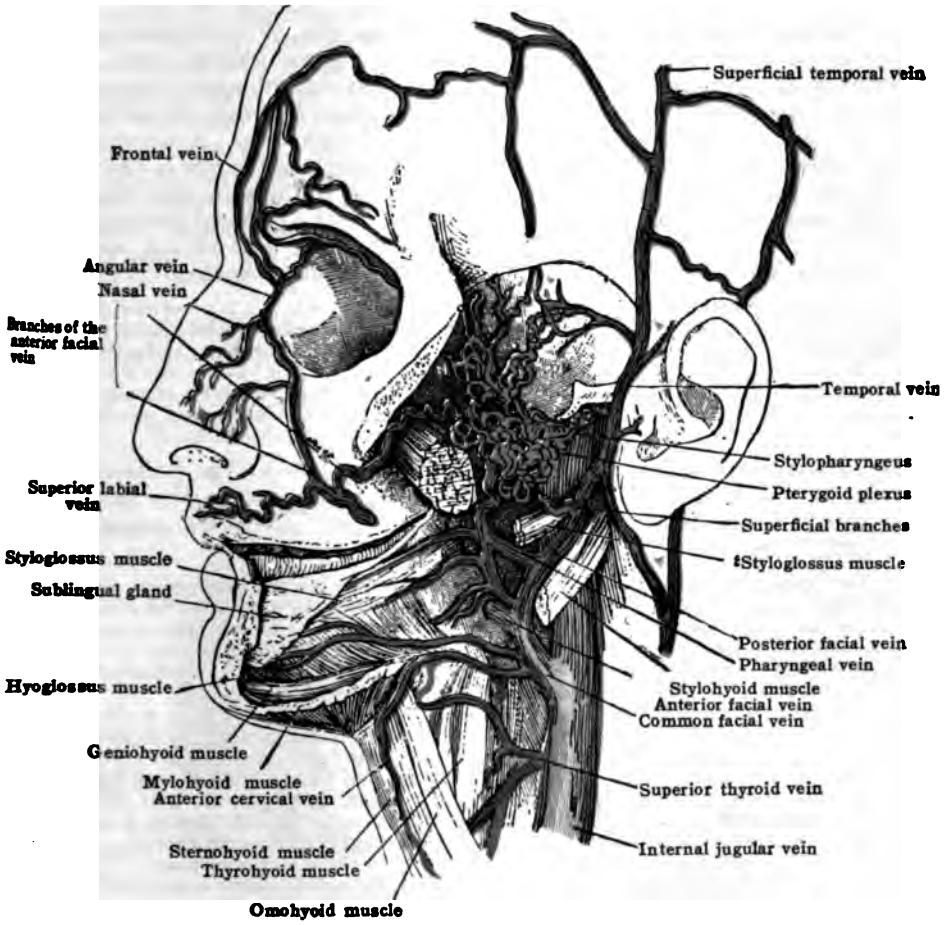
The **tributaries** received by the posterior facial vein are:—(a) the superficial temporal veins; (b) the middle temporal vein; (c) the transverse facial vein; (d) the articular veins; (e) the posterior parotid veins; (f) the anterior auricular veins; (g) the stylomastoid vein; and (h) the internal maxillary vein through which occurs the principal drainage of the pterygoid plexus.

(a) The **superficial temporal** vein [v. temporalis superficialis] returns the blood from the parietal region of the scalp. It is formed by the union of an anterior and a posterior branch: the former communicates with the supraorbital and frontal veins; the latter with the posterior auricular and occipital veins and the temporal vein of the opposite side. These branches lie superficial to the corresponding branches of the superficial temporal artery, which they roughly though not accurately follow. Like the artery, they lie between the skin and the galea aponeurotica, and descend over the temporal fascia to unite a little above the zygoma, and just in front of the auricle, to form the superficial temporal trunk. The vein thus formed continues its course downward with the trunk of the temporal artery, and opposite the zygoma is joined by the middle temporal vein to form the common temporal vein.

(b) **The middle temporal** vein [v. temporalis media] corresponds to the orbital branch of the temporal artery, and communicates in front with the ophthalmic vein, the external palpebral veins, and the infraorbital veins, and then runs backward between the layers of the temporal fascia to join the superficial temporal vein. The middle temporal vein communicates with the deep temporal veins, and through them with the pterygoid venous plexus.

(c) **The transverse facial** vein [v. transversa faciei] corresponds to the transverse facial artery. (d) **Articular** veins [vv. articulares mandibulæ] form the plexus around the temporomandibular joint; this plexus receives the **tympanic** veins [vv. tympanicæ], which, together with the corresponding artery, passes through the petrotympanic fissure. (e) **Posterior parotid** veins [vv. parotideæ posteriores] emerge from the substance of the parotid gland. (f) **Anterior auricular** veins [vv. auriculares anteriores], from the auricle. (g) **Stylomastoid** vein [v. stylomastoidea] from the facial canal. (h) The **internal maxillary** vein accompanies the first part of the internal maxillary artery. It begins at the posterior confluence of the veins forming the pterygoid pelxus, and passes backward between the stylomandibular ligament and the neck of the mandible. It ends by joining the posterior facial vein.

FIG. 553.—THE INTERNAL JUGULAR VEIN. (After Henle.)



The pterygoid plexus [plexus pterygoideus] is formed by the veins which correspond to the branches of the internal maxillary artery. It is situated, partly on the medial surface of the internal pterygoid muscle, and partly around the external pterygoid muscle. The veins entering into this plexus are:—the two **middle meningeal** veins [vv. meningeæ mediæ], which accompany the artery of that name; the **posterior superior alveolar** (dental); the **inferior alveolar** (dental); the **masseteric; the buccal;** the pterygoid veins from the pterygoid muscles; the **deep temporal** veins [vv. temporales profundæ], by which the plexus communicates with the temporal plexus; the **sphenopalatine** vein; the **infraorbital;** the **superior palatine;** a branch of communication with the lower branch of the **ophthalmic** vein, which courses through the inferior orbital (sphenomaxillary) fissure; and the **rete foraminis ovalis** and **Vesalian** vein, through which the plexus communicates with the cavernous sinus. The plexus ends posteriorly in the internal maxillary vein, which joins the posterior facial vein, and anteriorly in a communicating vessel (the deep facial vein), which passes forward and downward between the buccinator and masseter muscles to join the anterior facial vein.

The above-mentioned veins, forming by their confluence the pterygoid plexus correspond in their course so nearly with that of their companion arteries that a detailed description is not

necessary. Although for convenience described with the superficial veins, they are all deeply placed.

Near the angle of the mandible there is almost always a communicating branch between the posterior facial and the external jugular veins. When large, this branch may drain the greater part of the blood from the posterior facial.

C. The Common Facial Vein

The **common facial** vein [v. facialis communis] (fig. 552) is a short thick stem contained within the carotid triangle. It is formed, just below the angle of the mandible, by the union of the anterior and posterior facial veins. It ends opposite the hyoid bone, by opening into the internal jugular vein. In addition to the vessels which form it, sometimes it receives the superior thyroid, the pharyngeal, and the lingual or the sublingual veins.

D. The External Jugular Vein

The **external jugular** vein [v. jugularis externa] (fig. 52) is formed by the confluence of the posterior auricular and a short communicating trunk from the posterior facial near the angle of the mandible. It runs obliquely downward and backward across the sternomastoid muscle to a point opposite the middle of the clavicle, where it terminates as a rule in the subclavian vein. A line drawn from a point midway between the mastoid process and angle of the jaw to the middle of the clavicle will indicate its course. It is covered by the skin, superficial fascia, and platysma, and is crossed by a few branches of the cervical plexus, the great auricular nerve running parallel with it at the upper part of the neck. It is separated from the sternomastoid by the anterior layer of the deep cervical fascia.

Just above the clavicle it perforates the cervical fascia, by which it is prevented from readily collapsing, the fascia being attached to its walls. It then opens into the subclavian vein, occasionally into the internal jugular, or into the confluence of the subclavian and internal jugular veins. It contains a pair of valves about 2.5 to 5 cm. (1 to 2 in.) above the clavicle, and a second pair where it enters the subclavian vein. Neither of these valves is sufficient to prevent the blood from regurgitating, or injections from passing from the larger vein into the external jugular.

Tributaries and communications.—These include:—(a) The posterior auricular vein; (b) the occipital vein; (c) a branch of communication with the posterior facial vein; (d) the posterior external jugular vein; (e) the transverse scapular vein; and (f) the anterior jugular vein.

(*a*) The **posterior auricular** vein [v. auricularis posterior] begins in a venous plexus on the posterior part of the parietal bone. This plexus communicates with the vein of the opposite side across the sagittal suture, and with the posterior branch of the superficial temporal vein in front, and with the occipital vein behind. It descends over the back part of the parietal bone and the mastoid process of the temporal bone, lying with its artery behind the ear, and joins a branch from the posterior facial vein to form the external jugular.

(*b*) The **occipital** vein [v. occipitalis] begins at the back of the skull in a venous plexus which anastomoses with the posterior auricular and the posterior branch of the superficial temporal veins. It passes downward over the occipital bone, and usually perforates the trapezius with the occipital artery, to join a plexus drained by the deep cervical and vertebral veins. It also communicates with the posterior auricular, and in many cases this forms the chief path of drainage. One of its branches, usually the most lateral, receives a mastoid emissary vein [emissarium mastoideum] which issues through the mastoid foramen of the temporal bone, and in this way forms a communication with the transverse sinus.

(*c*) The branch of **communication with the posterior facial** vein occurs a short distance below the point at which the posterior facial receives the internal maxillary vein. It is very constant and is placed immediately behind the angle of the mandible. Through it the external jugular usually receives a considerable proportion of the blood returning from the temporal and pterygoid regions.

(*d*) The **posterior external jugular** vein (fig. 552) descends from the upper and back part of the neck, receiving small tributaries from the superficial structures and muscles. At times it communicates with the occipital, or may appear as a continuation of that vein. It opens into the external jugular as the latter vein is leaving the sternomastoid muscle.

(*e*) The **transverse scapular** vein [v. transversa scapulæ] corresponds to the transverse scapular (suprascapular) artery. If double, these venæ comitantes usually form one trunk before they open into the external jugular vein. They contain well-marked valves.

(*f*) The **anterior jugular vein** [v. jugularis anterior] begins below the chin by communicating with the mental, submental, inferior labial, and inferior hyoid veins. It descends a little lateral to the middle line, receiving branches from the superficial structures at the front and side of the neck, and occasionally a branch from the larynx and thyroid body. Just above the clavicle it turns laterally, and, piercing the fascia, passes beneath the sternomastoid muscle and opens into the external jugular vein just before the latter joins the subclavian; at times it opens into the subclavian vein itself. In its course down the neck it communicates with the

external jugular; and, as it turns laterally beneath the sternomastoid, sends a branch across the trachea, between the layers of cervical fascia, to join the anterior jugular of the opposite side. This communicating vein, the **jugular venous arch** [arcus venosus juguli], may open directly into the external jugular or into the internal jugular vein; occasionally one or both ends may open into the subclavian or innominate vein. It may be divided in the operation of tracheotomy, and is then often found greatly engorged with blood. Another branch, often of considerable size, courses along the anterior margin of the sternomastoid and joins the anterior facial vein. When the anterior jugular vein is large, the external jugular is small, and *vice versa*. It is usually also of large size when the corresponding vein on the opposite side is absent, as is frequently the case. It contains no valves.

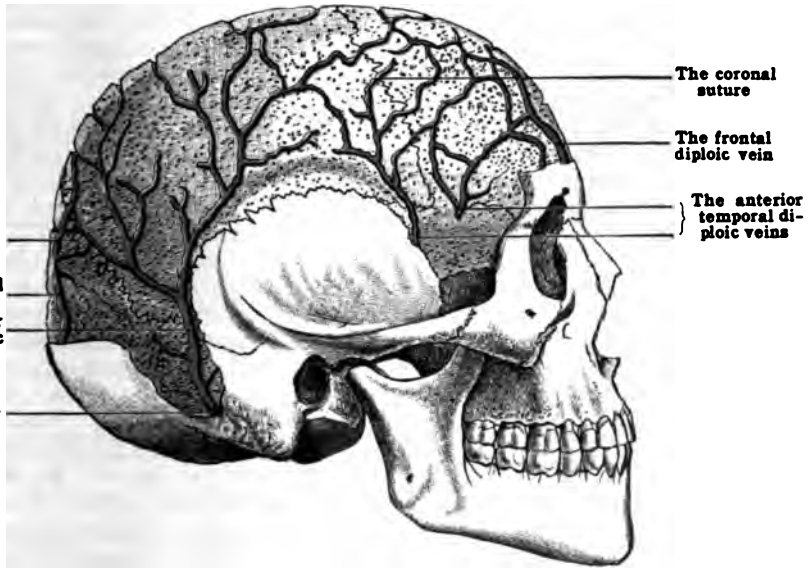
THE DEEP VEINS OF THE HEAD AND NECK

The **deep veins of the head and neck** may be divided into:—(1) the veins of the diploë; (2) the venous sinuses of the dura mater encephali; (3) the veins of the brain; (4) the veins of the nasal cavities; (5) the veins of the ear; (6) the veins of the orbit; (7) the veins of the pharynx and larynx; and (8) the deep veins of the neck. The veins of the diploë terminate partly in the superficial veins already described, partly in the venous sinuses of the cranium, and partly in the deep veins of the neck. The venous sinuses open into the deep veins of the neck. The veins of the brain terminate in the venous sinuses. The veins of the nasal cavities terminate partly in the deep, and to some extent in the superficial veins. The veins of the ear join both the superficial and deep veins and the venous sinuses. The veins of the orbit terminate partly in the superficial veins, but chiefly in the venous sinuses. The veins of the pharynx and larynx enter the deep veins of the neck.

1. THE VEINS OF THE DIPLOË

The **veins of the diploë** [venæ diploicæ] (fig. 554) are contained in bony channels in the cancellous tissue between the external and internal laminæ of the

FIG. 554.—THE VEINS OF THE DIPLOË
(From a specimen in St. Bartholomew's Hospital Museum).



cranium. They are of comparatively large size, with very thin and imperfect walls, and form numerous irregular communicating channels. They have no valves. They terminate in four or five main and descending channels, which open, some outward through the external cranial lamina into some of the superficial and deep veins of the head and face, and some inward through the internal lamina into the venous sinuses. They are divided into the frontal, anterior temporal, posterior temporal, and occipital.

The **frontal diploic veins** are contained in the anterior part of the frontal bone. They converge anteriorly to a single vein [v. diploica frontalis] which passes downward, perforates the

external table through a small aperture in the roof of the supraorbital notch, and terminates in the supraorbital vein. They also communicate with the superior sagittal sinus.

The **anterior temporal diploic veins** [v. diploica temporalis ant.] are contained in the posterior part of the frontal and in the anterior part of the parietal bone. They pass downward, and end, partly in the temporal veins by perforating the greater wing of the sphenoid bone, and partly in the sphenoparietal sinus.

The **posterior temporal diploic vein** [v. diploica temporalis post.] ramifies in the parietal bone, and coursing downward to the posterior inferior angle of that bone, passes either through a foramen in its inner table, or through the mastoid foramen into the transverse sinus.

The **occipital diploic vein** [v. diploica occipitalis] ramifies chiefly in the occipital bone, and opens into the occipital vein or into the transverse sinus.

The diploic veins freely anastomose with one another in the adult; but in the fetus, before the bones have united, each system of veins is distinct.

2. THE VENOUS SINUSES OF THE DURA MATER

The **venous sinuses of the dura mater** [sinus duræ matris] are endothelial-lined blood-spaces, situated between the periosteal and meningeal layers of the dura mater. They are the channels by which the blood is conveyed from the cerebral veins, and from some of the veins of the meninges and diploë, into the veins of the neck. The sinuses at the base of the skull also carry the chief part of the blood from the orbit and eyeball to the jugular veins. In certain places the sinuses communicate with the superficial veins by small vessels known as the emissary veins, which run through foramina in the cranial bones.

The venous sinuses are sixteen in number, six being median and unpaired, the remaining ten consisting of five lateral pairs. The median sinuses are:—(1) the superior sagittal; (2) the inferior sagittal; (3) the straight; (4) the occipital; (5) the circular; and (6) the basilar plexus. The lateral and paired sinuses are:—(7) the two transverse; (8) the two superior petrosal; (9) the two inferior petrosal; (10) the two cavernous; and (11) the two sphenoparietal. Occasionally there are two additional sinuses, the two petrosquamous.

(1) The **superior sagittal** (or longitudinal) **sinus** [sinus sagittalis superior] (fig. 556) lies in the median groove on the inner surface of the cranium along the attached margin of the falx cerebri. It extends from the foramen cecum to the internal occipital protuberance. It grooves from before backward the frontal bone, the contiguous sagittal margins of the parietal bones, and the squamous portion of the occipital bone. In the fetus, and occasionally in the adult, it communicates (through the foramen cecum) with the nasal veins. It communicates throughout life with each superficial temporal vein by means of a **parietal emissary** vein [emissarium parietale] which passes through the parietal foramen. It is triangular on section, the base of the triangle corresponding to the bone. Crossing it are a number of fibrous bands known as the *chords of Willis*, and projecting into it in places are the arachnoidal (Pacchionian) granulations. The parts of the sinus into which the arachnoidal granulations project are irregular lateral diverticula from the main channel known as the *lacunæ laterales* (fig. 558). In front the sinus is quite small, but it increases greatly in caliber as it runs backward. It receives at intervals the superior cortical cerebral veins and the veins from the falx. The former, for the most part, open into it in the direction opposite to that in which the blood is flowing in the sinus. They pass for some distance in the walls of the sinus before opening into it. Posteriorly, at the internal occipital protuberance, the superior sagittal sinus usually turns sharply to the right, and ends in the right transverse (lateral) sinus. In such cases the straight sinus usually terminates in the left transverse (lateral) sinus.

Occasionally, however, the superior sagittal sinus ends in the left transverse sinus, the straight then passing into the right. At the angle of union between the superior sagittal sinus and the transverse sinus into which it empties there is a dilation, the **confluens sinuum** or torcular Herophili. At this point there is a communication between the right and left transverse sinuses. In some cases the communication is so free that the blood from the sagittal sinus flows almost equally into each transverse sinus. The confluens may communicate with the occipital vein through the occipital emissary vein [emissarium occipitale], which, when present passes through a minute foramen in the occipital protuberance.

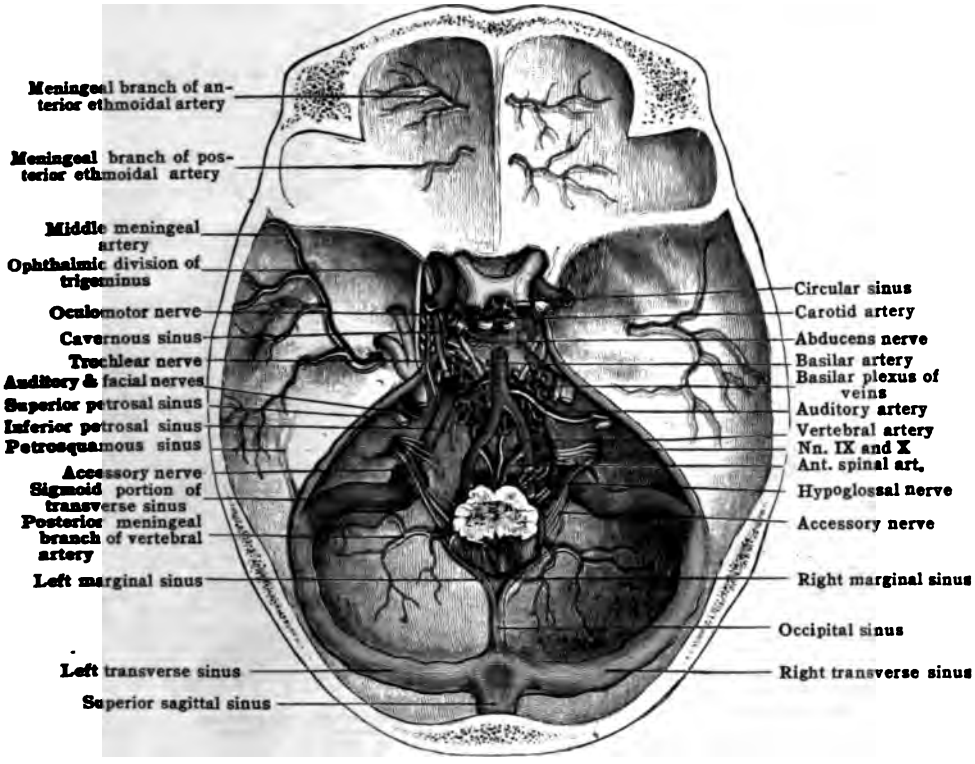
(2) The **inferior sagittal** (or longitudinal) **sinus** [sinus sagittalis inferior] (fig. 556) is situated at the free margin of the falx cerebri. Beginning about the junction of the anterior with the middle third of the falx, it is continued backward along the concave or lower margin of that process to the junction of the falx with the tentorium, where it ends in the straight sinus. The sinus is cylindrical in

shape and of small size, and receives some of the inferior frontal veins of the brain, some of the veins from the medial surface of the brain, and some of the veins of the falx.

(3) The **straight sinus** [sinus rectus] (fig. 556) lies along the junction of the falx cerebri with the tentorium cerebelli. It is formed by the union of the great cerebral vein (of Galen) and the inferior sagittal sinus. It receives in its course branches from the tentorium cerebelli and from the upper surface of the cerebellum. It runs downward and backward to the internal occipital protuberance, where it ends in the transverse sinus opposite to that joined by the superior sagittal sinus. On section it is triangular in shape, with its apex upward.

(4) The **occipital sinus** [sinus occipitalis] (fig. 555) ascends at the attached margin of the falx cerebelli, along the lower half of the squamous portion of the occipital bone from near the posterior margin of the foramen magnum to the internal occipital protuberance. It usually begins in a right and a left branch, known as the **marginal sinuses.**

FIG. 555.—THE VENOUS SINUSES IN THE CRANIAL FLOOR
(From a dissection by W.J. Walsham in St. Bartholomew's Hospital Museum)



These proceed from the termination of each transverse sinus, run around the foramen magnum where they communicate with the venous vertebral retia, and unite at a variable distance from the internal occipital protuberance to form the single occipital sinus. Sometimes they remain separate as far as the occipital protuberance, then forming two occipital sinuses. At the point where the marginal sinuses unite to form the single occipital sinus, there is a communication with the venous vertebral retia. The occipital sinus ends in the confluens sinuum. It receives in its course veins from the tentorium cerebelli, and from the inferior surface of the cerebellum. It communicates through the plexus of veins which surrounds the hypoglossal nerve [**rete canalis hypoglossi**] in the hypoglossal (anterior condyloid) canal with the vertebral vein and the longitudinal vertebral venous sinuses.

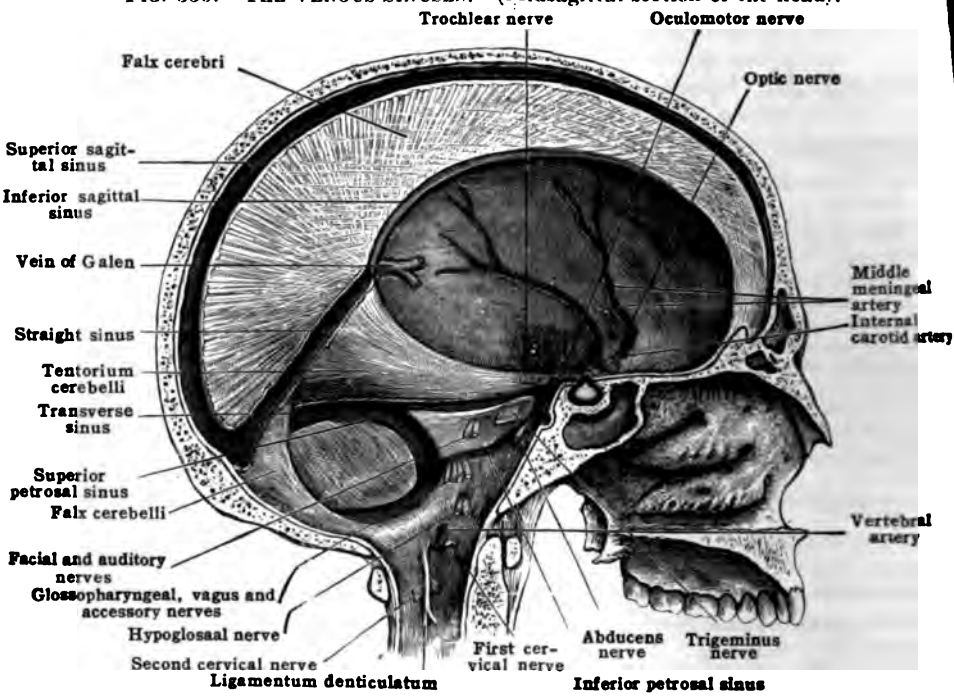
(5) The **circular sinus** [sinus circularis] (fig. 557) encircles the hypophysis cerebri. It consists of the two cavernous sinuses and their communications across the median line by means of the **anterior and posterior intercavernous sinuses.** The intercavernous sinuses are small and cross the median line in front of and behind the hypophysis, respectively.

(6) The **basilar plexus** [plexus basilaris] is a venous plexus in the substance of the dura mater over the basilar part of the occipital bone. It extends from

the cavernous sinus to the margin of the foramen magnum below. It communicates laterally with the inferior petrosal sinus, and inferiorly with the internal vertebral venous plexuses. One of the larger of the irregular venous channels forming the plexus passes transversely from one inferior petrosal sinus to the other. This venous plexus is serially homologous with the longitudinal vertebral venous sinuses on the posterior surfaces of the bodies of the vertebræ.

(7) The **transverse** (or lateral) **sinus** [sinus transversus] (figs. 555–557) extends from the internal occipital protuberance to the jugular foramen. In this course it lies in the corresponding groove along the squamous portion of the occipital bone, the mastoid angle of the parietal bone, the mastoid portion of the temporal bone, and the jugular process of the occipital bone. It at first runs laterally and forward horizontally between the two layers of the tentorium cerebelli, following the curve of the groove on the occipital and on the mastoid angle of the parietal bone. On reaching the groove in the mastoid portion of the temporal bone it leaves the tentorium and curves medially and downward and then forward over the jugular process of the occipital bone, and ends at the jugular fossa in the superior bulb of the internal jugular vein. The S-shaped part of the sinus which lies on the mastoid portion of the temporal and jugular portion of the occipital bone is sometimes known as the **sigmoid sinus.**

FIG. 556.—THE VENOUS SINUSES. (Midsagittal section of the head).



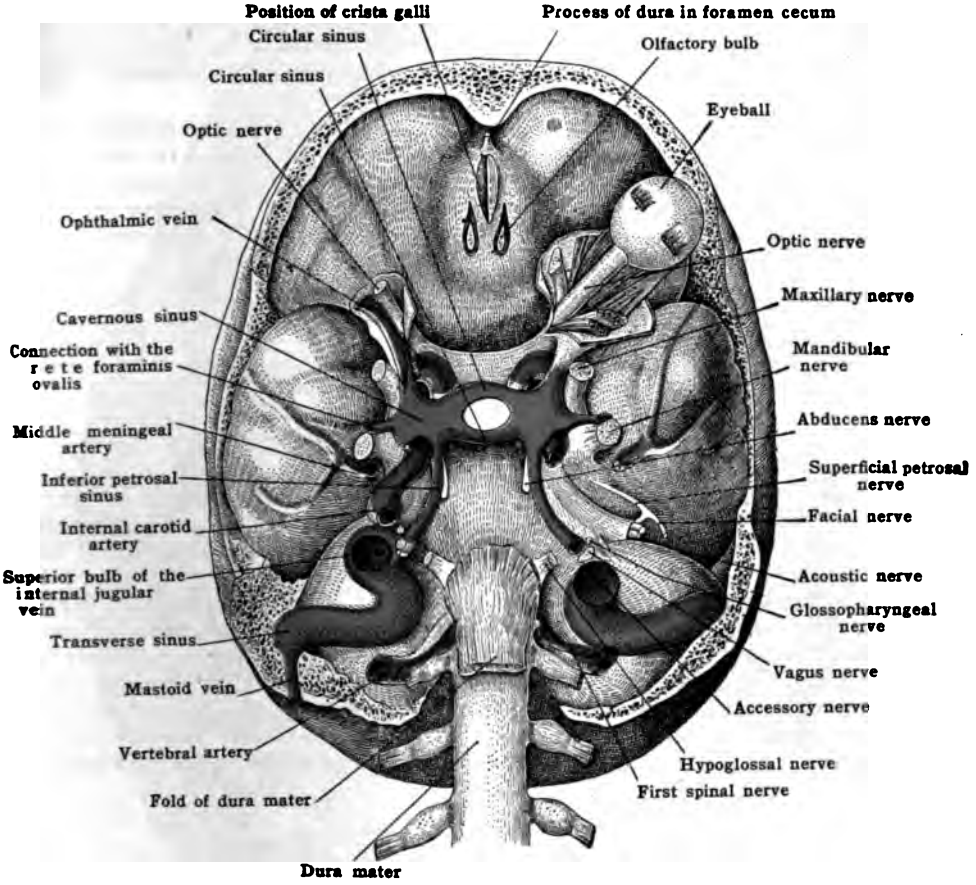
The transverse sinus receives from the labyrinth, the **internal auditory veins** [vv. auditivæ internæ] which emerge from the internal auditory meatus. It also receives veins from the temporal lobe of the cerebrum, some of the superior and inferior cerebellar veins, some of the veins of the medulla and pons, the occipital, and the posterior temporal and occipital veins of the diploë. At the point where it leaves the tentorium it drains the superior petrosal sinus and, when present, the petrosquamous sinus. It communicates with the occipital and vertebral veins through the mastoid and posterior condyloid foramina by means of the mastoid and condyloid emissary veins. As the transverse sinus lies between the layers of the tentorium it is on section prismatic in shape. The sigmoid portion is semicylindrical.

The right transverse sinus is usually the larger and the direct continuation of the superior sagittal sinus, and hence conveys the chief part of the blood from the cortical surface of the brain and vault of the skull. The left transverse sinus is usually the smaller and the direct continuation of the straight sinus, and hence returns the chief part of the blood from the central ganglia of the brain. The right and left sinuses communicate opposite the internal occipital protuberance.

The relation of the lateral sinus to the outside of the skull, especially to the mastoid process of the temporal bone, is of importance with reference to operations in this region. The course of the sinus corresponds to a line drawn from the external occipital protuberance to the base of the mastoid process, or to the asterion, and thence over the back of the mastoid process in a curved line toward its apex.

(8) The **superior petrosal sinus** [sinus petrosus superior] (figs. 555, 556) runs at the attached margin of the tentorium cerebelli, along the upper border of the petrous portion of the temporal bone. It connects the cavernous with the transverse sinus. Leaving the lateral and back part of the cavernous sinus just below the trochlear nerve, it crosses the trigeminus nerve, and, after grooving the petrous bone, ends in the transverse sinus as the latter turns downward on the mastoid portion of the temporal bone. It receives veins from the temporal lobe of the cerebrum, veins from the cerebellum, veins from the tympanum through the squamopetrosal fissure, and sometimes the anterior temporal veins of the diploë.

FIG. 557.—THE VENOUS SINUSES AT THE BASE OF THE BRAIN. The dura mater has not been removed. (After Toldt, 'Atlas of Human Anatomy', Rebman, London and New York).



(9) The **inferior petrosal sinus** [sinus petrosus inferior] (figs. 555–557) runs posteriorly from the cavernous sinus along the line of the petro-occipital suture, and passes through the jugular foramen to terminate in the commencement of the internal jugular vein. It is shorter than the superior petrosal, but considerably wider.

As it crosses the anterior compartment of the jugular foramen, it separates the glossopharyngeal from the vagus and accessory nerves. It receives veins from the inferior surface of the cerebellum, from the medulla and pons, and from the internal ear. The **vein of the cochlear canaliculus** [v. canaliculi cochleæ], issues through the canaliculus cochleæ and terminates in the lower part of the inferior petrosal sinus or the adjacent part of the internal jugular vein.

(10) **The cavernous sinus** [sinus cavernosus] (fig. 557) is an irregularly shaped venous space situated between the meningeal and periosteal layers of the dura mater on the side of the body of the sphenoid bone. It extends from the medial end of the superior orbital (sphenoidal) fissure in front to the apex of the petrous bone behind. Its lateral wall is the more distinct, and contains the oculomotor

and trochlear nerves, and the ophthalmic division of the trigeminus. The nerves take the above-mentioned order from above downward, and in the mediolateral direction. The internal carotid artery and the abducens nerve also pass through the sinus, being separated from the blood by the endothelial lining. The right and left cavernous sinuses communicate across the middle line with the opposite sinus in front and behind the hypophysis cerebri as before mentioned.

The cavernous sinus is traversed by numerous trabeculæ or fibrous bands, so that there is no central space, but rather a number of endothelial-lined irregular lacunar cavities communicating one another. Hence its name cavernous, from its resemblance to cavernous tissue. **In front** it receives the ophthalmic vein, with which it is practically continuous, and just above the third nerve, the sphenoparietal sinus. **Medially** it communicates with the opposite sinus, and **posteriorly** it ends in the superior and inferior petrosal sinuses. It also receives veins from the inferior surface of the frontal lobe of the brain, and some of the middle cerebral veins. Through the Vesalian vein, which occasionally perforates the greater wing of the sphenoid bone the sinus communicates with the pterygoid plexus of veins; through the **venous plexus around the petrosal portion of the internal carotid** [plexus venosus caroticus internus], with the internal jugular vein; and through a venous rete which leaves the cranium by the foramen ovale [rete foraminis ovalis] and by small veins passing through the foramen lacerum medium, with the pterygoid and pharyngeal plexuses.

(11) The **sphenoparietal sinus** [sinus sphenoparietalis] runs in a slight groove on the inferior surface of the lesser wing of the sphenoid bone. It originates in one of the meningeal veins near the apex of the lesser wing, and, running medially, passes through the sphenoidal fold of dura mater above the oculomotor nerve into the front part of the cavernous sinus. It generally receives the anterior temporal veins from the diploë.

The **petrosquamous sinus** is occasionally present. It lies in a groove which separates the anterior surface of the petrous from the cerebral surface of the squamous portion of the temporal bone. It opens posteriorly into the transverse sinus at the spot where the latter enters on its sigmoid course. In front it sometimes communicates, through a foramen between the mandibular fossa and the external acoustic meatus, with the deep temporal vein.

3. THE VEINS OF THE BRAIN

The **veins of the brain** present the following peculiarities:—(*a*) They do not accompany the cerebral arteries. (*b*) Ascending veins do not, as in other situations, run with descending arteries, but with ascending arteries, and *vice versa*. (*c*) The deep veins do not freely communicate. (*d*) The veins have very thin walls, no muscular coat, and no valves. (*e*) The veins opening into the sagittal and some of those opening into the transverse (lateral) sinus pour in their blood in a direction opposite to the current in the sinuses, so impeding the flow in both vein and sinus. (*f*) The flow of blood in the sinuses is further retarded by the trabeculæ stretching across their lumen, and in the sagittal sinus by the blood having to ascend, when the body is erect, through the anterior half of its course.

The veins of the brain may be divided into the **cerebral** and the **cerebellar.**

The Cerebral Veins

The **cerebral** veins, like the cerebral arteries, may be divided into the **cortical** and the **central.**

The **cortical** or **superficial** veins ramify on the surface of the brain and return the blood from the cortical substance into the venous sinuses. They lie for the most part in the sulci between the gyri, but some pass over the gyri from one sulcus to another. They consist of two sets: a superior and an inferior.

(1) The **superior cerebral** veins [venæ cerebri superiores] (fig. 558), some eight to twelve in number on each side, are formed by the union of branches from the convex and medial surfaces of the cerebrum. Those from the convex surface pass medially and forward toward the longitudinal fissure, where they are joined by the branches coming from the medial surface. After receiving a sheath from the arachnoid, they enter obliquely into the superior sagittal sinus, running for some distance in its walls. These veins freely communicate with each other, thus differing from the cortical arteries. They also communicate, with the inferior cortical veins. They may be roughly divided into (*a*) frontal; (*b*) paracentral; (*c*) central; (*d*) occipital.

(2) The **inferior cerebral** veins [venæ cerebri inferiores] (fig. 559), ramify on the base of the hemisphere and the lower part of its lateral surface. Those on the inferior surface of the frontal lobe pass, in part into the inferior sagittal sinus, and in part into the cavernous sinus. Those on the temporal lobe enter in part into the superior petrosal sinus, and in part into the transverse sinus, passing into the latter from before backward. A large vein from the occipital

winds over the cerebral peduncle and joins the great cerebral vein (of Galen) just before latter enters the straight sinus. One of the inferior cortical veins is called the **middle eral vein** [v. cerebi media], it runs in the lateral fissure (of Sylvius) and ends in the cavernous sinus. This vein is sometimes called the superficial Sylvian vein. Another, the great anastomosing vein of Trolard, establishes a communication between the superior sagittal and cavernous sinuses by connecting the middle cerebral veins with one of the superior cerebral veins. A second anastomotic vein, that of Labbé, is also a tributary of the middle cerebral, and connects the veins over the temporal lobe with the transverse sinus.

The small inferior cerebral vein, the **ophthalmomeningeal vein**, establishes a communication between the cerebral veins and those of the orbit. It communicates with the veins of the base

usually drained by the superior ophthalmic vein. It occasionally opens into the superior **al sinus.**

he central or deep (ganglionic) veins return blood from the internal parts of erebrum, and converge to the great cerebral vein.

The internal cerebral veins [vv. cerebri internæ] are two large venous trunks (the venæ i) which leave the brain at the transverse fissure, that is, between the splenium of the **callosum** and the corpora quadrigemina. In this region they unite to form the **great al vein** [v. cerebri magna, Galeni], which opens into the anterior end of the straight

The internal cerebral veins are formed by the union of the choroid vein with the vena

terminalis near the interventricular foramen. From this spot they run backward parallel to each other, between the layers of the tela chorioidea, and terminate in the way above mentioned.

Tributaries of the internal cerebral veins.—In addition to the vena terminalis and the chorioidal, the internal cerebral veins also receive the basal vein, the veins of the thalamus, the veins of the choroid plexus of the third ventricle, and veins from the corpus callosum, the pineal body, the corpora quadrigemina, and posterior horn of the lateral ventricle. The united trunk or great cerebral vein, receives veins from the upper surface of the cerebellum, and one of the posterior inferior cerebral veins.

The **choroid** vein [v. chorioidea] runs with the chorioid plexus. It begins in the inferior cornu of the lateral ventricle, and ascends on the lateral side of the chorioid plexus along the margin of the tela chorioidea to the interventricular foramen, where it unites with the vena terminalis to form the internal cerebral vein. It receives tributaries from the hippocampus, corpus callosum, and fornix.

Opening of the straight sinus into the left transverse sinus
Occipital sinus

The **terminal** vein (or vein of the corpus striatum) [v. terminalis], formed by veins from corpus striatum and thalamus, runs forward in the groove between those structures, passes in its course beneath the stria terminalis, and joins the chorioid (choroid) vein at the interventricular foramen. **Tributaries.**—It receives, in addition to the veins from the corpus striatum, thalamus and fornix, the **vena septi pellucidi** which receives blood from the septum pellucidum, and anterior cornu of the lateral ventricle.

The **basal** vein [v. basalis], runs backward over the cerebral peduncle, and enters the internal cerebral vein near the union of that vessel with the vein of the opposite side.

Tributaries.—A vein, the deep Sylvian, from the insula and the opercular gyri; the inferior striate veins from the corpus striatum, which they leave through the anterior perforated substance; and the anterior cerebral veins from the front of the corpus callosum. It is also joined by interpeduncular veins from the structures in the interpeduncular space; ventricular veins from the inferior cornu of the lateral ventricle; and by mesencephalic veins.

The Cerebellar Veins

The cerebellar veins are divided into the **superior** and **inferior.**

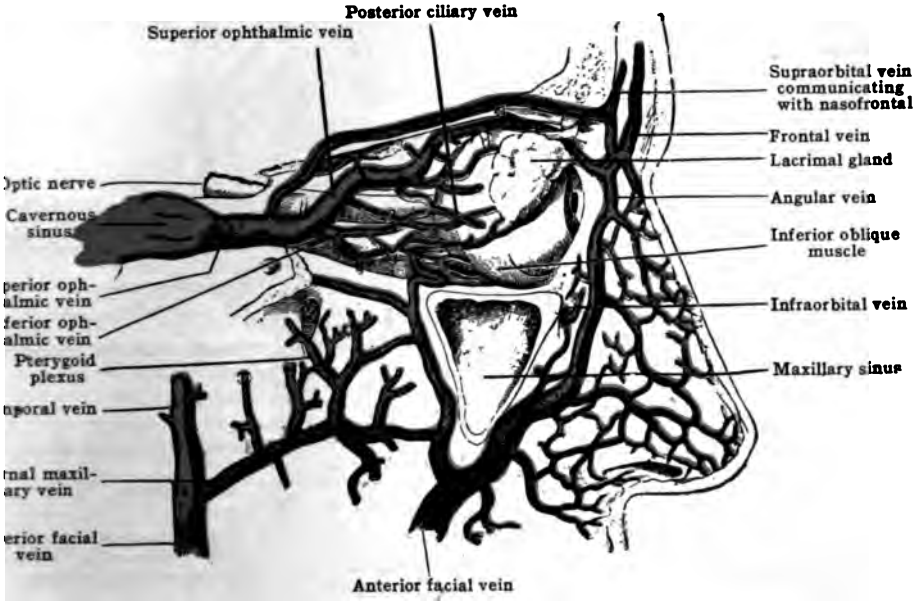
The superior [vv. cerebelli superiores] ramify on the upper surface of the cerebellum; some **them** run medially over the superior vermis to join the straight sinus and great cerebral ; others run laterally to the transverse and superior petrosal sinuses.

The inferior [vv. cerebelli inferiores], larger than the superior, run, some forward and **ally** to the inferior petrosal and transverse sinuses, and others directly backward to the **bital** sinus.

The Veins of the Medulla and Pons

The veins from the **medulla oblongata** and the **pons** terminate in the inferior **rosal** and transverse sinuses.

Fig. 560.—The Ophthalmic Veins. (After Quain).



4. THE VEINS OF THE NASAL CAVITIES

The venous plexuses on the inferior nasal concha (turbinate bone) and back **ne septum are described with the** Nose. The veins leaving the nasal cavities **ow roughly the** course of their corresponding arteries. Thus the spheno-**tine veins pass through** the sphenopalatine foramen into the pterygoid plexus; **anterior and posterior** ethmoidal veins join the ophthalmic. Small veins **ompany branches of** the external maxillary artery through the nasal bones and **ital processes of the maxillary** bones, and end in the angular and anterior facial **is; and other small veins pass** from the nose anteriorly into the superior labial, **thence to the anterior facial.**

5. THE VEINS OF THE EAR

The veins from the external ear and external acoustic meatus join the posterior **al and posterior auricular veins.** The veins from the tympanum open into **superior petrosal sinus and** posterior facial vein. The blood from the laby-**h flows chiefly through the internal auditory** veins [vv. auditivæ internæ], **ch accompany the internal** auditory artery in the internal acoustic meatus, and **ers the transverse or the** inferior petrosal sinus.

Some of the blood from the labyrinth, however, passes through the vestibular vein, which in the aqueductus vestibuli, into the inferior petrosal sinus. Some also passes through the canaliculi cochleæ which traverses the canal of the same name and empties into the commencement of the internal jugular vein or the terminal portion of the inferior petrosal sinus.

6. THE VEINS OF THE ORBIT

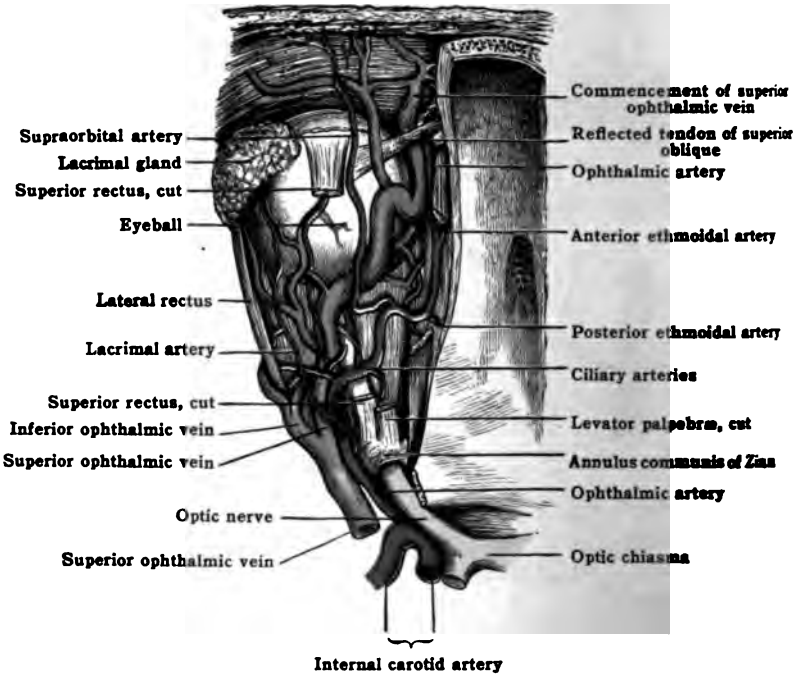
The blood from the eyeball and orbit is returned by the superior ophthalmic into the cavernous sinus. This vein and its tributaries have no valves, and

communicate with the frontal, supraorbital, inferior cerebral, and pterygoid veins (fig. 562).

Under certain conditions, as from pressure on the cavernous sinus, the blood may flow in the contrary direction to the normal—i.e., from behind forward into the frontal and supraorbital, and thence through the angular vein into the anterior facial; or upward into the cerebral venous system. In this way pressure on the retinal veins is quickly relieved, and little or no distension occurs in cases of obstruction in the cavernous sinus.

The **superior ophthalmic** vein [v. ophthalmica superior] (**fig. 561**) begins at the medial angle of the eyelid by a free communication with the frontal, supraorbital, and angular veins, and thence runs backward and laterally with the ophthalmic artery across the optic nerve to the medial end of the superior orbital (sphenoidal) fissure, where it is usually joined by the inferior ophthalmic vein. It then passes backward between the two heads of the lateral rectus muscle below the sixth nerve, leaves the orbit through the medial end of the superior orbital fissure and enters the anterior end of the cavernous sinus. In this course it is superficial to the ophthalmic artery.

FIG. 561.—THE VEINS OF THE ORBIT. (Superior View.)



Tributaries.—(1) The nasofrontal vein; (2) the superior muscular veins; (3) the veins of the lids and conjunctiva; (4) the ciliary veins; (5) the anterior and posterior ethmoidal veins; (6) the lacrimal vein; (7) the central vein of the retina; and (8) the inferior ophthalmic vein.

(1) The **nasofrontal** vein [v. nasofrontalis] begins by a free communication with the supraorbital vein and enters the orbit through the frontal notch or foramen. It frequently joins the superior ophthalmic vein quite far back in the orbit (see fig. 560).

(2) The **muscular** veins [vv. musculares] are derived from the levator palpebræ, superior rectus, superior oblique, and medial rectus.

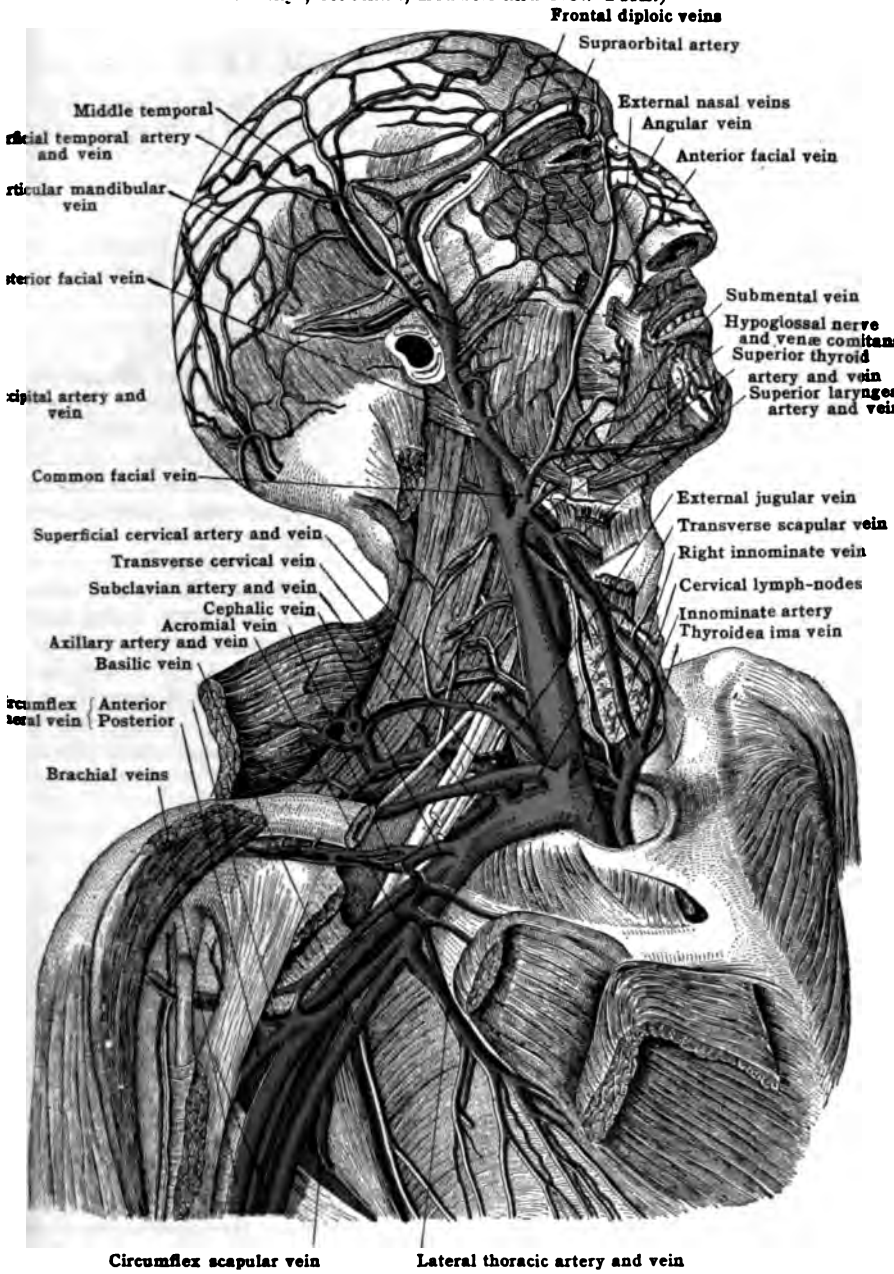
(3) The **palpebral** and **conjunctival** veins [vv. palpebrales; vv. conjunctivales ant. et post.], both anterior and posterior, open into the superior ophthalmic.

(4) The **ciliary** veins, the veins of the eyeball, are divided into anterior and posterior groups. The **anterior ciliary veins** [vv. ciliares ant.] emerge from the eyeball with the anterior ciliary arteries, and open into the muscular veins returning the blood from the four recti. They form a circumcorneal ring of episcleral veins [vv. episclerales]. The **posterior ciliary veins**, which drain the **venæ vorticosæ**, leave the globe midway between the cornea and the entrance of the optic nerve. The upper veins of this group end in the superior, and the lower in the inferior ophthalmic vein (fig. 560).

(5) The **anterior and posterior ethmoidal** veins [vv. ethmoidales ant. et post.], correspond in their course with the arteries of the same name. They enter the orbit through the anterior and posterior ethmoidal foramina, and join either the ophthalmic or one of superior muscular branches.

3) The **lacrimal** vein [v. lacrimalis] returns the blood from the lacrimal gland, and corre-
ds in its course to the lacrimal artery.
) The **central vein of the retina** [v. centralis retinæ] runs with the central artery in the
: nerve. It joins the superior ophthalmic at the back of the orbit.
8) The **inferior ophthalmic** vein [v. ophthalmica inferior], smaller than the superior, is
ed near the front of the orbit by the confluence of the inferior muscular with the lower

562.—The Veins of the Head, Neck, and Axilla. (After Toldt, 'Atlas of Human Anatomy', Rebman, London and New York.)



rior ciliary veins. It runs backward below the optic nerve, along the floor of the orbit **ither** joins the superior ophthalmic vein, or opens separately into the cavernous sinus. **ge** communicating branch passes downward through the inferior orbital (sphenomaxillary) **e** to join the pterygoid plexus of veins (fig. 560). It receives muscular twigs from the **or** and lateral rectus and from the inferior oblique, and some posterior ciliary veins.

7. THE VEINS OF THE PHARYNX AND LARYNX

The pharyngeal veins [vv. pharyngeæ] are arranged in the form of a plexus, **reen the constrictor** muscles and the prevertebral fascia. The **pharyngeal**

plexus receives branches from the mucous membrane, the pterygoid ca[nal] [vv. canalis pterygoidei] from the soft palate, the auditory (Eustachian) tube a[nd] the anterior recti and longus colli muscles. Above, it communicates with th[e] pterygoid plexus of veins; below it drains into the internal jugular vein.

The **veins of the larynx** end partly in the **superior laryngeal** vein [v. laryng[ea] superior], which opens into the internal jugular vein, and partly in the inferi[or] **laryngeal** vein [v. laryngea inferior], which terminates in the plexus thyroideus impar. The laryngeal plexus of veins communicates with the pharyngeal plexus.

8. THE DEEP VEINS OF THE NECK

The **deep veins of the neck** include the internal jugular, vertebral, deep cervical, inferior thyroid, thyroidea ima, thymic, tracheal, and esophageal veins.

The Internal Jugular Vein

The **internal jugular** vein [v. jugularis interna] begins at the jugular fossa, and is the continuation of the transverse sinus. It passes down the neck, in company first with the internal carotid artery and then with the common carotid artery, to a point a little lateral to the sternoclavicular articulation, where it joins the subclavian to form the innominate vein. At its commencement in the larger posterior and lateral part of the jugular foramen, it is somewhat dilated, forming the **superior bulb** of the jugular vein [bulbus v. jugularis superior]. This dilated part of the internal jugular vein lies in the jugular fossa of the temporal bone and is therefore in immediate relation to the floor of the tympanum. At first the internal jugular lies in front of the rectus capitis lateralis, and behind the internal carotid artery, from which it is separated by the hypoglossal, glossopharyngeal, and vagus nerves, and by the carotid plexus of the sympathetic. As it descends it passes gradually to the lateral side of the internal carotid, and retains this relation as far as the upper border of the thyroid cartilage. Thence it runs to its termination along the lateral side of the common carotid artery, being contained in the same sheath with it and the vagus nerve, but separated from these structures by a distinct septum. The vein generally overlaps the artery in front. About 2.5 cm. (1 in.) above its termination it contains a pair of imperfect valves below which a second dilation usually occurs in the vein. This, the **inferior bulb** [bulbus v. jugularis inferior], extends as low as the junction of the internal jugular with the subclavian. It not infrequently receives the termination of the external jugular vein.

Tributaries.—At the superior bulb the internal jugular vein receives the inferior petrosal sinus; the vein of the cochlear canaliculus (which may join the inferior petrosal sinus), and a meningeal vein; opposite the angle of the jaw, veins from the pharyngeal plexus, and often a communicating branch from the external jugular vein; opposite the bifurcation of the carotid it is joined by the common facial, and a little lower down by the lingual, sternomastoid, and the superior thyroid veins. At the level of the cricoid cartilage the internal jugular is joined by the middle thyroid when this vein is present.

The inferior petrosal sinus is described with the other sinuses of the brain (p. 687); the pharyngeal plexus with the veins of the pharynx (see p. 693); and the common facial vein with the superficial veins of the scalp and face (p. 682).

The **lingual** vein [v. lingualis], begins near the tip of the tongue, where it accompanies the arteria profunda linguæ. It lies at first beneath the mucous membrane covering the lower surface of the tongue. It then passes backward on the medial surface of the hyoglossus, in company with the lingual artery. After receiving the **sublingual vein** [v. sublingualis] and the **dorsal lingual** veins [vv. dorsales linguæ], which roughly correspond to their respective arteries, it is joined by the small **v. comitans nervi hypoglossi** which follows the upper border of the hypoglossal nerve. The trunk finally crosses the common carotid artery and opens into the internal jugular vein. The lingual vein communicates with the pharyngeal veins and with tributaries of the anterior facial. It occasionally terminates in the posterior or in the common facial vein. The **sternomastoid** vein [v. sternocleidomastoidea] accompanies the artery of the same name and empties into the internal jugular.

The **superior thyroid** vein [v. thyroidea superior] emerges from the upper part of the thyroid gland, in which it freely anastomoses with the other thyroid veins. This anastomosis, the **plexus thyroideus impar**, occurs both in the substance of the organ and on its surface beneath the capsule. The vein then passes upward and laterally into the internal jugular vein, crossing the common carotid artery in its course. At times it forms a common trunk with the common facial vein. Its tributaries are the sternohyoid, sternothyroid, and

roid veins from the muscles bearing those names; and the cricothyroid and superior al veins which correspond with the cricothyroid and superior laryngeal arteries ively. These require no special description.
eparate vein frequently passes out from the capsule of the thyroid gland near the lower the lateral lobe, crosses the common carotid, and opens into the main superior thyroid into the internal jugular vein a little below the cricoid cartilage. In the former case it ded as part of the superior thyroid vein system; in the latter it is generally known as the thyroid vein.

The Vertebral Vein

ie **vertebral** vein [v. vertebralis] does not accompany the vertebral artery in irth stage, that is, within the cranium, but begins in the posterior vertebral s plexus of the suboccipital triangle. It then enters the foramen in the erse process of the atlas, and passes with the vertebral artery through the ina in the transverse processes of the cervical vertebræ, forming a plexus d the artery. On leaving the transverse process of the sixth cervical verte- crosses in front of the subclavian artery and opens into the innominate vein. one or two semilunar valves at its entrance into the innominate vein. In iboccipital triangle it communicates with the internal vertebral venous es, with the deep cervical, and occipital veins, and is joined by veins from cti and oblique muscles and the pericranium.

utaries.—As it passes down the neck it receives (1) intervertebral veins, which issue with the cervical nerves, from the spinal canal; (2) tributaries from the anterior and or vertebral venous plexus from the bodies of the cervical vertebræ and their transverse es; and (3) tributaries from the deep cervical muscles. Just before it terminates in the nate it is joined by (4) the anterior vertebral vein, a small vein which accompanies the ing cervical artery, and, sometimes, by the deep cervical vein.

The Deep Cervical Vein

he **deep cervical** vein [v. cervicalis profunda], larger than the vertebral, s down the neck posterior to the cervical transverse processes. It corre- ls to the deep cervical artery from which it is separated by the semispinalis cis muscle.

begins in the posterior vertebral venous plexus and receives tributaries from the deep s of the neck. It communicates with, or entirely drains, the occipital vein by a branch perforates the trapezius muscle. The deep cervical vein then passes forward beneath ansverse process of the seventh cervical vertebra to open into the innominate vein near rtebral, or into the latter near its termination. Its orifice is guarded by a pair of valves.

The Inferior Thyroid and Thyroidea Ima Veins

he **inferior thyroid** veins [vv. thyreoideæ inferiores] descend from the lower of the *plexus thyroidea impar* which invests the surface of the thyroid gland. ight vein crosses the innominate artery just before its bifurcation, and ends right innominate vein a little above the vena cava superior or joins the left to a single vena thyroidea ima. It receives inferior laryngeal veins and veins from achea. The **left vein** passes obliquely over the trachea behind the sterno- id muscle, and opens into the left innominate vein. It also receives laryn- nd tracheal veins, and may be joined by the right inferior thyroid vein. uarded by valves where it opens into the innominate trunk.

e thyroidea ima vein [v. thyreoidea ima] can be said to exist only when the veins from ver part of the plexus thyroidea impar unite at once to form a single trunk which opens e left innominate vein, or when the right inferior thyroid vein joins the left before the lat- ich then becomes the v. thyroidea ima, opens into the left innominate.

The Thymic, Tracheal and Esophageal Veins

ese small veins usually open into the left innominate vein. The **thymic** [vv. thymicæ], small in the adult, open into the left innominate vein or into nferior thyroid or thyroidea ima. The **tracheal** veins [vv. tracheales] mose with the laryngeal and bronchial veins. The **esophageal** veins sophageæ] from the upper part of the esophagus, anastomose with the esophageal veins and with the pharyngeal plexus.

THE VEINS OF THE THORAX

THE SUPERFICIAL VEINS OF THE THORAX

The **superficial veins** of the front of the thorax can be seen in fig. 563. They form a plexus over the entire chest, of which the portion over the mammary gland

is called the mammary plexus. The lateral thoracic vein drains the mammary plexus and the costoaxillary veins; it communicates with the thoracoepigastric

and terminates in the axillary vein (p. 705). The veins nearer the median ıre drained by the internal mammary vein and its anterior intercostal uperior epigastric tributaries. The veins over the entire thorax are in free ıunication with the superficial veins of the abdominal wall, which drain into reat saphenous and femoral veins and into the deeper veins of the abdomen.

THE DEEP VEINS OF THE THORAX

he **deep veins of the thorax** are:—the pulmonary veins, and the vena cava ior and its innominate and other tributaries. Of these veins, the pulmonary, ena cava superior, and the innominate veins have already been described, ve the tributaries of the latter arising in the neck.

he following veins are described below:—(1) The azygos and ascending ar veins, which discharge their blood into the vena cava superior; (2) the of the vertebral column, which are tributary to the azygos veins through the costals; (3) the internal mammary veins, and (4) the superior phrenic, an- r mediastinal and pericardiac veins, all of which open into the innominate

1. THE AZYGOS AND ASCENDING LUMBAR VEINS

he **azygos system** consists of a series of longitudinal collecting trunks for the *costal veins*. They lie along the sides of the thoracic vertebræ, and are the ard continuation of the **ascending lumbar veins** which take origin in the men. The **azygos** veins are three in number: the azygos (azygos major) ıe right side, and the hemiazygos (azygos minor) and accessory hemiazygos gos tertia) on the left.

he **azygos vein** [v. azygos] (figs. 564, 577) begins in the abdomen as the right ıding lumbar vein. It is in this way linked with the right common iliac right renal veins and has other connections with the vena cava inferior which become very important in cases of obstruction of the latter vessel. It up through the posterior mediastinum on the right side of the front of the es of the thoracic vertebræ as high as the fourth thoracic vertebra, in this part s course lying to the right of the aorta and thoracic duct; it then curves ard over the root of the right lung, and opens into the vena cava superior iediately before the latter pierces the pericardium.

he azygos vein usually contains an imperfect pair of valves at the point where it turns for- from the fourth thoracic vertebra to arch over the root of the lung; and still more imperfect s are found at varying intervals lower down the vein.

receives the intercostal veins of the right side, except the first two or three. These (usually excepting the first) are collected into a common trunk, the right superior inter- l vein, before joining the azygos. It also receives the hemiazygos and accessory hemiazy- he right posterior bronchial vein, and small esophageal and posterior mediastinal veins.

he **hemiazygos** vein [v. hemiazygos] (fig. 564) begins in the abdomen by nunicating, like the azygos vein, with the ascending lumbar vein of its own It courses up the posterior mediastinum to the left of the bodies of the r thoracic vertebræ as high as the eighth or ninth, where it turns obliquely to ight, and, crossing in front of the vertebral column behind the aorta and sophagus, opens into the vena azygos. In its course it crosses over three ur of the lower left intercostal arteries, and is covered by the pleura.

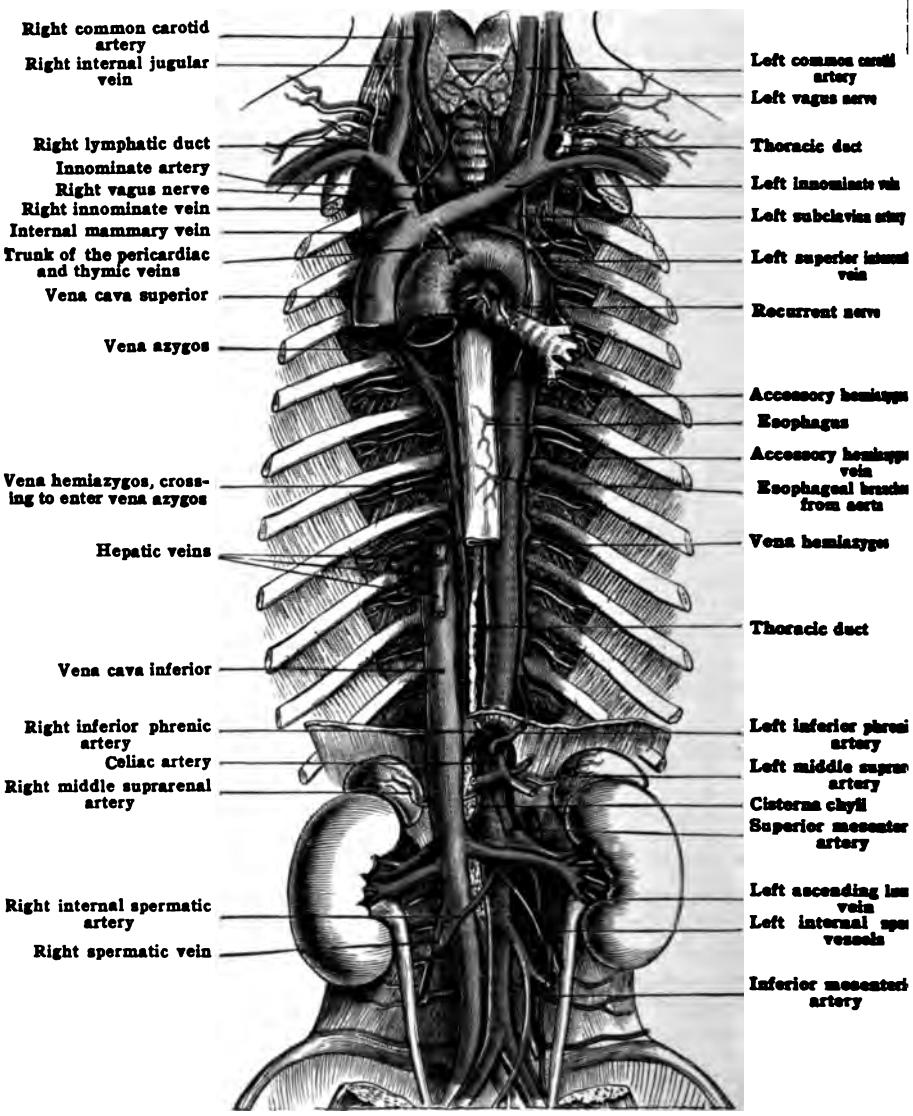
ıe hemiazygos receives the lower four or five left intercostal veins the lower end of the ıory hemiazygos vein (sometimes), the small left mediastinal veins, and the lower left ageal veins.

he **accessory hemiazygos** [v. hemiazygos accessoria] (fig. 564) varies much ıe, position, and arrangement, and is often continuous with, or drained by, eft superior intercostal vein. It lies in the posterior mediastinum by the ide of the bodies of the fifth, sixth, and seventh or eighth thoracic vertebræ, s more or less vertical in direction. It may communicate above with the ıperior intercostal vein, and below either joins the hemiazygos or passes uely across the seventh or eighth thoracic vertebra to join the azygos vein. sses the corresponding left intercostal arteries, and is covered by the pleura.

The accessory hemiazygos receives the fourth, fifth, sixth, seventh, sometimes the eighth intercostal veins, and the left posterior bronchial veins.

The **ascending lumbar** vein [v. lumbalis ascendens] (fig. 564) begins on each side in the neighborhood of the sacral promontory. It is here in free communication, by means of the anterior sacral plexus, with the middle and lateral sacral veins, and with the common iliac, hypogastric and iliolumbar veins. It ascends in front of the lumbar transverse processes communicating with the lumbar veins, the vena cava inferior and, usually, with the renal vein. The right

FIG. 564.—THE VENÆ CAVÆ SUPERIOR AND INFERIOR, THE INNOMINATE VEINS, AND THE AZYGOS VEINS.



enters the thorax between the aorta and the right medial crus of the diaphragm and is continued upward as the vena azygos. The left vein pierces the left medial crus and becomes the hemiazygos.

The intercostal veins [vv. intercostales].—The intercostal veins are twelve in number on each side, the last one being subcostal. They accompany the intercostal arteries, the vein lying above the artery whilst in the intercostal spaces. Each vein receives a dorsal tributary [ramus dorsalis] which accompanies the posterior ramus of an intercostal artery between the transverse processes of the vertebra and the neck of the rib. These dorsal branches not only return blood from the muscles of the back, but receive each a spinal branch [r. spinalis

from the vertebral venous plexuses and small tributaries from the bodies of the vertebræ.

The intercostal vein from the first space may join the superior intercostal vein, but commonly opens directly into the innominate or one of its tributaries, most frequently the vertebral. All the intercostal veins, usually excepting the first, lie posteriorly to the sympathetic trunk.

On the right side.—The second intercostal vein joins with the third or with the third and fourth to form the **right superior intercostal** vein [v. intercostalis suprema dextra]. This vein opens into the azygos vein as the latter is arching over the root of the right lung. The rest open in the azygos directly. The upper of these have well-marked valves where they join the azygos vein; in the lower veins these valves are imperfect. All the intercostal veins are provided with valves in their course between the muscles.

On the **left side** the second intercostal vein joins the third and fourth to form a single trunk, the **left superior intercostal** vein [v. intercostalis suprema sinistra]. This vein passes upward across the arch of the aorta and opens into the left innominate vein. The left superior intercostal frequently communicates at its lower end with the accessory hemiazygos vein, which is occasionally tributary to it. In most cases a small tributary runs up over the front of the aortic arch to join the superior intercostal vein; it is a vestige of the left common cardinal and from it a small fibrous cord can often be traced through the vestigial fold of the pericardium to the oblique vein of the left atrium (p. 564).

The left fifth, sixth and seventh intercostal veins commonly open into the accessory hemiazygos, and the eighth or ninth and succeeding veins into the hemiazygos. The method of termination of the intercostal veins of the left side is subject to such variation that a normal arrangement can scarcely be said to exist at all. The eighth may open directly into the azygos, as may the seventh and ninth or even more or all of the veins; the hemiazgyos and accessory hemiazygos veins may thus be very limited in extent or even altogether absent.

The **posterior bronchial** veins [vv. bronchiales posteriores] correspond to the bronchial arteries, but do not return the whole of the blood carried to the lungs by those vessels—that part which is distributed to the smaller bronchial tubes and the alveoli being brought back by the pulmonary veins. The posterior bronchial veins issue from the lung substance behind the structures forming the root of the lung. The right vein generally joins the vena azygos just before the latter vein enters the vena cava superior. The left vein opens into the accessory hemiazygos vein. The bronchial veins at the root of the lung receive small tributaries from the bronchial glands, from the trachea, and from the posterior mediastinum.

The **esophageal** veins [vv. œsophageæ] from the thoracic portion of the esophagus end in part in the vena azygos, and in part in the vena hemiazygos. They anastomose with the upper esophageal veins, which empty into the left innominate vein, and with the coronary vein of the stomach (fig. 572).

The **posterior mediastinal** veins, small and numerous, open into the azygos and hemiazygos veins.

2. THE VEINS OF THE VERTEBRAL COLUMN

The venous plexuses around and within the vertebral column extending from the cranium to the coccyx (fig. 565) may be divided into two categories:—(1) the **external** and (2) the **internal vertebral venous plexuses.** The external plexuses consist of two parts, the *anterior vertebral venous plexuses* situated on the anterior aspect of the vertebral bodies and the *posterior vertebral venous plexuses* ramifying over the posterior aspect of the vertebral arches, spines, and transverse processes. The internal plexuses consist of *two longitudinal venous sinuses* situated between the vertebræ and the posterior longitudinal ligament, and of two *vertebral venous retia* which ramify externally to the dura mater. The sinuses of the internal plexuses communicate freely with one another and with the internal retia and external plexuses. They receive the external spinal veins and the *basivertebral veins* from the bodies of the vertebræ. The venous circulation of the vertebral column is drained by the vertebral, intercostal, lumbar and sacral veins either directly or by means of (3) the **intervertebral** veins.

1. The **external vertebral venous plexuses** [plexus venosi vertebrales externi] include the following:—

(*a*) The **anterior vertebral venous plexuses** [plexus venosi vertebrales anteriores] (fig. 565) consist of small veins ramifying in front of the bodies of the vertebræ. These veins communicate with the basivertebral veins and are larger in the cervical region than elsewhere.

(*b*) The **posterior vertebral venous plexuses** [plexus venosi vertebrales posteriores] (fig. 565) are situated around the transverse, articular, spinous processes and laminæ of the vertebræ. Communications take place between the plexuses of each segment and with the veins of the neighboring muscles and integuments. Branches are also sent, through the ligamenta flava, to the internal vertebral venous plexuses, and, between the transverse processes, to the intervertebral veins.

2. The **internal vertebral venous plexuses** [plexus venosi vertebrales interni] (figs 565, 566):—

(*a*) The two **longitudinal vertebral sinuses** [sinus vertebrales longitudinales] run throughout the entire length of the vertebral canal. They are situated behind the bodies of the vertebræ on either side, between the bone and the posterior longitudinal ligament. The sinuses have extremely thin walls, and their interior is made irregular by numerous folds but no true valves are present. The caliber of the longitudinal sinuses is reduced by constrictions opposite the

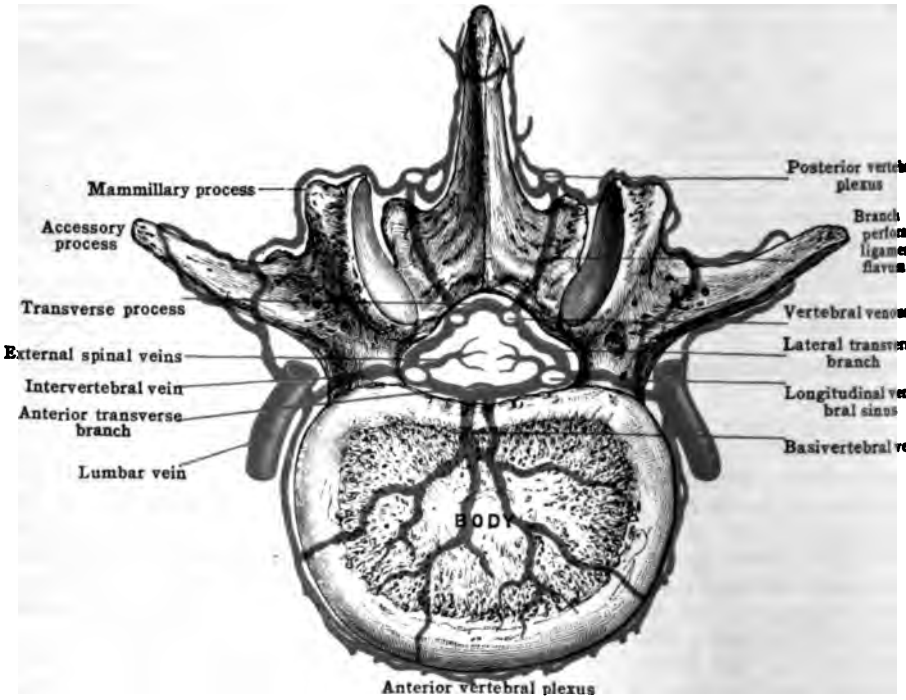
intervertebral disks; the constrictions alternating with dilatations opposite the vertebral bodies. At each dilatation there occurs a cross communication between the longitudinal sinuses on either side, and each receives a basivertebral vein from the corresponding vertebral body. Opposite every intervertebral foramen and anterior sacral foramen each longitudinal sinus is joined by the corresponding intervertebral vein. The longitudinal sinuses communicate very freely with one another, and with the vertebral retia. At the foramen magnum they communicate with the basilar plexus and, by means of the **rete canalis hypoglossi**, with the internal jugular vein.

(*b*) The **venous retia of the vertebræ** [retia venosa vertebrarum] (**fig. 565**) extend from the foramen magnum to the coccyx. They consist of two main retia situated posteriorly and laterally to the dura between the latter and the vertebral arch. They communicate very freely with one another across the median line; with the posterior external plexus by means of twigs perforating the ligamenta flava; and with the longitudinal vertebral sinuses by means of lateral branches. At the foramen magnum they communicate with the occipital sinus.

(*c*) The **external spinal** veins (fig. 565) consist of two sets—anterior and posterior—which are drained by means of veins following the nerve roots, into the internal vertebral venous plexus.

The **anterior external spinal** veins [vv. spinales externæ anteriores] form a tortuous anastomosing vessel in the region of the anterior median fissure.

FIG. 565.—THE VEINS OF THE VERTEBRAL COLUMN.



The **posterior external spinal** veins [vv. spinales externæ posteriores], smaller than the anterior run longitudinally on the posterior surface of the cord.

The external spinal veins form a wide-meshed plexus in the pia mater which drains into the **internal spinal** veins [vv. spinales internæ] (see SPINAL CORD).

(*d*) The **basivertebral** veins [vv. basivertebrales] (fig. 565) collect the blood from the cancellous tissue of the bodies of the vertebræ, and consist of a tunica intima only. They take a radial direction converging to the transverse vessels connecting the longitudinal vertebral sinuses. They communicate with the anterior external plexus and with the intercostal veins.

3. The **intervertebral** veins [vv. intervertebrales] (figs. 565, 566), emerge from each longitudinal sinus and pass out through the intervertebral or anterior sacral foramina. They open into the vertebral, intercostal, lumbar or sacral veins according to region and receive numerous tributaries from the anterior and posterior external vertebral venous plexuses. They are instrumental in draining the venous system of the vertebral column and spinal cord.

3. THE INTERNAL MAMMARY VEIN

The internal mammary vein [v. mammaria interna] (**fig. 506**) **is formed by** the union of the venæ comitantes corresponding to the **superior epigastric** and musculophrenic arteries. The right and left internal **mammary veins pass** upward, in company with the corresponding arteries, to open **into the right and** left innominate veins, respectively.

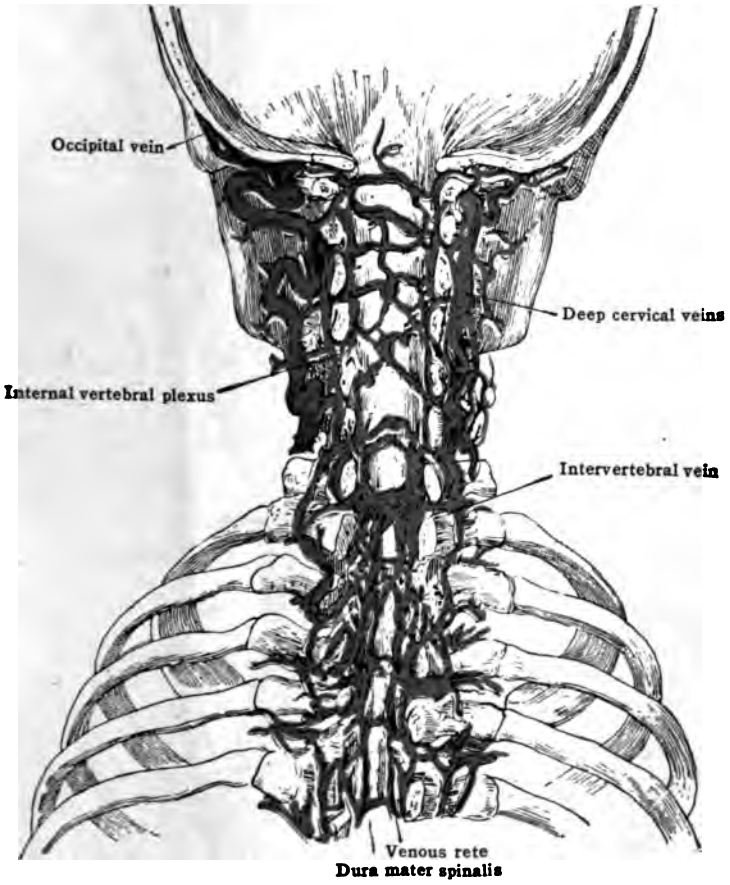
ributaries.—In addition to the superficial veins of the thorax, the internal mary veins receive the anterior intercostal, anterior bronchial and peri- iac veins.

he superior epigastric vein [v. epigastrica superior] assists in the drainage of the subcu- us abdominal veins [vv. subcutaneæ abdominis].
he anterior bronchial veins [vv. bronchiales anteriores] arise in the bronchial walls and unicate with the tracheal and posterior bronchial veins.

THE SUPERIOR PHRENIC, ANTERIOR MEDIASTINAL, AND PERICARDIAC VEINS

he superior phrenic [vv. phrenicæ superiores], the **anterior mediastinal** [vv. mediastinales iores], and **pericardiac** [vv. pericardiacæ] veins are small vessels, corresponding to the ar- of those names. They pass over the arch of the aorta and open into the lower and an- part of the left innominate.

FIG. 566.—THE VERTEBRAL VENOUS PLEXUSES. (After Henle.)



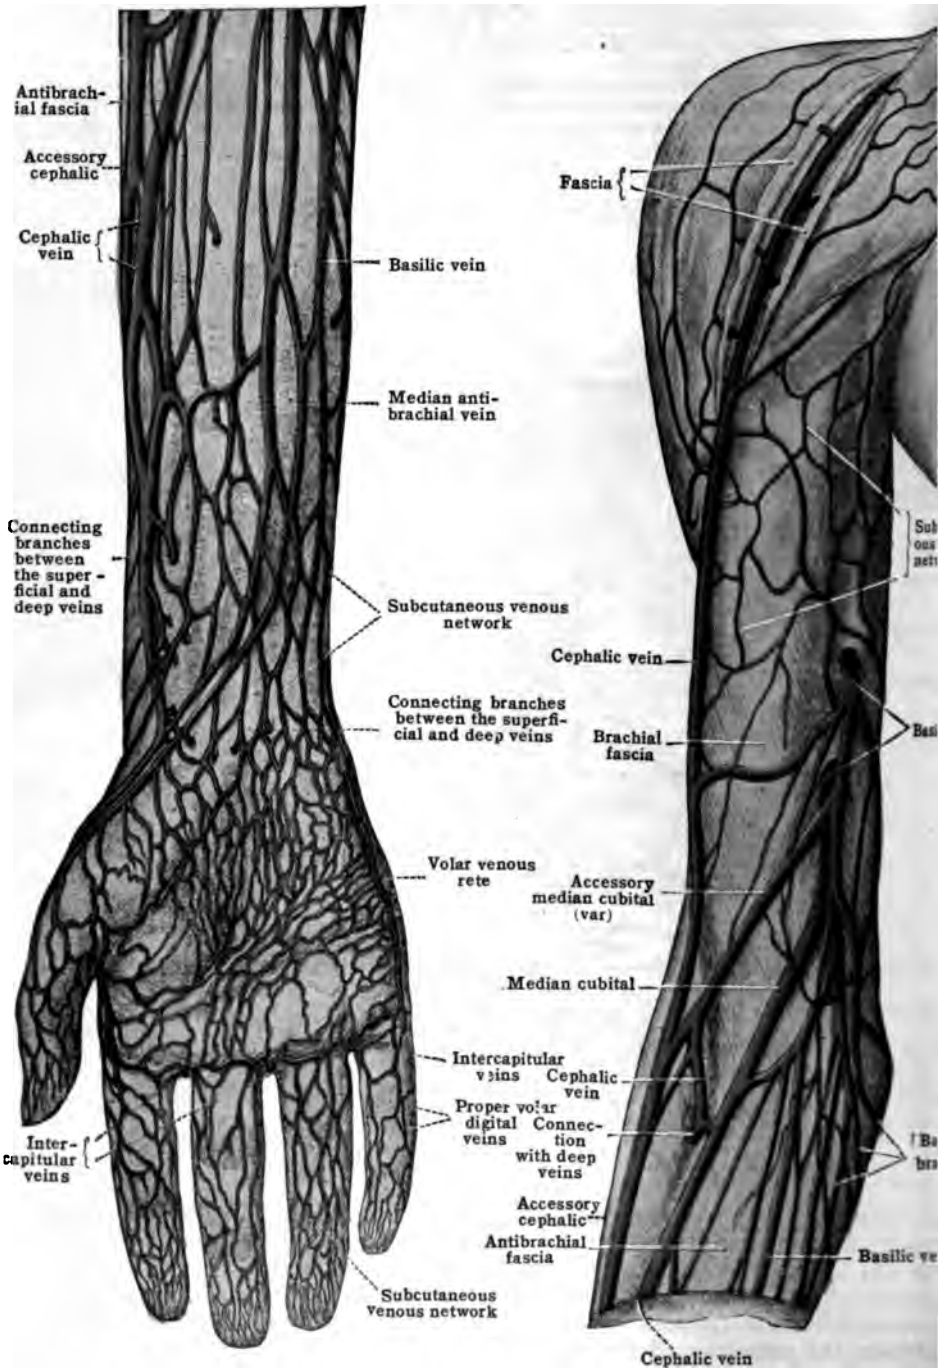
THE VEINS OF THE UPPER EXTREMITY

he veins of the upper limb consist of two sets—a **superficial** and a **deep.** uperficial veins ramify in the subcutaneous tissue above the deep fascia, and do not accompany arteries. The deep veins accompany the arteries, and practically the same relations as those vessels. The superficial and deep communicate at frequent intervals through the intermuscular veins which etween the muscles and perforate the deep fascia. Both sets of veins are ded with valves, but the valves are more numerous in the deep than in the ficial. There are usually valves where the deep veins join the superficial. uperficial veins are larger than the deep, and take the greater share in ning the blood.

A. THE SUPERFICIAL VEINS OF THE UPPER EXTREMI

The **superficial veins** begin in two irregular plexuses, one in the palm and other on the back of the hand. The plexus in the palm is much finer, and c

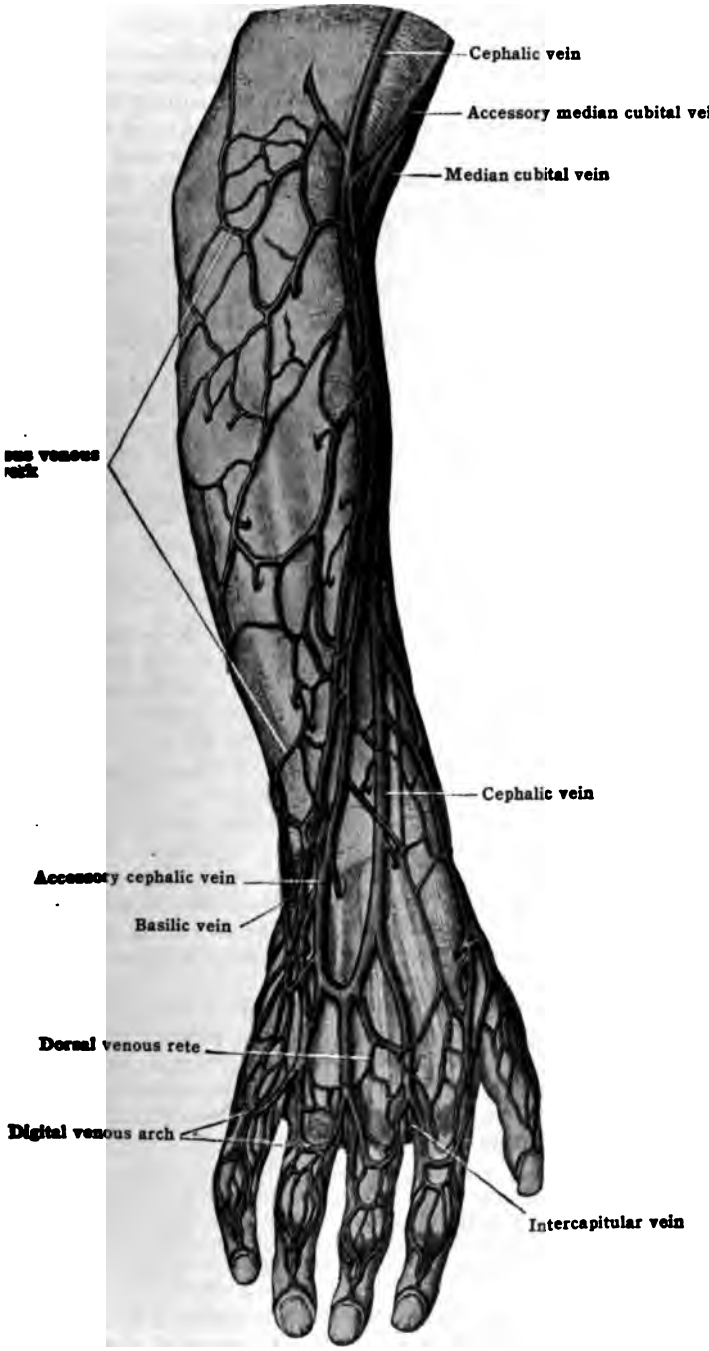
FIG. 567.—THE SUPERFICIAL VEINS OF THE ARM AND FOREARM. (After Toldt, 'Atla Human Anatomy,' Rebman, London and New York.)



municates with the superficial volar veins of the fingers. **The latter disc** their blood into the dorsal venous rete by means of the **veins of the folds be** the fingers, or the **intercapitular** veins [vv. intercapitulares] **(fig. 567).**

eins of the back of the hand begin in a longitudinal plexus over the d at the bases of the fingers the veins of the adjacent digits are con- **digital venous arches** [arcus venosi digitales], from which arise the

VEINS OF THE BACK OF THE FOREARM. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



tacarpal veins [vv. metacarpeæ dorsales]; these form upon the back **d a dorsal venous rete** [rete venosum dorsale manus] (fig. 568).

veins of the arm, two stand out prominently, the basilic and the Both of these arise from the veins of the back of the hand, curve the volar surface of the forearm, and pass to the arm (fig. 567).

below the clavicle it turns into the depth, and empties into the axillary v

At the elbow there is usually an oblique connecting branch, the **cubital** vein [v. mediana cubiti] (figs. 567, 569) (formerly termed median which, beginning from the cephalic a little distally to the crease of the ends in the basilic just proximally to the elbow.

NOTE.—In the limb shown in fig. 567 the direct venous channel on the radial sid forearm, the accessory cephalic (formerly radial) vein, is continued directly into the above the elbow. The cephalic in the forearm (formerly median) is mainly drained basilic through the median cubital. The vein opposite the bend of the elbow, wh ally forms the segment of the cephalic formerly known as the median cephalic vein, small channel draining into an accessory median cubital. The basilic vein of the (formerly posterior ulnar) is represented largely by a plexus of small venous channels.

There are several longitudinal or oblique tributaries of the basilic and cephalic ve the volar surface of the forearm. One of these, the **accessory cephalic** (formerly th vein, lies on the medial side of the cephalic, into which it opens a short distance prox the crease of the elbow; the others are not named.

B. THE DEEP VEINS OF THE UPPER EXTREMI

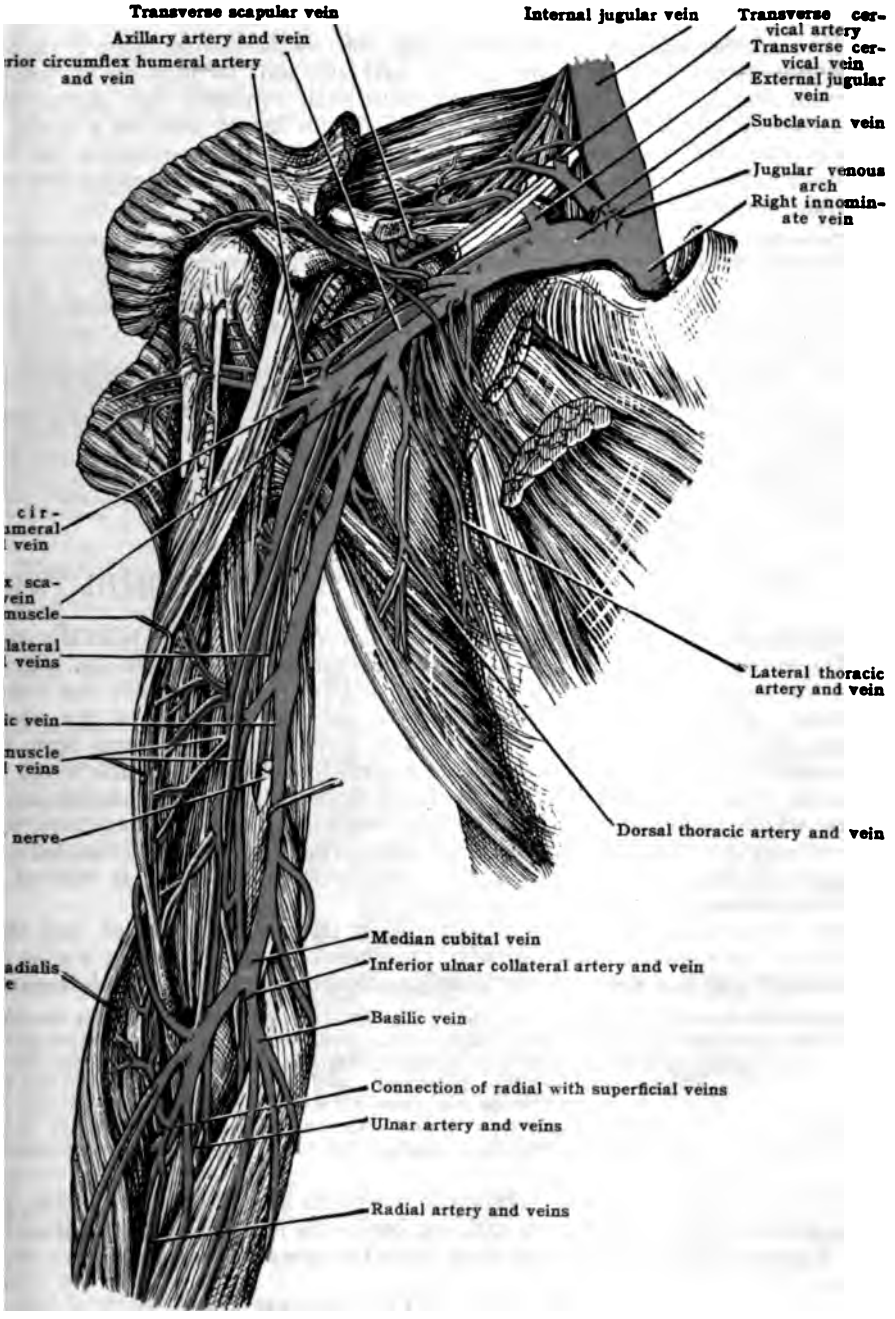
The **deep veins of the upper extremity** accompany their corres arteries. Distal to the axilla, each artery is accompanied by two veins as the venæ comitantes. The deep veins all contain numerous valv communicate at frequent intervals through intermuscular veins with th ficial vessels.

Beginning at the fingers, two minute **proper volar digital veins** [venæ volares propriæ], accompany each digital artery along the sides of the and uniting at the cleft, form **common volar digital veins** [vv. digitales communes], which join the venæ comitantes of the arteries, forming th ficial volar arch. In like manner the veins accompanying the arteries the deep arch receive tributaries, **the volar metacarpal veins** [vv. met volares], corresponding to the branches of that arch. **A superficial and volar venous arch** [arcus volaris venosi, superficialis et profundus] are thu accompanying the arterial arches. The venæ comitantes from the ulna the superficial and deep arches unite at the spot where the ulnar artery into the superficial and deep branch to form two **ulnar venæ comitan** ulnares]; whilst those on the radial side of the superficial and deep arch ac the superficial volar artery and the termination of the radial artery resp and unite at the spot where the superficial volar is given off from the radi to form the **radial venæ comitantes** [vv. radiales].

venæ comitantes of the arteries of the arm anastomose with one another **uent** cross branches.

axillary vein [v. axillaris], is formed by the junction of the medial brachial **omitans** with the basilic vein at the lower border of either the teres major

).—Deep Veins of the Arm and Axilla. (Ater Toldt, 'Atlas of Human Anatomy, Rebman, London and New York.)



scapularis muscle. It is a vessel of large size, conveying as it does nearly **ole** of the blood returning from the upper extremity. It accompanies the **y artery through** the axillary fossa, lying to its medial side and, at the upper **the space, on a slightly** posterior plane. At the lateral border of the first **hanges its name to** the subclavian. It has one or two axillary lymphatic

5

nodes in close connection with it. The vein contains a pair of valves, usually placed near the lower border of the subscapularis muscle.

Tributaries of the axillary vein are as follows:—(1) The **subscapular** veins which accompany the subscapular artery; (2) the **circumflex** veins accompanying the circumflex arteries; (3) the **lateral thoracic** vein [v. thoracalis lateralis] a large vein which accompanies the lateral thoracic artery and receives numerous **thoracoepigastric** veins [vv. thoracoepigastricæ] from the epigastric and lower thoracic regions; (4) the **costoaxillary** veins [vv. costoaxillares] the radicles of which arise in the pectoral region from the **mammary plexus** [plexus venosus mamillæ]; and (5) the **cephalic** vein.

The **subclavian** vein [v. subclavia] (fig. 569), is the continuation of the axillary. It begins at the lateral border of the first rib, and terminates by joining the internal jugular to form the innominate vein opposite the sternoclavicular articulation. It lies anterior to the subclavian artery and on a lower plane, and is separated from the artery in the second part of its course by the scalenus anterior muscle. The subclavian vein, just before it is joined by the external jugular, contains a pair of valves.

Tributaries.—The subclavian vein receives the thoracoacromial vein near its distal end, and the external jugular vein near the lateral border of the sternomastoid muscle. The transverse cervical veins terminate in the subclavian near the external jugular, or in the latter vein, or in a plexiform arrangement formed between the transverse scapular, transverse cervical and external jugular veins. The external jugular vein is described with the superficial veins of the head and neck (p. 682).

The **thoracoacromial** vein [v. thoracoacromialis], receiving tributaries corresponding to the branches of the artery of the same name, terminates near the lateral border of the first rib.

The **transverse cervical** veins [vv. transversæ colli] receive tributaries corresponding in distribution to the branches of the transverse cervical artery. They emerge from beneath the trapezius muscle, cross the posterior triangle, and usually terminate in the subclavian vein. They usually terminate as a single vein the orifice of which is guarded by a pair of valves. Occasionally the cephalic vein, or a branch from the cephalic (the **jugulocephalic**), passes over the clavicle to the subclavian.

C. THE VENA CAVA INFERIOR AND ITS TRIBUTARIES

All the veins of the abdomen, pelvis, and lower extremities, with the exception of the superior epigastric (p. 682), and ascending lumbar vein (p. 698), which join the superior caval system, enter directly or indirectly into the vena cava inferior. The veins corresponding to the parietal branches of the abdominal aorta, except the middle sacral vein, open directly into the vena cava inferior; the middle sacral vein only indirectly through the left common iliac vein. Of the visceral veins corresponding to the visceral branches of the abdominal aorta, those which return the blood from the stomach, intestines, pancreas, and the spleen end in a common trunk called the portal vein. The portal vein breaks up into capillaries (sinusoids) in the liver, whence the blood is carried by the hepatic veins to the vena cava inferior.

Of the other visceral veins, both renals, the right suprarenal, and the right spermatic or ovarian open directly into the vena cava inferior; whilst the left suprarenal and left spermatic or ovarian are drained through the left renal.

Two of the superficial veins of the lower part of the anterior abdominal wall, the superficial epigastric and superficial circumflex iliac, enter the great saphenous vein; and two of the deep veins from the like situation, the inferior epigastric and deep circumflex iliac, enter the external iliac vein. The blood in these vessels, however, can flow upward as well as in the normally downward direction. In obstruction of the vena cava inferior they become greatly enlarged, and form, with the superior epigastric vein and with other superficial veins of the thorax with which they anastomose, one of the chief channels for the return of the blood from the lower limbs.

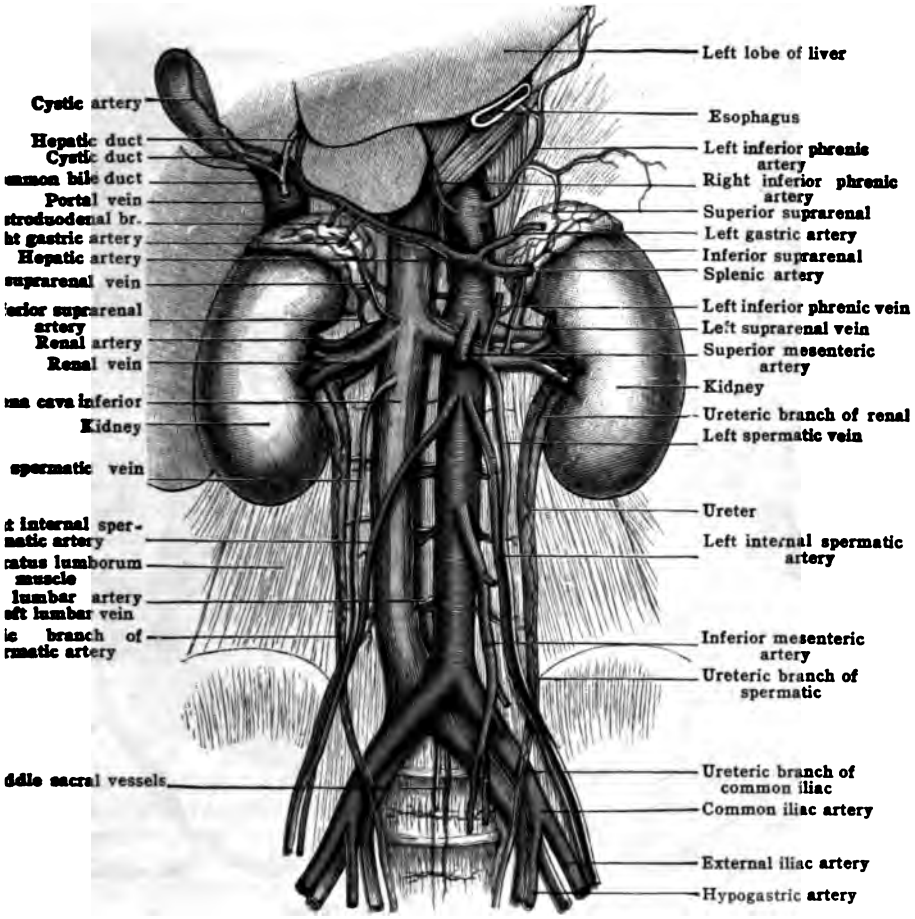
Most of the veins of the pelvis, the perineum and the gluteal region, join the hypogastric vein. The hypogastric on each side joins the external iliac to form the common iliac, and these in turn unite to form the vena cava inferior.

THE VENA CAVA INFERIOR

The **vena cava inferior** (fig. 570) is the large vessel which returns the blood from the lower extremities and the abdomen and pelvis. It is formed by the confluence of the right and left common iliac veins opposite the body of the fifth lumbar vertebra, ascends in front of the lumbar vertebra to the right of the abdominal aorta, passes through the caval opening in the diaphragm, and ends in

lower and back part of the right atrium of the heart usually about the level ne ninth thoracic vertebra. At its origin it lies behind the right common artery on a plane posterior to the aorta, but as it ascends it passes slightly ard and to the right, reaching a plane anterior to the aorta, and becomes rated from that artery by the right medial crus of the diaphragm and the ate lobe of the liver. While in contact with the liver it lies in a deep groove a venæ cavæ] on the posterior surface of that organ, the groove being often erted into a distinct canal by a thin portion of the hepatic substance bridging ss it. As it passes through the diaphragm its walls are attached to the inous margins of the caval opening, and are thus held apart when the muscle racts. On the thoracic side of the diaphragm it lies for about 1.2 cm. (½ in.) in the pericardium, the serous layer of that membrane being reflected over g. 480).

FIG 570.—THE ABDOMINAL AORTA AND VENA CAVA INFERIOR.



lations.—**In front** it is covered by the peritoneum, and crossed by the right spermatic , branches of the aortic plexus of the sympathetic, the transverse colon, the root of the tery, the duodenum, the head of the pancreas, the portal vein, and the liver. The lumbar lymphatic nodes are also in front of it below, and at its commencement the right on iliac artery rests upon it. **Behind,** it lies on the lumbar vertebræ, the right lumbar e, the right renal artery, the right celiac (semilunar) ganglion, and the right medial crus diaphragm. To the **right** are the peritoneum, liver, and psoas muscle. To the **left** is rta, and higher up the right medial crus of the diaphragm.

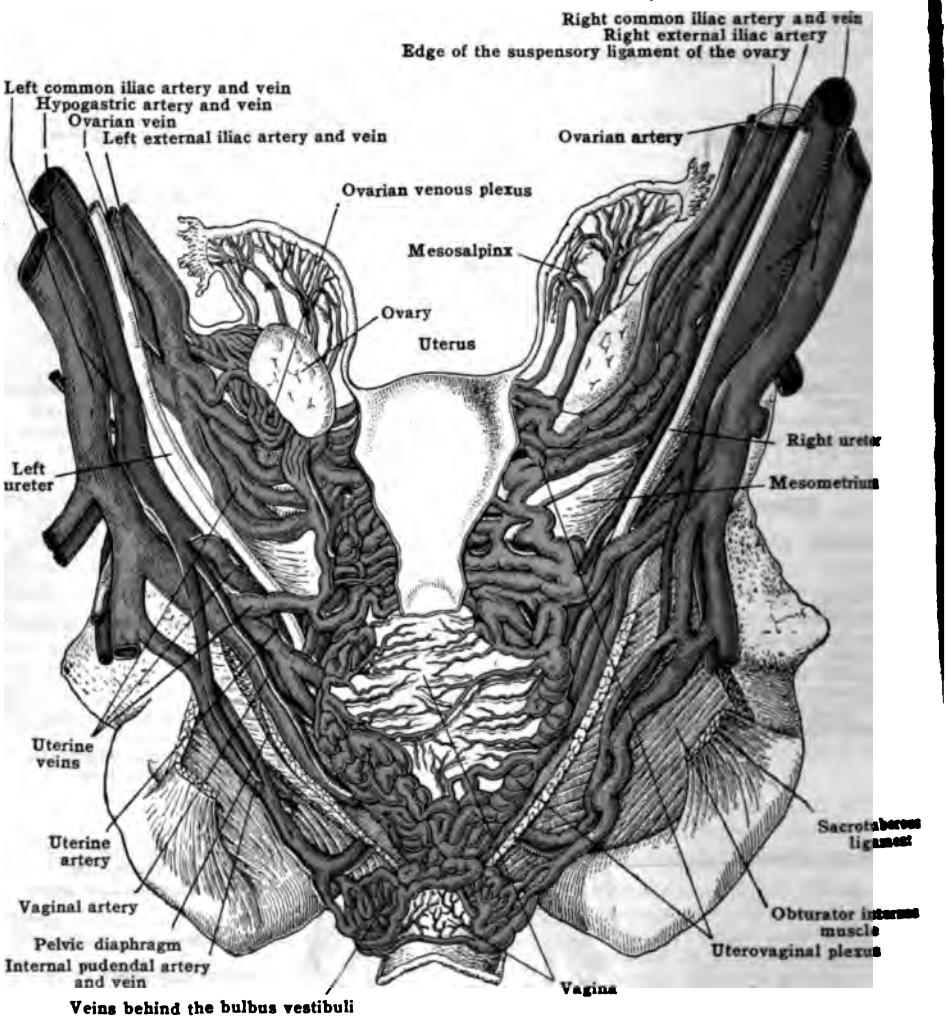
ributaries.—The vena cava inferior receives the following veins:—(1) the veins; (2) the right suprarenal vein; (3) the right spermatic or the right an vein; (4) the lumbar veins; (5) the inferior phrenic veins; (6) the hepatic (which indirectly receive blood from the portal); and (7) the right and ommon iliac veins.

) The **renal** veins [vv. renales] (fig. 570) return the blood from the kidneys.

They are short but thick trunks, and open into the vena cava nearly at right angles to that vessel. The vein on the left side, like the kidney, is a little higher than on the right, and is also longer, in consequence of its having to cross the aorta.

Each renal vein lies in front of its corresponding artery. The left vein crosses in front of the aorta, just below the origin of the superior mesenteric artery. It is covered by the inferior portion of the duodenum, and receives the left spermatic, or the left ovarian in the female, and usually the left suprarenal, and sometimes the left phrenic. There are rudiments of valves in each vein where it joins the vena cava. Those on the right side, however, are less well marked.

FIG. 571.—THE VEINS OF THE FEMALE PELVIS. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



(2) **The suprarenal** veins [vv. suprarenales] (fig. 570).—**There is usually only** one suprarenal vein on each side to return the blood **brought to the suprarenal** body by the three suprarenal arteries. On the **right side the vein opens directly** into the vena cava, above the opening of the right renal vein. **On the left side,** it opens into the left renal.

(3) The **spermatic** veins [vv. spermaticæ] (fig. 570) **return the blood from** the testes. They begin by the confluence of small branches **from the body of the** testis and epididymis. As they proceed up the spermatic cord, **in front of the** internal spermatic artery and ductus deferens, they **become dilated and plexiform,** constituting the **pampiniform plexus** [plexus pampiniformis] **(fig. 582).**

Veins. Along with the artery the veins pass up beneath the peritoneum, and on the left side also beneath the sigmoid colon, across the psoas muscle and ureter. They receive small tributaries from the ureter and peritoneum, and proceed as a single trunk, on the right side to the vena cava inferior, and on the left side to the left renal vein. There are commonly a number of imperfect valves in the spermatic plexus and a perfect pair at the termination of each spermatic vein. On the left side, however, the terminal valve may be wanting.

The **ovarian** veins [vv. ovaricæ] begin at the plexus pampiniformis near the ovary, between the layers of the broad ligament (figs. 525, 526, 571). This plexus is larger than in the male and communicates freely with the uterovaginal plexus of veins, and with the plexus of veins which extends from the hilus of the ovary into the ovarian ligament.

After passing from between the layers of the broad ligament, the plexus unites to form at first two vessels and then a single vessel, which accompanies the ovarian artery, following a course similar to that of the spermatic veins in the male. The right ovarian veins open into the vena cava inferior, the left into the left renal. They usually contain imperfect valves in their plexiform part, and a perfect valve where they join the vena cava and renal vein respectively.

(4) The **lumbar** veins [vv. lumbales], four to five on either side accompany the lumbar arteries and collect venous blood from the muscles of the back and abdomen.

They terminate by passing beneath the tendinous arches of the psoas major, along the sides of the lumbar vertebræ, and opening into the vena cava inferior. The veins of the left side are longer than those of the right and pass behind the aorta. Each vein receives a dorsal tributary corresponding in distribution to the dorsal branch of the lumbar artery. Between the dorsal tributaries and the posterior vertebral venous plexus there occurs a free communication. There is also an anastomosis between the main lumbar veins and the anterior vertebral venous plexus around the bodies and transverse processes of the lumbar vertebræ. By means of these communications the intervertebral veins, the internal and external vertebral and spinal plexuses are partly drained. In addition to these anastomoses the lumbar veins are connected with one another and with common iliac, hypogastric, iliolumbar, renal, azygos and hemiazygos veins by means of the *ascending lumbar veins* (p. 682).

(5) The **inferior phrenic** veins [v. phrenica inferior] follow the course of the inferior phrenic arteries; the right opens into the vena cava direct; the left into the suprarenal, the left renal, or the vena cava.

(6) The **hepatic** veins [vv. hepaticæ], the largest visceral tributaries of the vena cava, return the blood from the liver. Commencing in the substance of the liver (see LIVER), they converge as they approach its posterior surface, and unite to form two or three large trunks, which open into the vena cava as it lies in the fossa venæ cavæ.

Some smaller vessels from the caudate lobe, and other parts of the liver in the neighborhood of the caval fossa, open directly into the vena cava. The hepatic veins contain no valves, but, in consequence of opening obliquely into the vena cava, a semilunar fold occurs at the lower margin of each orifice. The hepatic veins transmit the blood brought into the liver by both the hepatic artery and the portal vein.

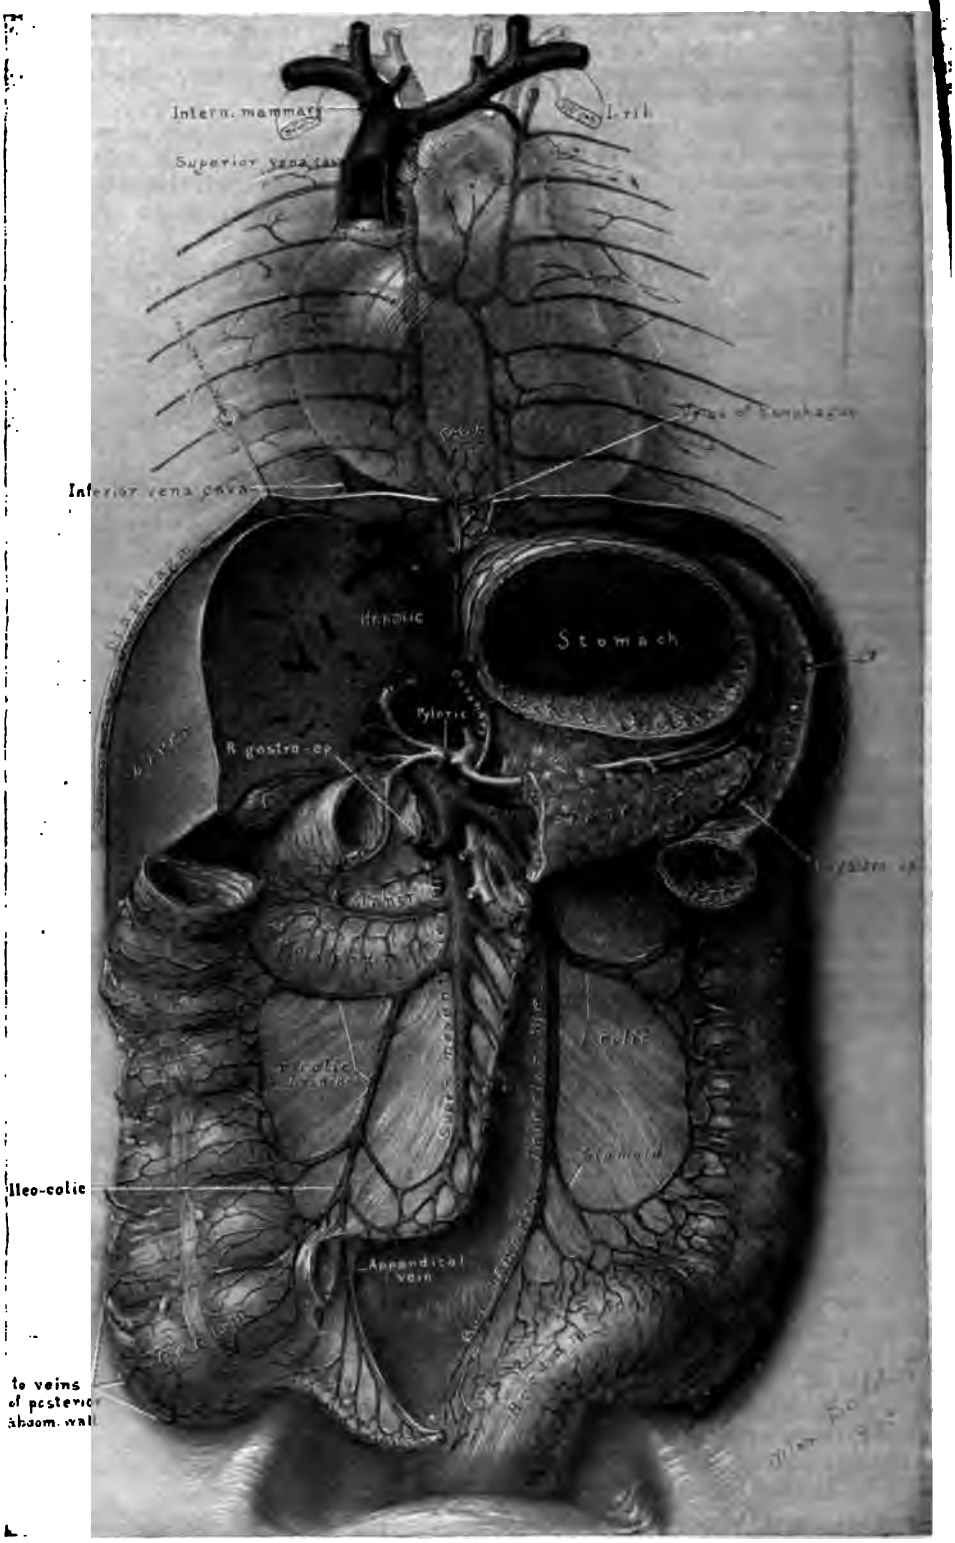
THE PORTAL VEIN

The veins corresponding to the inferior mesenteric, the superior mesenteric, and to some of the branches of the celiac artery, do not join the vena cava inferior directly, but unite to form a common trunk—the **portal vein.** This vein enters the liver, and breaks up in its substance into **sinusoids** from which the blood is again ultimately collected by the hepatic veins, and carried by them into the vena cava inferior. The portal vein and its tributaries have no valves.

The **portal** vein [v. portæ] (fig. 572), is a thick trunk 7 or 8 cm. (3 in.) in length. It is formed behind the neck of the pancreas, opposite the right side of the body of the second lumbar vertebra, by the union of the superior mesenteric with the splenic veins. It passes upward and to the right behind the superior part of the duodenum, and then between the layers of the lesser omentum. In the latter situation it passes in front of the foramen epiploicum and is accompanied by the hepatic artery and the bile-duct. Finally it enters the porta of the liver, and there divides into a right and a left branch.

In this course the hepatic artery and the common bile-duct are in front, the former to the left, the latter to the right. It is surrounded by branches of the hepatic plexus of the sympathetic nerve, and by numerous lymphatic vessels and some glands. The connective tissue sheath enclosing these structures is called the fibrous capsule of Glisson [capsula fibrosa, Glissoni]. Just before it divides it is somewhat dilated, the dilated portion being called the sinus of the portal vein. The division into right and left branches takes place toward the right end of the

FIG. 572.—THE PORTAL VEIN. (From Kelly, by Brödel.)



porta of the liver. The **right branch** is shorter and thicker than the left, and supplies the right **lobe** of the liver and a branch to the quadrate lobe. The **left branch** is longer and smaller than **the right**, and supplies the left lobe, and gives a branch to the caudate (Spigelian) and quadrate **lobes.** It is joined, as it crosses the left sagittal fossa, by a fibrous cord, known as the **ligamentum teres hepatis** (obliterated **vena umbilicalis**), and posteriorly by a second fibrous cord, the **ligamentum venosum** (obliterated **ductus venosus**). The position of the original course of the **umbilical** vein across the left portal is marked, in adult life, by a dilation of the latter vein, **called the umbilical recess** (fig. 573).

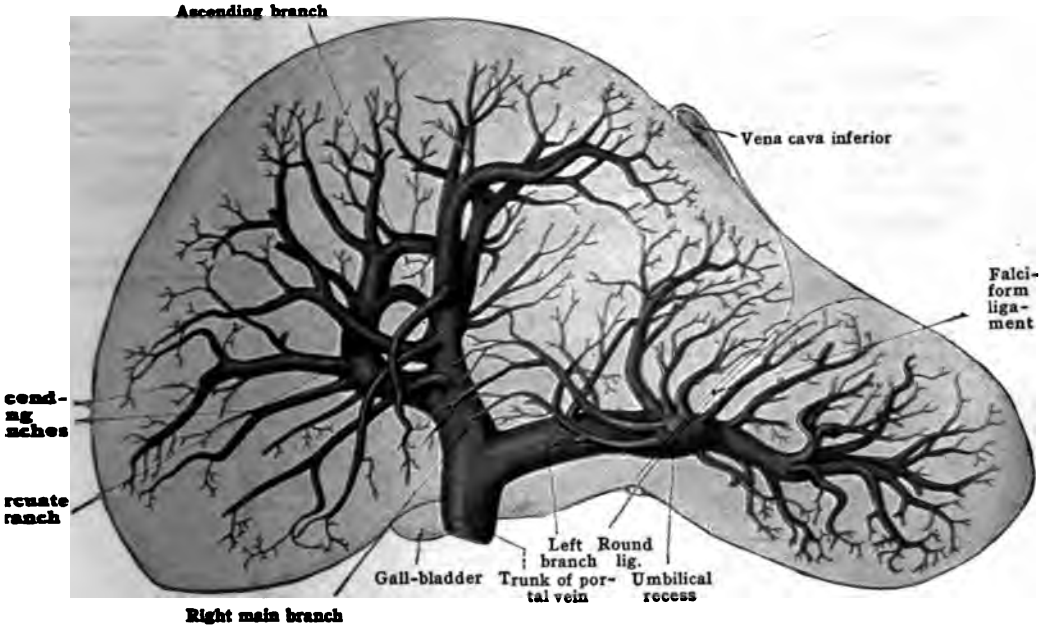
Tributaries.—The portal vein receives (1) the pyloric; (2) the coronary (**gastric**); (3) the cystic; (4) the superior mesenteric; and (5) the splenic veins.

1. **The pyloric** vein (figs. 572, 574) begins near the pylorus in the lesser curve of the stomach, **and,** running from left to right with the right gastric artery, opens directly into the lower part **of the portal** vein. It receives branches from the pancreas and duodenum.

2. **The coronary** vein [v. coronaria ventriculi] (figs. 572, 574) runs with the left gastric **artery,** first from right to left, along the lesser curvature of the stomach, toward the cardiac **end, and** then, turning to the right, passes across the spine from left to right to end in the **portal trunk** a little higher than the pyloric vein. At the cardiac end of the stomach it receives **small branches** from the esophagus.

3. **The cystic** vein [v. cystica] (fig. 574) returns the blood from the gall-bladder. It usually **opens into** the right branch of the portal vein.

FIG. 573.—THE PORTAL VEIN WITHIN THE LIVER. (After Rex.)



4. **The superior mesenteric** vein [v. mesenterica superior] (fig. 575) begins in **tributaries which correspond** to the branches of the superior mesenteric artery. **It courses upward a little** in front and to the right of the artery, passing with that **vessel from between** the layers of the mesentery. It passes in front of the **inferior portion of the duodenum,** and behind the pancreas, where it joins the **splenic vein to form** the portal trunk (fig. 572).

Tributaries.—In addition to the tributaries corresponding to the branches of **the superior mesenteric** artery—viz. the **ileocolic, right colic, middle colic** and **intestinal veins** (fig. 575)—it receives the **right gastroepiploic** and the **pancreatico-duodenal veins** just before its termination in the portal vein.

The **right gastroepiploic** vein [v. gastroepiploica dextra] (fig. 574) accompanies the artery of that name. It runs from left to right along the greater curvature of the stomach, receiving branches from the anterior and posterior surfaces of that viscus, and from the great omentum, and, passing behind the superior portion of the duodenum, ends in the superior mesenteric vein just before that vessel joins the portal trunk.

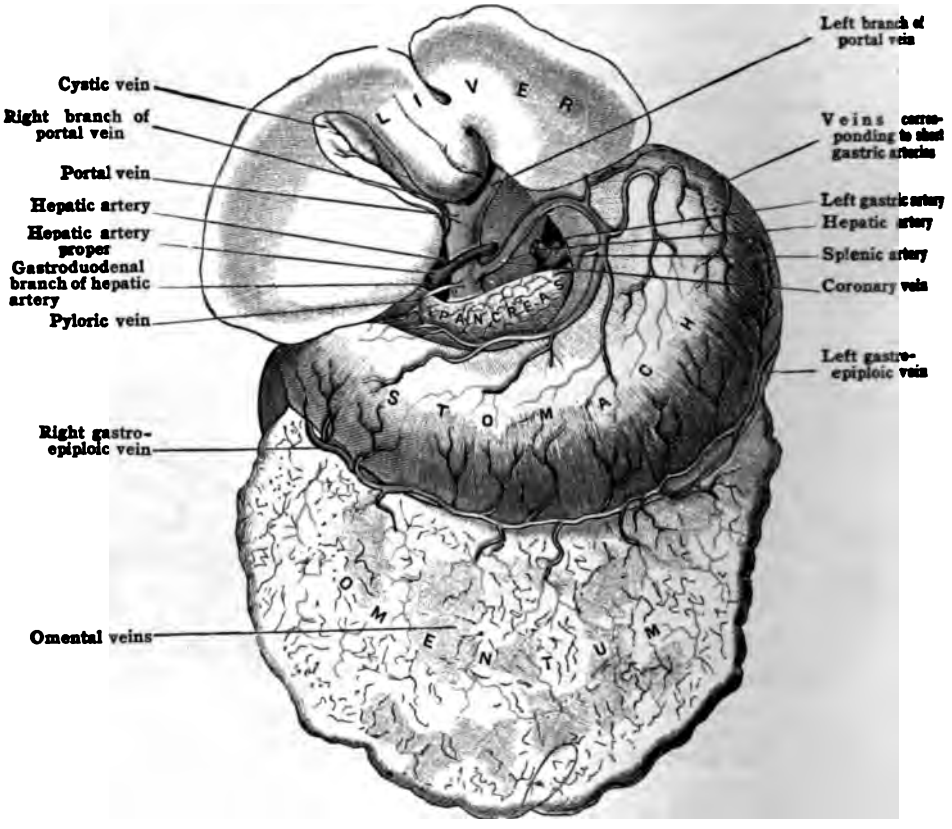
The **pancreatioduodenal** veins [vv. pancreaticoduodenales] (fig. 572) run with the superior and inferior pancreaticoduodenal arteries between the head of the pancreas and the second portion of the duodenum. They receive **pancreatic** and **duodenal** veins [vv. pancreaticæ et duodenales] and are collected into a single stem which follows the inferior pancreaticoduodenal artery and ends in the superior mesenteric vein a little below the right gastroepiploic vein.

5. The **splenic** vein [v. lienalis] (fig. 572) issues as several large branches from the hilus of the spleen. These soon unite to form a large trunk, which passes across the aorta and vertebral column in company with the splenic artery, below which it lies, to join the superior mesenteric vein at nearly a right angle. In this course it lies behind the pancreas; and at its union with the superior mesenteric to form the vena porta it is in front of the vena cava inferior.

Tributaries.—The splenic vein receives the **short gastric** veins [vv. gastricæ breves], from the fundus of the stomach, the **left gastroepiploic vein**, and the **inferior mesenteric** vein. As it lies in contact with the pancreas it receives also some small **pancreatic** veins [vv. pancreaticæ].

The **left gastroepiploic** vein [v. gastroepiploica sinistra] (fig. 574) accompanies the left gastroepiploic artery. It runs from right to left along the greater curvature of the stomach, receives branches from the stomach and omentum, and opens into the commencement of the splenic vein.

FIG. 574.—THE VEINS OF THE STOMACH AND THE PORTAL VEIN.
(From a dissection by W. J. Walsham.)

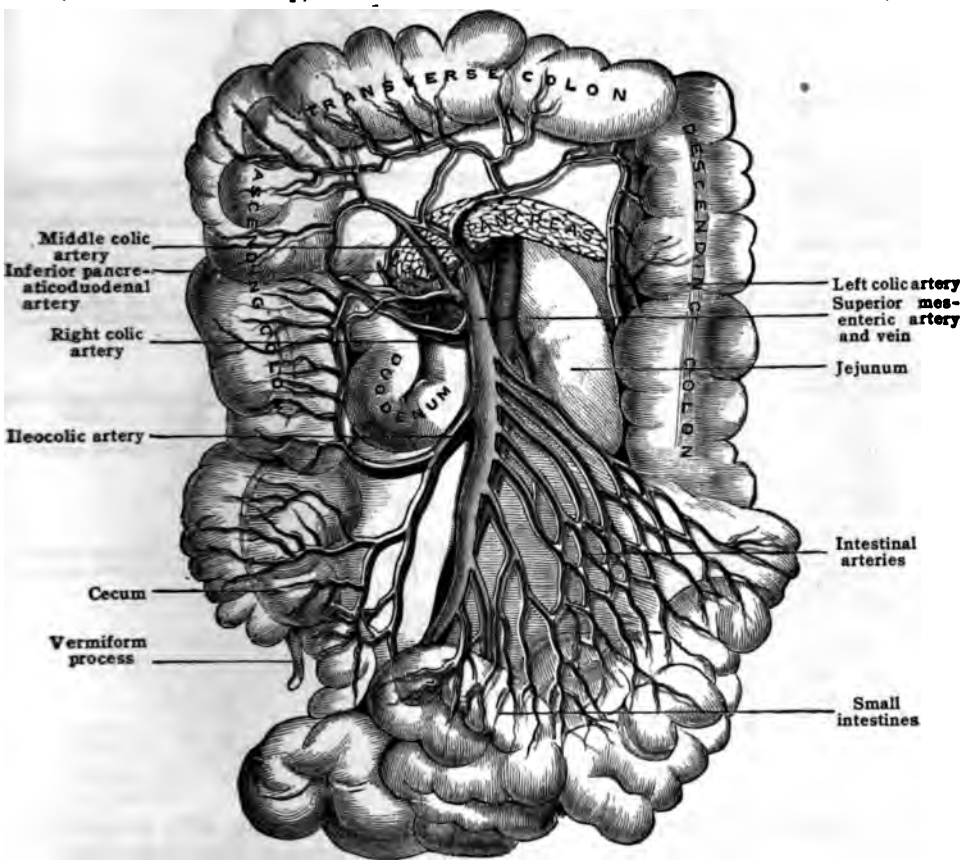


The **inferior mesenteric** vein [v. mesenterica inferior] (**fig. 572**) begins at the rectum as the superior hemorrhoidal vein. This emerges from the hemorrhoidal plexus in which it communicates freely with the middle and inferior hemorrhoidal veins. It passes out of the pelvis with the inferior mesenteric artery; but, after receiving the **sigmoid** and **left colic veins** [vv. sigmoideæ et v. colica sinistra] which accompany the arteries of the same names, it leaves the artery and runs upward on the psoas to the left of the aorta and behind the peritoneum. On approaching the pancreas it turns medially, and passes obliquely behind that gland to join the splenic vein just before the latter unites with the superior mesenteric to form the vena porta.

The adult portal vein and its tributaries contain no valves, a circumstance which adversely affects the circulation of blood within this system. The liability to excessive pressure in the most dependent part of the portal system is evidenced by the great frequency of the condition known as piles (hemorrhoids), due to dilation of the veins of the internal hemorrhoidal plexus. In early life valves are present in the veins of the stomach and of the intestinal wall but these undergo retrogression.

The accessory portal veins.—Since the blood returning from the abdominal portion of the digestive tract and spleen must pass through the hepatic capillaries before returning to the heart, extensive obliteration of these capillaries, such as occurs in certain diseases of the liver, would prevent the return of the portal blood to the heart were it not for anastomoses between tributaries of the portal vein and those of the caval systems, constituting what have been termed accessory portal veins. Some of the more important of these are—(1) between the branches of the coronary vein of the stomach and the esophageal veins which open into the vena azygos; (2) between the **parumbilical** veins [vv. parumbilicales], which communicate with the portal vein above and descend upon the ligamentum teres to the anterior abdominal wall to anastomose with the superior and inferior epigastric and superior vesical veins; (3) between the superior and middle hemorrhoidal veins, the latter opening into the hypogastric, and (4) between a wide-meshed retroperitoneal plexus of veins which communicates with the portal vessels over the posterior surface of the liver and the veins of the pancreas, duodenum and ascending and descending colon on the portal side, and with the phrenic and azygos veins on the systemic.

FIG. 575.—THE SUPERIOR MESENTERIC VEIN.
(The colon is turned up, and the small intestines are drawn over to the left side.)



THE COMMON ILIAC VEINS

The common iliac veins [vv. iliacæ communes], (fig. 577) are formed opposite the sacroiliac articulation by the confluence of the external iliac and hypogastric (internal iliac) veins. They converge as they ascend, and unite opposite the upper border of the fifth lumbar vertebra and a little to the right of the median line to form the vena cava inferior.

The right vein, shorter and more vertical in direction than the left, passes obliquely behind the right common iliac artery to its lateral side, where it is joined by the left common iliac vein.

The left vein lies to the medial side of the left common iliac artery, and, after crossing in front of the promontory of the sacrum and the fifth lumbar vertebra below the bifurcation of the aorta, passes beneath the right common iliac artery to join the right vein and form the vena cava inferior. The left vein may contain an imperfect valve.

Tributary.—The iliolumbar veins may enter the lower part of the common iliac, or open into the hypogastric vein. The left vein receives the middle sacral vein.

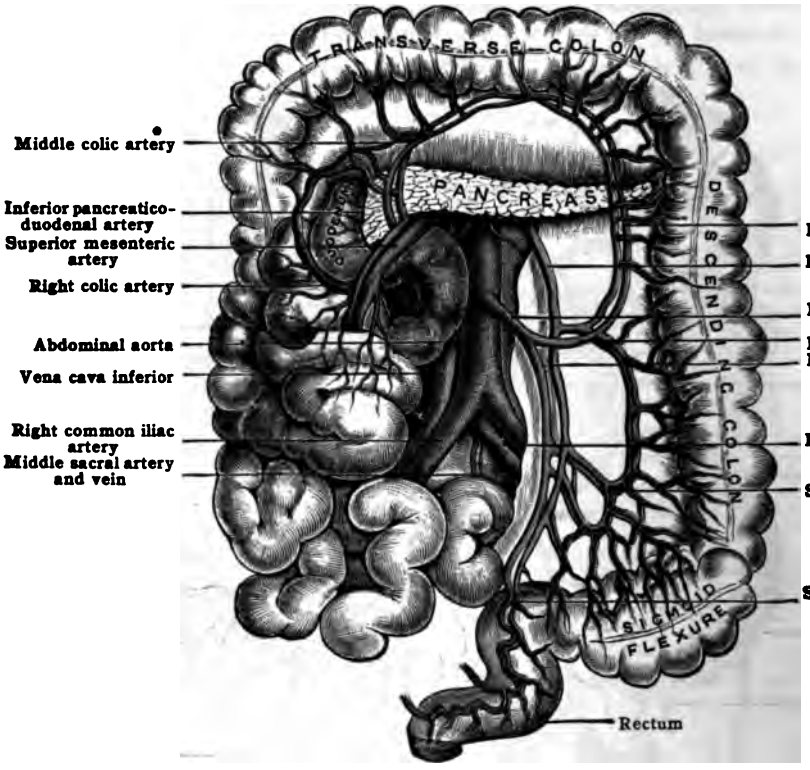
The middle sacral vein [v. sacralis media] opens usually as a single trunk into the left common iliac vein. The venæ comitantes which form it ascend on either side of the middle sacral

artery in front of the sacrum. They communicate with the lateral sacral veins, forming the anterior sacral plexus [plexus sacralis anterior] which receives the sacral intervertebral veins, and anastomoses freely with the neighboring lumbar and pelvic veins. Below, the middle sacral veins communicate with the hemorrhoidal veins.

THE VEINS OF THE PELVIS

The veins of the pelvis consist of the hypogastric vein, the spermatic or ovarian veins (according to sex) and the middle sacral vein. The spermatic and ovarian veins (p. 708) and the middle sacral vein have already been described.

FIG. 576.—THE INFERIOR MESENTERIC VEIN.
(The colon is turned up, and the small intestines are drawn to the right side.)



THE HYPOGASTRIC VEIN

The **hypogastric (internal iliac)** vein [v. hypogastrica] **(fig. 577)** is formed by the confluence of the veins (except the umbilical) corresponding to the branches of the hypogastric artery on each side. It varies considerably in length, but is usually quite a short trunk, extending from the upper part of the great sciatic foramen to the sacroiliac articulation, where it joins the external iliac to form the common iliac vein. It lies behind and a little medially to the hypogastric artery. It contains no valves.

Tributaries.—The hypogastric vein receives directly or indirectly the following vessels on each side:—the superior gluteal, iliolumbar, lateral sacral, obturator, inferior gluteal (sciatic), internal pudendal, and (in the female) the uterine veins; also branches from the pudendal, vesical, and hemorrhoidal plexuses. The single umbilical vein—corresponding to the right and left umbilical arteries—does not enter the pelvis, but, leaving the umbilical arteries at the navel, passes along the falciform ligament to the liver. After birth it is converted into the ligamentum teres hepatis. (See PORTAL VEIN, p. 711.)

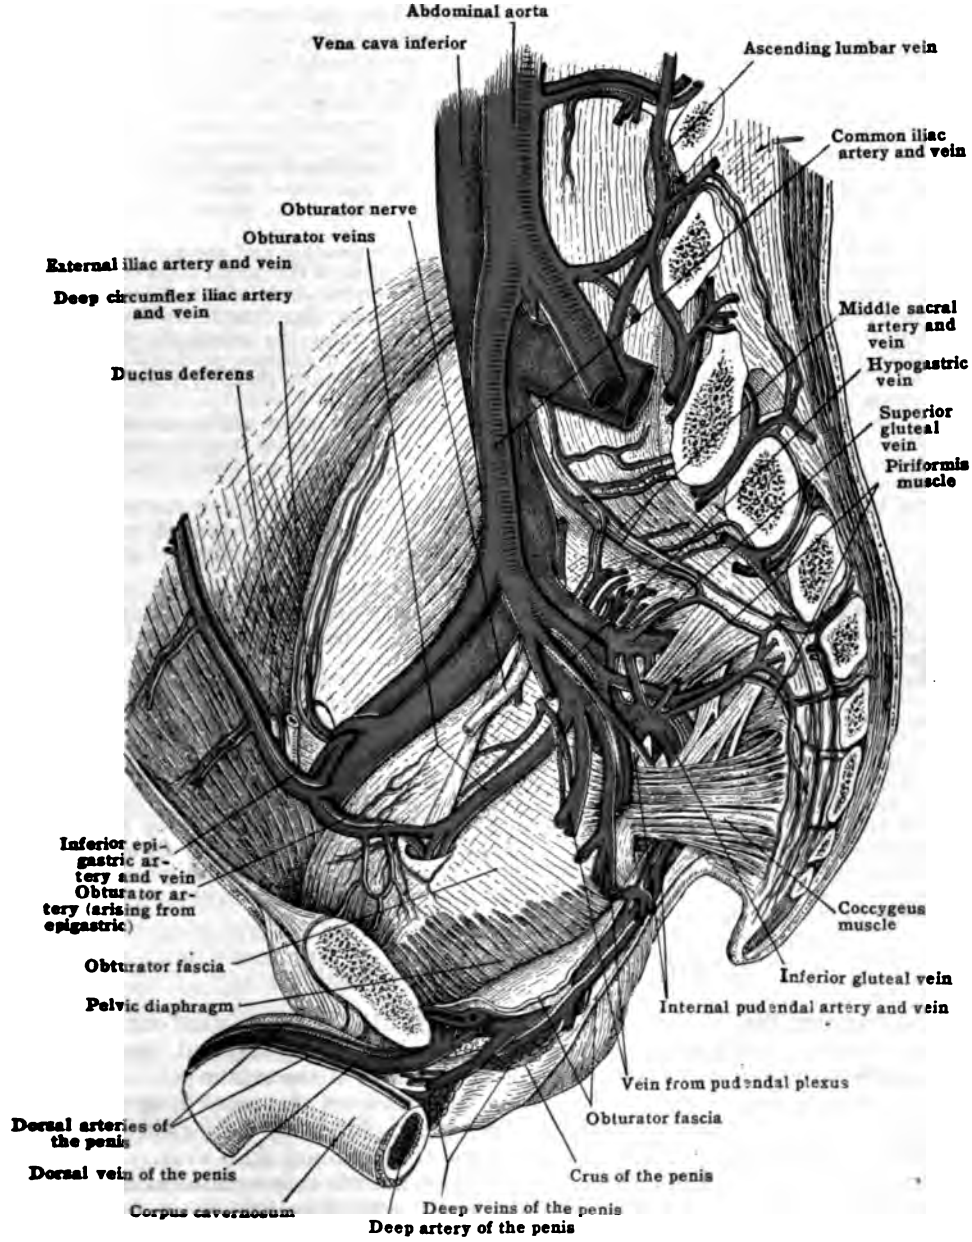
The superior gluteal veins [vv. glutææ superiores] (fig. 577) accompany the superior gluteal artery and, passing through the upper part of the great sciatic foramen, open into the hypogastric vein near its termination, either separately or as a single trunk.

The iliolumbar veins [vv. iliolumbales] open into the hypogastric a little higher than the superior gluteal. At times they join the common iliac vein.

The lateral sacral veins [vv. sacrales laterales] (fig. 577) join the superior gluteal or the hypogastric at or about the same situation as the gluteal. They form with the middle sacral veins a plexus in front of the sacrum, which receives tributaries from the sacral canal.

The obturator vein [v. obturatoria] (fig. 577), which lies below the obturator artery as it crosses the side of the pelvis, opens into the front of the hypogastric vein a little below the superior gluteal. Its branches correspond to those of the artery.

FIG. 577.—THE VEINS OF THE PELVIS, MALE. (After Toldt, 'Atlas of Human Anatomy, Rebman, London and New York.)



The inferior gluteal veins [vv. gluteæ inferiores] accompany the inferior gluteal (sciatic) artery, and, as a rule, unite to form a single trunk before joining the hypogastric a little below the obturator vein.

All the above veins so closely follow the ramifications of their respective arteries that no further special description is required. They all contain valves.

The **internal pudendal** vein [v. pudenda interna] (fig. 577) begins at the

termination of the deep veins of the penis [vv. profundæ penis] which issue from the corpus cavernosum penis with the artery of that body. These veins communicate with the dorsal vein at the root of the penis. In its course the internal pudendal vein runs with the internal pudendal artery, receiving tributaries corresponding to the branches of that vessel. It terminates in the lower part of the hypogastric vein.

The **dorsal vein of the penis** [v. dorsalis penis] (fig. 577) begins in a plexus around the corona glandis, then runs along the center of the dorsum of the penis between the two dorsal arteries. In this course it receives large tributaries from the interior of the organ, which, emerging for the most part between the corpus cavernosum urethra and corpus cavernosum penis, wind obliquely over the lateral surface of the latter structure to the dorsum of the penis to end in the dorsal vein. At the root of the penis the dorsal vein communicates with the subcutaneous veins of the dorsum of the penis and, leaving the arteries, passes straight backward between the two layers of the suspensory ligament. It then goes between the arcuate ligament and the transverse ligament of the pelvis, formed by the upper part of the fascia of the urogenital diaphragm. Here it bifurcates, each branch passing backward and downward to the pudendal plexus of veins. At times the dorsal vein begins as two branches, which run between the dorsal arteries and only unite to form a single trunk about 3.7 cm. ($1\frac{1}{2}$ in.) from the symphysis. After dividing into a right and a left branch within the pelvis, each vessel generally communicates with the obturator vein by a branch passing over the back of the pubis to the obturator foramen.

The **pudendal plexus** [plexus pudendalis] surrounds the prostate and the neck and fundus of the bladder. It receives in front the right and left divisions of the dorsal veins of the penis, and communicates with the posterior scrotal veins [vv. scrotales posteriores] and with the hemorrhoidal plexus. The prostatic veins and the vesical plexus open into it, and it also communicates with the internal pudendal vein. The veins forming the plexus are of large size, especially in old men, in whom they often become varicose, and contain phleboliths, or vein-stones. The plexus is surrounded by the *fascia prostata* (prostatic sheath); it terminates in a single stem on each side which opens into the hypogastric vein.

In the female the smaller pudendal plexus surrounds the urethra and receives the **dorsal and deep veins of the clitoris** [vv. dorsales et profundæ clitoridis], veins from the vestibule, and the **posterior labial** veins [vv. labiales posteriores]. It communicates freely with the uterovaginal plexus and is drained by the hypogastric veins.

The vesical plexus [plexus vesicalis] surrounds the apex, the sides, and the anterior and posterior surfaces of the bladder. It is situated between the muscular coat and the peritoneum, and where the bladder is uncovered by peritoneum external to the muscular coat in the pelvic cellular tissue. It opens into the pudendal plexus.

The **uterovaginal plexus** [plexus uterovaginalis] connects with the hemorrhoidal, vesical, and uterine plexuses. Its lower part drains through the internal pudendal veins and the pudendal plexus, and its upper portion largely through the ovarian veins, and partly through the **uterine veins** [vv. uterinæ] to the hypogastric (fig. 571).

The **hemorrhoidal plexus** [plexus hemorrhoidalis] surrounds the rectum, and is situated at the lower part of that tube. It consists of two portions, one of which, the internal hemorrhoidal plexus, is situated between the muscular and mucous coats, while the other, the external hemorrhoidal plexus, rests upon the outer surface of the muscular coat. The veins of this latter plexus terminate in the inferior, middle, and superior hemorrhoidal veins. The inferior [vv. hemorrhoidales inferiores] join the internal pudendal; the middle [v. hemorrhoidalis media] accompanies the middle hemorrhoidal artery and opens into the hypogastric and superior hemorrhoidal veins; the superior (p. 712) forms the commencement of the inferior mesenteric vein, and through this the blood gains the portal vein. None of these veins has any valves, hence the enlargement of the inferior hemorrhoidal veins, when the portal vein is obstructed, as in cirrhosis of the liver. Through the hemorrhoidal veins a free communication is established between the systemic and portal system of veins.

THE EXTERNAL ILIAC VEIN

The **external iliac** vein [v. iliaca externa] (fig. 577), is the upward continuation of the femoral. Beginning at the distal border of the inguinal ligament, it accompanies the external iliac artery along the brim of the minor pelvis, lying at first on the superior ramus of the pubis, and then on the psoas major muscle. It terminates by joining the hypogastric vein behind the hypogastric artery, opposite the sacroiliac articulation, to form the common iliac vein. It lies at first medially to the external iliac artery, and on the left side remains medial to the artery throughout its course. On the right side, however, as it ascends, it gradually gets behind the artery. It contains one or two valves.

In addition to the femoral, the external iliac receives the **inferior epigastric** veins [v. epigastrica inferior] (fig. 577) and the **deep circumflex iliac vein** [v. circumflexa ilium profunda] (fig. 582), which accompany the arteries of the same name. They anastomose with the superior epigastric, lumbar, iliolumbar, and superior gluteal veins, and with the superficial epigastric and superficial circumflex iliac veins.

THE VEINS OF THE LOWER EXTREMITY

The **veins of the lower extremity** are divided into (I) the superficial and (II) the deep. The **superficial** veins lie in the subcutaneous tissue superficial to the deep fascia, through which they receive numerous communicating branches from the deep veins. They are collected chiefly into two main trunks, which, beginning on the foot, extend upward, one, the great saphenous, lying anteromedially, and the other, the small saphenous, posterolaterally. The former finally joins the femoral vein by passing through the deep fascia at the groin; the latter reaches the popliteal by perforating the fascia at the ham. The **deep** veins, on the other hand, accompany their corresponding arteries. All the veins of the lower limb have valves which are more numerous than in the veins of the upper extremity and more numerous in the deep than in the superficial veins.

I. THE SUPERFICIAL VEINS OF THE LOWER EXTREMITY

The **superficial veins of the lower limb** begin in the plexuses of the foot. The **dorsal digital** veins [vv. digitales pedis dorsales] collect blood from the dorsal surfaces of the toes and unite in pairs, around each cleft, to form the **dorsal metatarsal** veins [vv. metatarseæ dorsales pedis]. The dorsal metatarsal veins, of which the first and fifth are larger than the others, join the **dorsal venous arch** [arcus venosus dorsalis pedis]. This arch is convex toward the toes and crosses near the bases of the metatarsal bones. From the medial and lateral ends of the arch the great and small saphenous veins, respectively, take origin. The area of the dorsum of the foot contained between the arch and the two saphenous veins is covered by the **dorsal venous rete** [rete venosum dorsale pedis] which extends as high as the ankle-joint (figs. 578, 580).

On the plantar surface the **plantar digital** veins [vv. digitales plantares] return the venous blood to the clefts of the toes and unite to form the **common digital** veins [vv. digitales communes pedis]. The common digital veins join freely with one another on the sole to form the **plantar venous rete** [rete venosum plantare]. There are numerous communications between the superficial veins of the dorsum and sole. These occur both in the clefts of the toes, by means of the **intercapitular** veins [vv. intercapitulares], and around the margins of the foot. Communications between the superficial and deep veins of the foot are very free (fig. 581).

The **great** (or internal) **saphenous** vein [v. saphena magna] (fig. 578) commences at the medial end of the dorsal venous arch, and, after receiving branches from the sole which join it by turning over the medial border of the foot, it turns proximally in front of the medial malleolus. It passes about a finger's breadth behind the medial border of the tibia in company with the saphenous nerve, which becomes superficial just below the knee. It then passes behind the medial epicondyle, and then runs up on the medial side of the front of the thigh to about 3.7 cm. (1¼ in.) below the inguinal ligament, where it dips through the fossa ovalis (saphenous opening) in the fascia lata, and ends in the femoral vein.

Tributaries.—In its course through the leg and thigh the great saphenous receives numerous unnamed cutaneous tributaries. In the thigh it often receives a large vein, the femoropopliteal which communicates with the small saphenous, and several of the cutaneous veins on the lateral part of the thigh, and a second vein, the **accessory saphenous** [v. saphena accessoria], formed by the union of the cutaneous veins from the medial and back part of the thigh (fig. 578). The great saphenous vein contains from ten to twenty valves.

Immediately before entering the fossa ovalis the great saphenous vein receives the superficial epigastric, superficial circumflex iliac, and external pudendal veins, though any of these veins—or all of them—may pierce the fascia separately and enter the femoral vein.

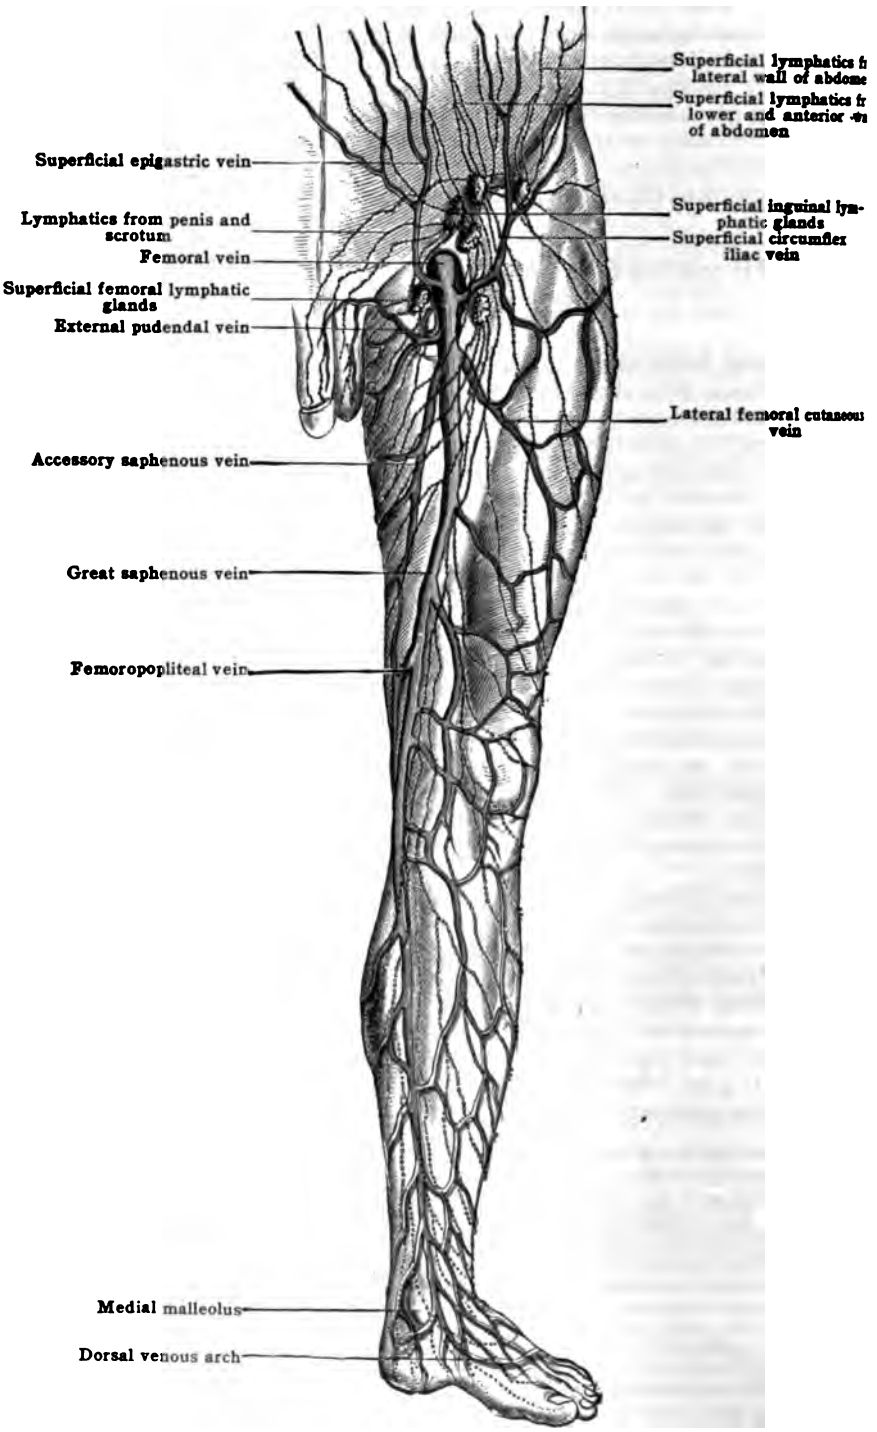
The **superficial epigastric** vein [v. epigastrica superficialis] anastomoses with the superficial abdominal, and parumbilical veins.

The **superficial circumflex iliac** vein [v. circumflex ilium superficialis] anastomoses with the thoraco-epigastric and the superficial circumflex iliac veins.

The **external pudendal** veins [vv. pudendæ externæ] collect venous blood from the **anterior scrotal or labial veins**, which anastomose with the posterior scrotal or labial veins, and from the **subcutaneous veins of the dorsum of the penis** [vv. dorsales penis subcutaneæ].

The **small saphenous** vein [v. saphena parva] (fig. 579) begins at the la end of the venous arch on the dorsum of the foot. After receiving branches the sole, which turn over the lateral border of the foot, it passes behind the la

FIG. 578.—THE SUPERFICIAL VEINS AND LYMPHATICS OF THE LEFT LOWER LIM (Walsham).

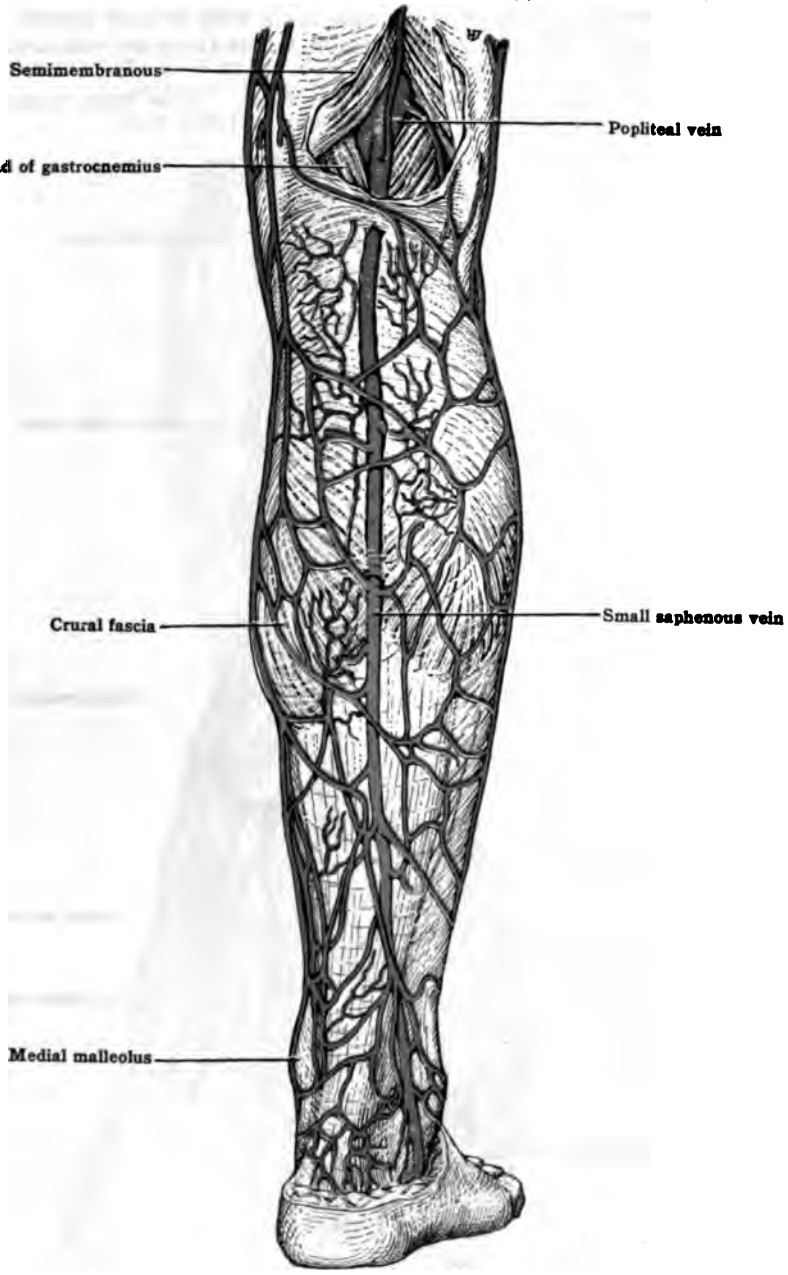


malleolus, and turns proximally, passing at first along **the lateral side of the calcaneus** (Achillis), afterward along the back of the **calf, in company wi ral** (short saphenous) nerve, to about the lower part of **the popliteal fossa,**

ates the deep fascia, and, sinking between the two heads of the gastrocne-
ens into the popliteal vein.

taries.—As it passes along the calf between the superficial and deep fascia, it receives
s cutaneous veins from the heel, and the lateral side and back part of the leg, and
icates at intervals, through transverse or intermuscular branches, with the deep veins

FIG. 579.—SMALL SAPHENOUS VEINS. (After Bonamy, Broca and Beau).

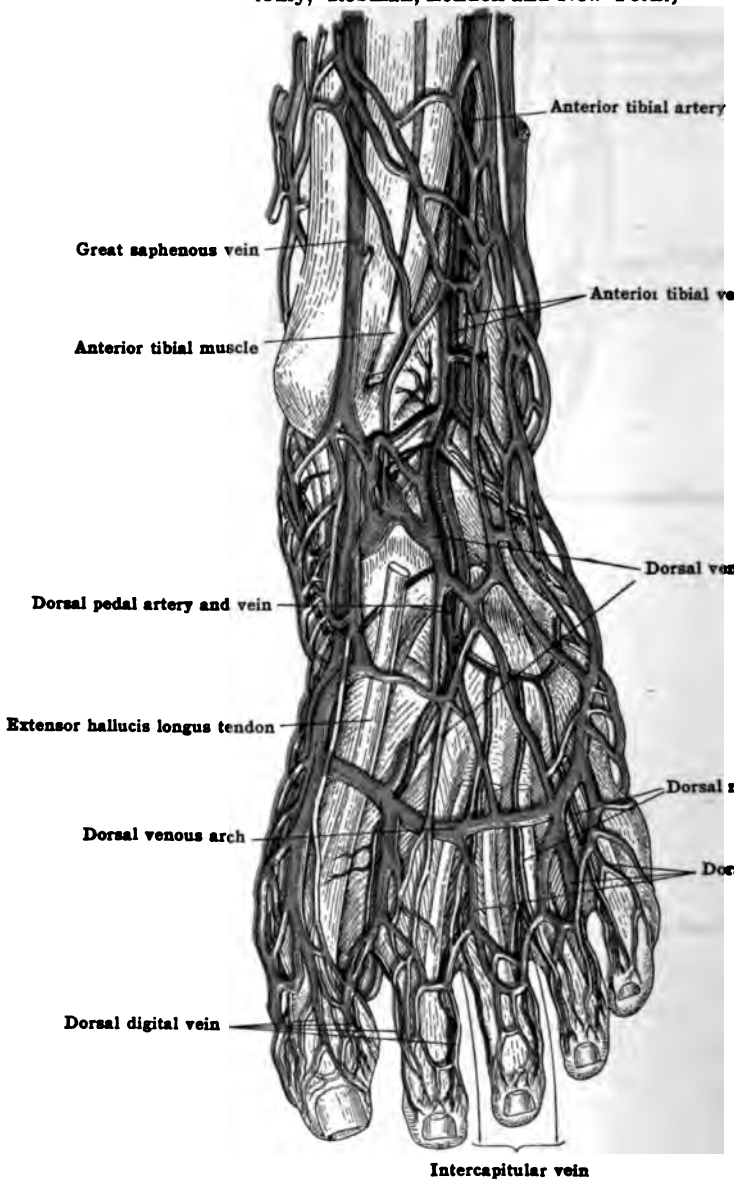


nying the peroneal artery. Just before perforating the deep fascia, it receives a large
ng branch, the **vena femoropoplitea** (fig. 578), from the lower and back part of the thigh.
mmunicates with a plexus of veins upon the posterior and lateral regions of the thigh and
great saphenous. In many cases the small saphenous vein is entirely drained, by means
moropopliteal, into the great saphenous. Under these circumstances the usual place
nation of the small saphenous is marked by a small vein opening into the popliteal. A
shoot from the inferior sural branch of the popliteal artery accompanies this vein for
listance along the back of the calf. The small saphenous vein contains from nine to
alves.

II. THE DEEP VEINS OF THE LOWER EXTREMITY

The **deep veins of the lower extremity** [venæ comitantes] accompany the arteries, and have received corresponding names. From the foot to the knee there are two veins to each artery. These veins run on either side of the corresponding artery, and communicate at frequent intervals with each other across it. From the knee upward there is a single main vein to each artery, except at the back of the thigh and in the gluteal region, where there are commonly two.

FIG. 580.—THE VEINS OF THE DORSUM OF THE FOOT. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



The veins of the foot and leg.—The deep veins of the foot become separated from the superficial where the plantar metatarsal veins [vv. metatarseæ plantares] leave the plantar digital and intercapitular veins to accompany the plantar metatarsal arteries. The plantar metatarsal veins empty into the plantar venous arch [arcus venosus plantaris] which accompanies the arterial plantar arch in the depth of the sole (fig. 581).

terior tibial veins [vv. tibiales posteriores] drain the plantar venous e superficial rete (fig. 583).

w the posterior tibial artery through the leg, receiving tributaries corresponding to the largest of which are the **peroneal veins** [vv. peroneæ]. They unite with the venæ comitantes at the lower border of the popliteus muscle.

rior tibial veins [vv. tibiales anteriores] begin in the dorsal venous rete any the anterior tibial artery through the leg receiving tributaries corto branches of the artery.

backward between the interosseous membrane and the tibia and fibula to unite terior tibial veins. The posterior and anterior tibial veins unite at the distal popliteus muscle to form the popliteal vein.

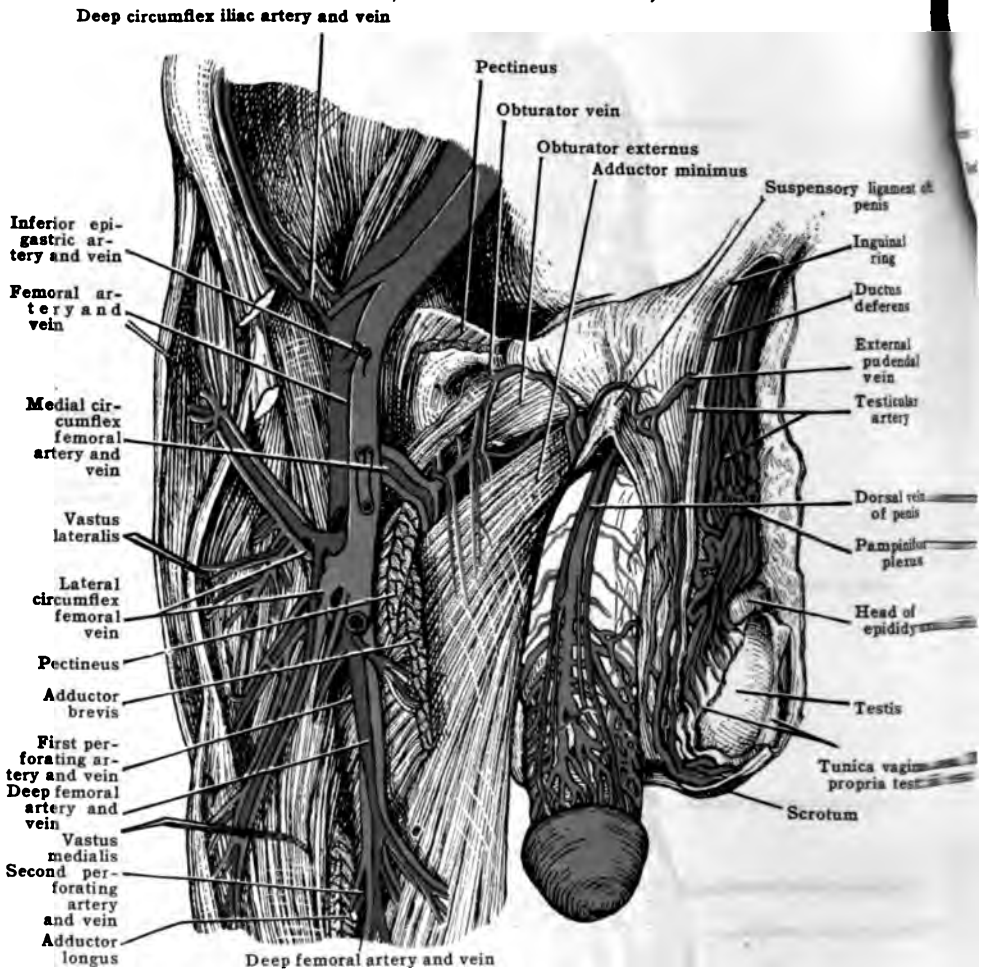
veins contain numerous valves, and communicate, by means of intermuscular h the superficial veins.

liteal vein [v. poplitea] (fig. 583), is formed by the confluence of the antes of the anterior and posterior tibial arteries at the distal border

of the popliteus, and extends proximally to the opening in the adductor magnus at the junction of the middle and distal third of the thigh, where it changes its name to femoral.

The popliteal vein accompanies the popliteal artery, lying superficial to it in the whole of its course, and tightly bound down to it by its fascial sheath. At the lower part of the fossa it is a little medial to the artery, but, crossing the vessel obliquely as it ascends, lies a little lateral to it at the proximal part of the fossa. The tibial (internal popliteal) nerve lies superficial to the vein, being lateral to it above, then posterior to it, and then a little to its medial side. The popliteal vein contains two or three valves.

FIG. 582.—VEINS OF THE THIGH, PENIS AND TESTIS. (After Toldt, 'Atlas of Human Anatomy', Rebman, London and New York.)



The popliteal receives the small saphenous vein. It is also joined on its lateral and medial sides by the *accessory popliteal* veins [vv. popliteæ accessoriæ] which form common trunks of termination of the sural and articular veins of the respective sides. The medial vein receives in addition, through a plexus extending as high as the opening in the adductor magnus, the veins accompanying the a. genu suprema.

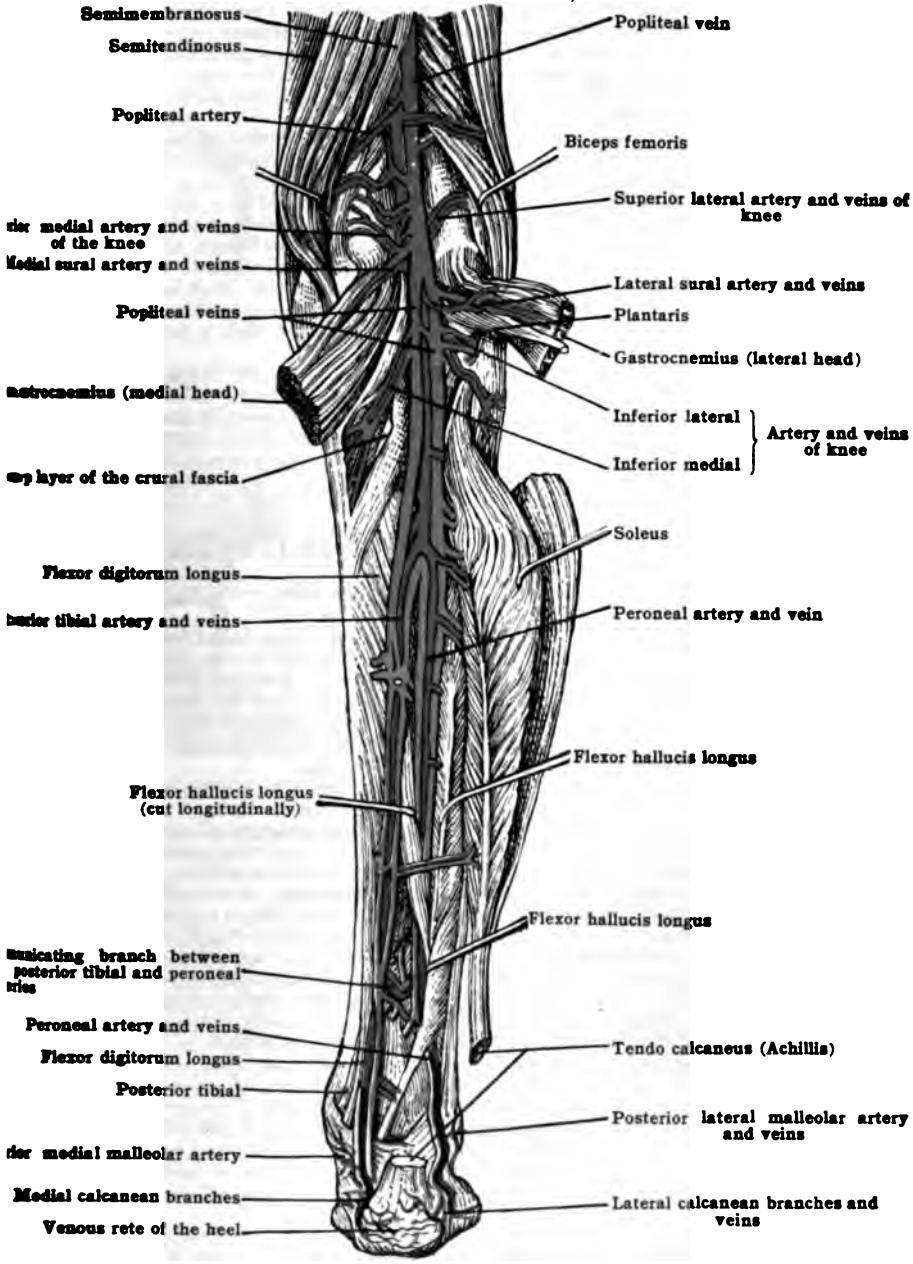
The **femoral** vein [v. femoralis], the continuation of the popliteal extends from the tendinous opening in the adductor magnus to the inguinal ligament. In this course its relations are similar to those of the femoral artery. As the vein passes through the adductor canal, it lies behind and a little lateral to the artery. At the apex of the femoral trigone (Scarpa's triangle) it is still posterior to the artery, but gradually passes to the medial side as it passes through the trigone (fig. 582).

In the neighborhood of the inguinal ligament the femoral vein lies on the same plane as the artery from which it is separated by a delicate prolongation of the fascia stretching between the front and back layers of the femoral sheath. On the medial side the vein is separated by a

r septum from the femoral canal. For relations of the femoral sheath and canal to femoral , see p. 1398. The femoral vein contains five pairs of valves.

ributaries.—The femoral vein receives (in addition to the great saphenous and, in some cases the superficial veins of the epigastrium and groin) the nda veins and a variable number of small femoral venæ comitantes.

83.—The Deep Veins of the Leg. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



e profunda femoris veins [vv. profundæ femoris] arise from the venæ comitantes correing to branches of the profunda femoris artery. The **medial and lateral circumflex** veins t blood from the muscles of the adductor and lateral rotator regions. The **perforating** anastomose with femoropopliteal and other veins of the posterior femoral region, and with rcumflex and accessory popliteal veins. They return blood from the femur and the tor, hamstring and vasti muscles.

addition to the main femoral vein, there are two very small **venæ comitantes,** which ipany the femoral artery on either side. They anastomose with one another, with the

femoral, and often with the popliteal vein. They terminate in the femoral a short distance above the profunda veins.

MORPHOGENESIS AND VARIATIONS OF THE VEINS

The developing heart, as soon as it has assumed the simple tubular form, is found to receive two pairs of veins, the vitelline and umbilical (fig. 34). The right and left vitelline veins return blood from the yolk-sac and reach the heart by traversing the splanchnic mesoderm. The single umbilical vein, which returns blood from the placental part of the chorion, reaches the embryo by way of the body-stalk. Before entering the body-wall it divides into two branches, each of which traverses the somatopleure of its own side to unite with the corresponding vitelline vein near the venous end of the heart. The heart thus receives two short common vitelloumbilical trunks which join the parts of the sinus venosus known as the right and left sinus-horns.

During the further course of development two pairs of veins appear which are entirely intraembryonic; they are the right and left precardinals and postcardinals. The precardinal veins drain the head and neck, while the postcardinals drain the trunk and developing extremities. Each precardinal vein joins the postcardinal vein of its own side to form a medially directed vessel called the common cardinal. Each common cardinal unites with the common vitelloumbilical stem of its own side. The two common cardinal veins, although they undergo a considerable amount of shifting, are recognizable until a relatively late stage of development, while the proximal parts of the vitelline and umbilical veins, on the other hand, are partially destroyed. The *duct of Cuvier*, the venous trunk which leads into either horn of the sinus venosus, probably includes the entire common cardinal vein together with a portion of the original vitelloumbilical trunk.

Little is known regarding the development of the PULMONARY VEINS. The efferent components of the embryonic capillary plexus from which the pulmonary arteries arise are probably connected with the left atrium. That these components occasionally form abnormal connections with systemic veins is indicated by some of the anomalies which may occur. One or other of the pulmonary veins has been found to open into the vena cava superior, into the left innominate, or into the vena azygos.

THE VENA CAVA SUPERIOR AND ITS TRIBUTARIES

1. MORPHOGENESIS

(*a*) **Vena cava superior.**—The *precardinal veins* at first return blood from the head and neck only (fig. 34). As the heart gradually migrates toward the thorax, however, relative positions become altered and the precardinal veins soon receive, through the subclavian veins, the blood returning from the upper extremities also. By the time the venous end of the heart has entered the thoracic region the Cuverian ducts no longer preserve their original transversely dorsoventral position. They begin to assume a longitudinal direction and become the proximal portions of the symmetrically placed venæ cavæ superiores.

At a stage of about 16 mm. the thymicothyroid veins, which open into the right and left precardinals, become connected and form a transverse venous channel between the two precardinal veins. This soon becomes a large vessel, and its presence allows of a revision of the nomenclature of the neighboring venous channels. The cross-branch itself becomes the major part of the *left innominate vein*. The part of the right precardinal which extends from the right extremity of the cross-branch to the proximal end of the right subclavian vein, becomes the *right innominate vein*, while the part extending from the cross-branch to the right duct of Cuvier becomes the distal portion of the right *superior cava*. On the left side the parts immediately above and below the cross-branch, become the left end of the left innominate and the distal portion of the left superior cava respectively. The left innominate vein rapidly increases in size and the right superior cava gradually usurps the function of the corresponding vessel of the left side. The left vena cava superior eventually disappears but evidences of its former presence are recognizable in the adult as the *oblique vein of Marshall* (p. 564).

(*b*) **The veins of the neck and upper extremity.**—The portion of the precardinal vein extending from the innominate vein to the base of the skull on either side appears to become divided longitudinally to produce the *internal jugular* and *vertebral* veins (Thyng). The former drains the dural sinuses, while the latter receives the segmental veins which drain the vertebral plexuses. The embryonic *linguofacial vein* drains the submental and anterior and posterior facial regions into the internal jugular veins (F. T. Lewis), and becomes the *common facial vein*. The *external and anterior jugular veins*, which appear relatively late in development, may take over parts of the original linguofacial area of drainage.

The veins of the *upper extremity* at first form part of the general superficial venous plexus of the neck and thorax, which is drained by the umbilical vein and by the cardinals. A marginal vein soon becomes apparent upon the free border of the developing limb, the preaxial and postaxial limbs of which are known as the radial and ulnar vein respectively. The drainage of the upper extremity and the chest is now taken over by a large channel which connects the ulnar vein with the precardinal. The ulnar vein receives the largest vein of the chest, the thoracoepigastric, while the radial vein becomes reduced to a plexus. The ulnar vein becomes the *basilic* and the *axillary vein*, the thoracoepigastric becomes the *lateral thoracic*. The *subclavian* vein replaces the original channel of connection between the ulnar vein and the precardinal. The *venæ comitantes* of the deep arteries of the limb, and the *cephalic vein* appear later in development; the latter at first opens into the external jugular.

ıe **venous sinuses of the dura mater** (fig. 584).—The forebrain and midbrain are **vested, at an early stage of development, by a plexus of capillaries which eventually** ›nverted into the circulus arteriosus and the cerebral and choroidal arteries and veins. **us is drained on either side by a vein which courses along the ventrolateral aspect of** ›rain and is connected by an occipital intersegmental vein with the corresponding **al.** The longitudinal vein which forms the first part of the drainage line of the fore-

l **midbrain has long been known as the** *v. capitis medialis*, for it lies upon the medial **e cranial ganglia.** It was formerly thought to pass, by a form of anastomotic migra- **he lateral side of the ganglia, and thus become converted into the** *v. capitis lateralis*. **wever, finds that these vessels are formed independently and substitutes for them the** ***a primitiva rhombencephali*** **and** *vena capitis prima*, respectively.
lexus formed from the vasa primitiva rhombencephali is fed by arterial offshoots of ı **arch system.** It is subsequently converted into the arteries and veins of the hind- **n addition to receiving the venous stem of the forebrain and midbrain plexus, the** **tis prima receives two other branches from the plexuses of the anterior and posterior** **he hindbrain, respectively.** By the time the three main tributaries of the *v. capitis*

prima are fully formed, the forebrain and midbrain plexus consists of a superficial part, which drains the dura, and of the original deeper part in which cerebral arteries and veins are undergoing differentiation. The blood entering the three tributaries is derived very largely from the dural layer of the head. On this account the terms *anterior*, *middle*, and *posterior dural plexus* have been substituted by Streeter for the terms anterior, middle and posterior cerebral veins (of Mall).

The main dural venous channels present in embryos of the stage of 4 mm., and the alterations in their arrangements which lead to the production of the adult arrangement, are indicated in fig. 584. It will be seen that at the stage of 18 mm. (C), a new connection has arisen between the middle and posterior plexuses; this, together with the stem of the posterior plexus, will become the sigmoid part of the *sinus transversus*. At the stage of 21 mm. (D), the anterior and middle dural plexus have coalesced to form the sagittal and tentorial plexuses. The part of the *v. capitis prima* upon the medial side of the trigeminal ganglion, now the *sinus cavernosus*, receives the *ophthalmic* and *middle cerebral* veins. The remainder of the v. capitis prima having been lost, the blood from the cavernous sinus drains into the transverse sinus through the *sinus petrosus superior*, originally the lower part of the stem of the middle plexus. The drainage of the entire venous system of the dura mater is now effected through the sinus transversus. During the succeeding stages of development (E and F) the *inferior petrosal sinus* appears and the sagittal plexus becomes differentiated into the *sagittal sinuses* and *sinus rectus*. The tentorial plexus becomes the *confluens sinuum* and the horizontal part of the s. transversus, its connections with the posterior dural plexus form the *sinus occipitalis*, and the plexus itself persists, in part, as the *marginal sinuses*.

(*d*) **The azygos system of veins.**—The azygos, hemiazygos, accessory hemiazygos and superior intercostal veins are the adult representatives of the thoracic portion of a pair of embryonic veins to which Huntington and McClure have applied the term *supracardinal*. The supracardinal veins pursue a longitudinal course through the abdomen and thorax lying dorsolaterally to the aorta. They take over the drainage of the lumbar and intercostal veins from the postcardinals which eventually disappear almost entirely. The right and left supracardinal veins intercommunicate in several places, the persistence of one or two communications, at about the level of the eighth thoracic segment, usually determines the eventual drainage of the larger part of the left supracardinal vein into the right. The latter vein is connected superiorly, through a small persisting portion of the postcardinal, with the right duct of Cuvier (vena cava superior); its intrathoracic part becomes the vena azygos. The part of the left supracardinal above the fourth thoracic segment becomes the *left superior intercostal* vein. The part of the supracardinal which now drains downward, and across into the azygos becomes the *accessory hemiazygos*, while the remainder of the intrathoracic portion of the left supracardinal becomes the *hemiazygos* vein.

2. VARIATIONS

(*a*) **Vena cava superior.** The connection between the embryonic thymicothyroid veins of the two sides may fail to persist. In this case both embryonic venæ cavæ will persist and each receive the subclavian and internal jugular vein of its own side, the innominate veins being absent. The left vena cava superior may coexist with the right even when the embryonic connection between them has appeared in the usual way. The innominate veins are present in such cases, but the left is commonly small. A left vena cava superior may altogether replace the right of the adult in association with *situs inversus* or as an independent variation. The left superior cava is formed from the left duct of Cuvier and the adjacent part of the left precardinal vein and joins the coronary sinus. The abnormal termination of the vena cava inferior into the vena cava superior is mentioned below under the azygos system.

(*b*) **Veins of the neck and upper extremity.** The comparative size of the two internal jugular veins depends upon the manner of drainage of the dural sinuses. Either *the anterior* or *the external* jugular vein may be absent. In such cases the *common facial* vein resembles more closely than usual the embryonic linguofacial from which it is derived. The external or the anterior jugular vein may, on the other hand, almost entirely replace the common facial; variations in the relative extent of the areas drained by these three veins are extremely common.

The *cephalic* vein may be absent, or it may cross the clavicle to enter the external jugular. The *lateral thoracic* (embryonic thoracoepigastric) may be very large. The *subclavian* vein occasionally passes between the subclavius muscle and the clavicle.

(*c*) **Venous sinuses of the dura mater.** The *superior sagittal sinus* may be partially reduplicated, or it may bifurcate at the lambda and follow the limbs of the lambdoid suture to join the lateral ends of the ss. transversi (Malcarne). It may be small, or altogether absent. In either case the s. rectus and s. sagittalis inferior are large and receive the superior cerebral veins through dilated channels in the falx.

An accessory sinus or series of sinuses in the falx may drain both the s. sagittalis inferior and the v. magna cerebri in cases in which the *s. rectus* is absent. The s. rectus may drain only the v. magna cerebri in cases in which the *s. sagittalis inferior* is absent, or, being present, is drained into the superior sagittal sinus by large veins of the falx.

The *transverse sinuses* may be equal in size when the confluens sinuum is large, or the horizontal part may be absent from one side. Both ss. transversi may be small in cases in which the *s. occipitalis* is large enough to carry most of the blood from the confluens to the *marginal sinuses* and so to the jugular veins. The occipital and marginal sinuses may be absent.

The variations mentioned above seem to afford instances of lack of uniformity in the selection of channels from amongst the many alternative routes afforded by a plexiform system. The appearance of the *s. petrosquamosus* depends, in all probability, upon the occasional persistence of an anterior tributary to the stem of the middle dural plexus.

(*d*) **The azygos system of veins.** Variations in the details of the drainage of the intercostal veins are very common. They are referable either to an increase in the number of transverse

[redacted]ections between the two embryonic supracardinal veins or to their entire absence. In [redacted]me cases, all of the left intercostal veins may terminate in the v. azygos, the hemiazygos [redacted] and accessory hemiazygos being entirely absent. In such cases the single azygos vein [redacted]lly opens into the vena cava superior; it may, however, open through a persistent left duct [redacted]Cuvier into the coronary sinus (Gruber). In the absence of the part of the vena cava in[redacted]ior normally derived from the right subcardinal connecting with the hepatic vein, the lower [redacted]rt of the vena cava may be continued into the azygos (Winslow, etc.), or into the hemiazygos [redacted]d so into the azygos (Quain), or into a left-sided azygos vein which opens into the coronary [redacted]us.

B. THE VENA CAVA INFERIOR AND ITS TRIBUTARIES

1. MORPHOGENESIS

The vena cava inferior is a vessel of a composite origin. The upper part of it receives the [redacted]patic veins, which contain the venous blood returning from the alimentary viscera; its devel[redacted]pment is described in connection with that of the portal system of veins. The lower part of [redacted]e vena cava inferior receives venous blood from the remainder of the abdominal viscera, and [redacted]rom the abdominal walls and lower extremities; its development is described with that of its [redacted]ributaries.

(a) The portal system of veins arises by means of a series of transformations which take place [redacted]in the vitelline and umbilical veins of the embryo. The proximal ends of the vitelline veins, [redacted]where they lie between the umbilicals, are early enveloped in, and invaded by, the growing

A B C

liver. The columns of liver cells, while not penetrating the endothelium, subject the vitelline veins to a process of fenestration by which the original channels are subdivided into innumerable smaller vessels or sinusoids. The *sinusoids* arising from the two vitelline veins intercommunicate to form a continuous network within the liver in which the vessels are larger in the afferent (portal) and efferent (hepatic) areas than in the intermediate zone.

The two umbilical veins now form communications with the portal area of the sinusoidal network and eventually lose their original connection with the sinus venosus (fig. 585). The fate of the umbilical veins differs on the two sides; the right degenerates, from the sinus venosus to the common umbilical vein, while the left persists to receive all the blood flowing from the placenta. The left umbilical vein, having lost its connection with the sinus venosus, discharges its blood partly into the portal sinusoidal zone, and partly, by means of a direct channel of new formation, the *ductus venosus*, into the right vitelline (fig. 585).

The hepatic portion of the left vitelline vein eventually loses its connection with the sinus venosus and becomes reduced to sinusoidal channels, while that of the right increases very considerably in caliber. The hepatic portion of the right vitelline now forms the only means of transit between the hepatic sinusoids and the sinus venosus of the heart, and is called the *common hepatic* vein. The main venous channels of the lower abdomen, having undergone a series of changes meanwhile, acquire a connection with the common hepatic vein, which thus becomes the upper part of the *vena cava inferior*.

The single vitelline vein of the yolk-stalk separates into right and left veins before entering the liver. In a position intermediate between the proximal and distal anastomoses between the right and left vitelline veins, which occur (ventrally to the intestine) within the liver and upon the yolk-stalk, respectively, a third connection appears on the dorsal aspect of the duodenum. The formation of the *portal vein* is effected by the disappearance of the portion of the right vitelline vein on the distal side of the dorsal connection and of the portion of the left vitelline upon the proximal side. The portal vein is joined by the *superior mesenteric* vein upon the left

side of the duodenum and by the *splenic vein* behind it; the portion of the common vitelline vein beyond the junction of the superior mesenteric with the left vitelline subsequently disappears.

(*b*) **The lower part of the vena cava inferior.** At an early stage of development the postcardinal veins are invaded by the growing Wolffian bodies and here become transformed into an intercommunicating system of sinusoids, which is drained by three longitudinal venous channels. One of these traverses the dorsal region of the organ, and retains the name postcardinal; one traverses the medial region and is called the *subcardinal* vein (F. T. Lewis). The third vein traverses the ventral region and does not share in the development of the vena cava inferior or its tributaries. The subcardinals are united across the median line, on a level subsequently occupied by the kidneys, by what is commonly known as the *renal anastomosis*, and each subcardinal receives a vein from the suprarenal gland and from the gonad of its own side. The postcardinal veins for a long time remain the chief drainage channels for the Wolffian bodies and for the iliac veins; they later, however, relinquish the drainage of the veins of the body-wall to a pair of veins of later formation, the *supracardinals* (Huntington and McClure, Am. Jour. Anat., vol. 6, 1907).

Each supracardinal vein pursues a longitudinal course near the dorso-lateral aspect of the aorta; it is connected with the postcardinal near the place of entry of the iliac veins, and extends to the anterior end of the postcardinal vein of its own side, into which it opens a short distance below the duct of Cuvier. The supracardinal veins intercommunicate at frequent intervals and eventually replace the thoracic portion of the postcardinal veins. A large communication between the supracardinal and the subcardinal vein occurs, at the level of the renal anastomosis, so that the aorta is surrounded by a venous ring, the renal collar.

The drainage of the left common iliac vein is now transferred by means of a cross anastomosis, to the right supracardinal, which becomes the part of the vena cava inferior below the renal anastomosis. The remainder of the vena cava inferior is formed from the right half of the renal collar, part of the right subcardinal vein above the renal anastomosis and a venous communication between this and the common hepatic vein. The embryonic components of the vena cava inferior become enormously enlarged and the left supracardinal vein diminishes in size.

As soon as the kidneys have attained their permanent position, the ureter is found to pass between the supracardinal vein and the postcardinal; the dorsal loop of the periureteral ring described by Hochstetter in 1893 is, therefore, a part of the supracardinal vein. Two veins (dorsal and ventral) leave each kidney to open into the corresponding side of the renal collar. The left ventral kidney-vein retains its connection with the renal anastomosis, forming the left renal vein of the adult. The ventral kidney-vein of the right side persists as the right renal vein of the adult, which opens into the vena cava inferior. The portion of the left subcardinal vein above the renal anastomosis becomes the left suprarenal vein. The corresponding portion of the right subcardinal vein forms a part of the vena cava inferior and the entire right suprarenal vein. The part of the postcardinal vein contained within the Wolffian body diminishes in size and forms a connection between the gonadic vein of each side and the corresponding subcardinal. Some part of the postcardinal vein persists, therefore, as the spermatic (or ovarian), the right opening into the vena cava inferior and the left into the left renal vein.

(*c*) **The veins of the lower extremity.** The superficial plexus of the developing limb is at first drained by the postcardinal and umbilical veins. It soon becomes condensed into a marginal vein, the fibular limb of which enters the pelvis as the hypogastric vein and continuing as the common iliac vein, joins the postcardinal. The external iliac vein grows from the common iliac, and forms a connection with the plexiform tibial limb of the marginal vein. This connecting branch receives the venous drainage of the thigh and lower abdomen and subsequently forms the proximal part of the femoral and great saphenous veins. The deep veins of the limb appear somewhat later. The popliteal takes over the distal part of the fibular marginal vein, which then becomes the small saphenous. The proximal part of the fibular vein is transformed into a plexus upon the back of the thigh, which is drained by the great saphenous vein and the hypogastric veins. The drainage of the common iliac veins is later transferred from the postcardinal to the supracardinal veins, and the upper part of the left common iliac vein is formed by an inter-supracardinal anastomosis.

2. VARIATIONS

(*a*) **The portal system of veins.** Major variations of the *portal system* of veins are practically unknown. In cases in which the lower part of the vena cava inferior is continued into the vena azygos, or into the v. hemiazygos in postnatal life, the common hepatic vein is smaller than usual and transmits blood from the portal system only.

(*b*) **The lower part of the vena cava inferior.** The left renal vein not uncommonly passes on the dorsal (instead of the ventral) side of the aorta. This condition is due to the persistence of the dorsal, and not the ventral, of the two embryonic kidney-veins which open into the left side of the 'renal collar.' The left suprarenal, and the left spermatic vein open, in such cases, into the vena cava inferior and not into the left renal vein.

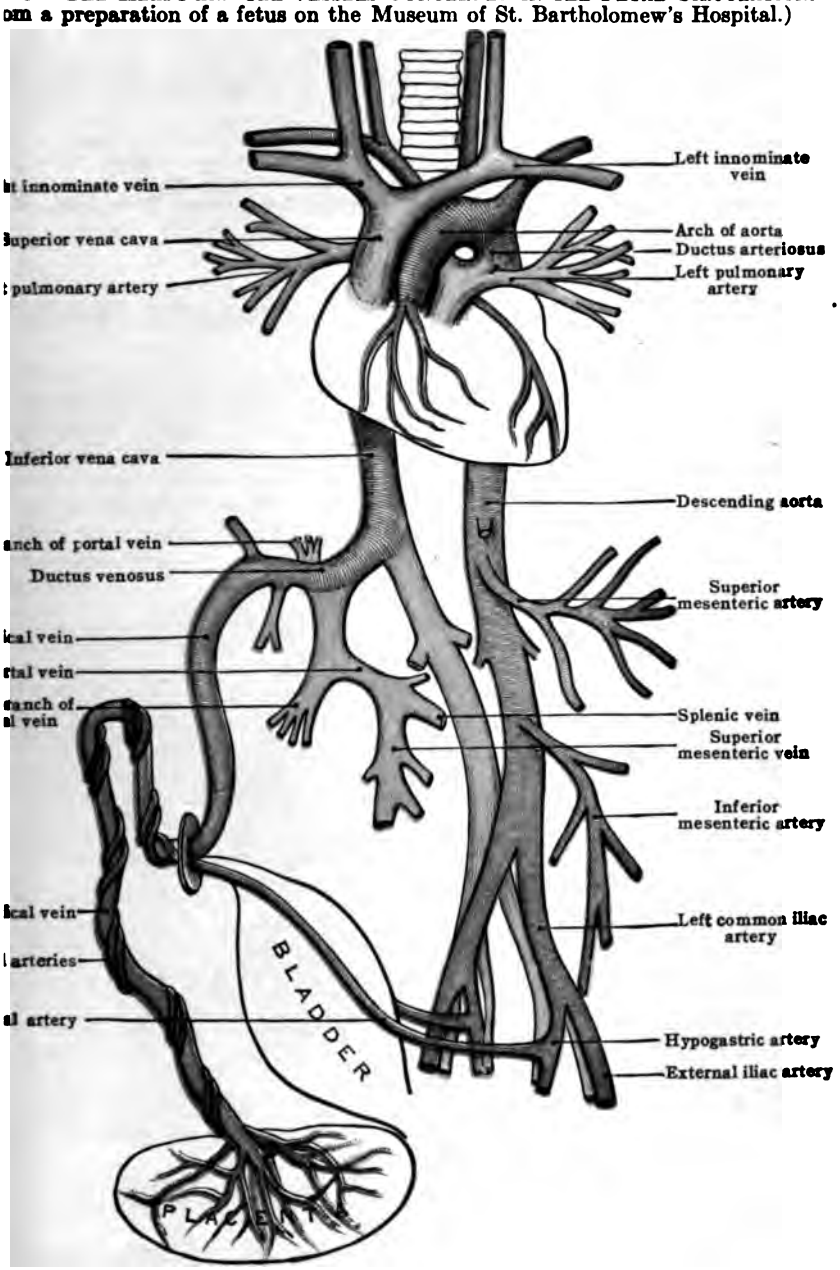
The *vena cava inferior* lies upon the left side of the aorta in cases of *situs inversus*, and in some cases without situs inversus. In the latter case the left supracardinal vein, instead of the right, has persisted below the level of the renal veins; the left inferior vena cava is continued across the front of the aorta and, receiving the left spermatic and the left suprarenal vein, passes to the right atrium in the usual way. There are occasionally two venæ cavæ, one on each side of the aorta; the two persisting supracardinal veins are united, in such cases, by the embryonic renal anastomosis. In all cases in which the left vena cava is present, with or without a right, the part which crosses the aorta is derived from the embryonic renal anastomosis and, therefore, corresponds in origin to the proximal part of the left renal vein.

Cases of dissociation of the embryonic antecedents of the vena cava inferior have already been mentioned (see azygos system). The venous blood from the lower part of the vena cava

such cases finds an outlet through the thoracic portion of one of the supracardinal

al vein of either side may open into the common iliac, particularly in cases in which is lower than usual. The vein of a pelvic kidney may open into the middle sacral ny interesting anomalies of a less striking character may occur.

586.—THE HEART AND THE VESSELS CONCERNED IN THE FETAL CIRCULATION. om a preparation of a fetus on the Museum of St. Bartholomew's Hospital.)



e veins of the lower extremity. Major variations of the veins of the lower extremity nmon. The small saphenous vein is frequently continued upon the back of the thigh, thout communication with the popliteal. It is drained in such cases into the great , either by means of a plexus or through a definite femoropopliteal vein.

SECTION VII

THE LYMPHATIC SYSTEM

REVISED FOR THE SIXTH EDITION

BY ELIOT R. CLARK, A.B., M.D.

PROFESSOR OF ANATOMY, UNIVERSITY OF MISSOURI

I. GENERAL ANATOMY OF THE LYMPHATIC SYSTEM

THE blood-vascular system has, as a part of its function, the collection of substances from the various tissues of the body which are to be conducted to the other tissues. In carrying on this function it is assisted by a second system of collecting vessels, the lymphatics. The lymphatic system consists of a set of closed vessels which start as closed capillaries in the various organs and tissues, continue as closed vessels, pass through lymph-nodes in which the vessels break up into capillaries and spaces separated from the outside fluid by endothelium, and again collect into closed vessels, which eventually terminate in the veins of the neck.

This second system resembles the blood-vascular system in many ways, but differs markedly in others. Like the blood-vascular system, it is made up of minute endothelial-lined capillaries, where the absorption of substances occurs, and of larger conducting vessels. It differs from the blood-vascular system in two important particulars. While the blood-vascular system is provided with a pumping mechanism by which its fluid content is driven through a complete circuit from the heart, through artery, capillary, vein and back to the heart, the lymphatics merely conduct fluid *from* the capillaries to the larger vessels, which eventually empty their contents into the large veins of the neck. The second important difference between the two systems is found in the presence, along the course of the lymphatic vessels, of glands or nodes (fig. 590) [lymphoglandulæ] in which the vessels branch out into lymph-capillaries. These are lined, as are the absorbing capillaries, with a single layer of endothelial cells, thus permitting an interchange of substances between the contents of the lymph-capillaries and the lymphoid tissue around them.

Our present knowledge does not permit an exact statement of the complete extent of the lymphatic system. While, in a general way, the lymphatics may be said to be present wherever blood-capillaries occur, there are certain tissues where lymphatics have not been definitely demonstrated. The *tissue-spaces* outside the lymphatic endothelium, which are filled with a fluid or semifluid material, which has often been termed 'lymph' but which would better be termed 'tissue-fluid, are not part of the lymphatic system. Similarly, the various serous cavities —pleural, percardial, synovial, cerebrospinal, etc.—while they may serve, as in the case of the cerebrospinal spaces and the intraocular spaces, a somewhat similar function, are not considered as parts of the lymphatic system.

The general constitution of the lymphatic system will be considered under three heads—(1) the capillaries, (2) the collecting vessels and (3) the lymphoid organs.

1. *THE LYMPHATIC CAPILLARIES*

The lymphatic capillary, like the blood-capillary, is the portion of the lymphatic system which is chiefly concerned in the specific function of this system. In the blood-capillaries, where the blood is separated from the outside tissues by a single layer of flat endothelial cells, there occurs the interchange of fluid substances and of cells, while the heart, arteries and veins serve to transport the blood, modified in the capillaries, to other parts of the body. Similarly in the lymphatic system, it is in the capillaries, both those most peripheral and those in the lymph nodes, where the absorption and interchange of fluid substances and of cells takes place. Consequently it becomes of prime importance to obtain a clear understanding of the structure of the lymphatic capillaries, their relation to the other

tissues, and their mode of functioning. At the outset, however, it must be admitted that our knowledge on this subject is far from complete.

Historical.—Previous to the development of microscopic anatomy, in the middle third of the 19th century, there was no accurate knowledge of such small structures as the lymphatic capillary. In order to explain the absorption of substances by the lymphatics, as well as the passage of substances from the blood-vessels through the tissues, various theories were invented. Prominent among such theories was that of the 'vasa serosa,' of H. Boerhaave and other 18th century anatomists and physiologists, which was perhaps most elaborately developed by Bichat, 1801-03. According to this theory there are two sets of minute vessels. The one set leads from the blood-capillaries onto the various surfaces and into the loose spaces in the tissues—the 'exhalants.' The other set leads from the body surfaces (including the serous cavities) and the loose spaces in the tissues to the lymphatics—the inhalants or 'absorbants.' This theory was somewhat shaken by the criticism of early 19th century anatomists who developed the technic of injection of lymphatics to a high point.

Our present conception of the lymphatic capillaries may be said to have started with Kölliker who, in 1846, saw, with the aid of the microscope, the lymphatic capillaries in the transparent tails of living frog larvæ. Like Schwann who, in 1837, had studied the blood-capillaries in the tail of the frog larva, he erroneously supposed that the fine processes of the lymphatic capillaries were continuous with similar processes of the surrounding connective tissue cells. Since, according to the conception current at the time, cells were thought to be hollow structures, it was concluded that the mode of transmission of fluid from blood to lymphatic capillary took place through canaliculi inside these cells. This conception was elaborated by Virchow, in his Cellular-Pathologie.

In 1862 von Recklinghausen by means of the silver nitrate staining method discovered that the lymphatic vessels are lined with an endothelium made up of flattened cells whose outlines show as fine dark lines after this treatment. Von Recklinghausen, however, held that unstained parts outside the lymph-vessels represent a system of irregularly shaped lymph-canaliculi ('Saftkanälchen') which are in open communication on one the hand with the blood-capillaries, and on the other with the lymphatics. This conclusion has since been disproved by numerous investigators.

Von Recklinghausen also described open communications ('stomata') between the lymphatics and the peritoneal cavity. Cohnheim described similar though smaller openings in blood-capillaries, and His described them in other lymphatic capillaries. Arnold termed the openings in the vessels 'stigmata,' as distinguished from the openings into the peritoneal cavity, or 'stomata.' More recent investigators (Kolossow, A. W. Meyer, W. G. MacCallum) have failed to find these 'stomata.' Careful studies of the lymphatic capillaries in the transparent tails of living frog larvæ, which may be clearly seen with the higher magnifications of the microscope, show that the endothelial lining of these capillaries is complete, with no trace of an opening into the spaces in the tissue outside (E. R. Clark).

With the advent into microscopical technic of the various dyes for staining cell-nuclei and protoplasm, and the more precise methods for making histological studies, the endothelial wall of the lymphatic capillary has been definitely established, although much remains to be learned concerning the differences between the lymphatics of the various tissues.

Form.—The shape of the lymphatic capillaries has been found to vary enormously in the different parts of the body where they have been studied. In general they form richly anastomosing plexuses, from which may extend cul-de-sacs, which end blindly. Such cul-de-sacs are especially noticeable in the dermal papillæ, in the filiform papillæ of the tongue, and in the intestinal villi. The plexuses are often present in two layers—a superficial and a deep. The vessels of the superficial plexus are of smaller caliber than those of the deep. These two sets of plexuses are particularly well seen in the skin and the gastrointestinal tract. In relation to the blood-capillaries, the lymphatic capillaries are generally the more deeply placed. In caliber, unlike the comparatively uniform diameter of blood-capillaries, the lymphatics vary enormously. In the same capillary a very narrow part may be succeeded by a very wide one (figs. 587, 588). Teichmann found lymphatic capillaries varying in diameter from a few micra to one millimeter or more. The capillaries are without valves.

Activity.—That the lymphatic endothelium is not exclusively a passive membrane has been shown by Clark in studies on the lymphatics in the transparent tails of living frog larvæ. The lymphatics here are seen to send out protoplasmic processes which, somewhat like an ameba, actively take into the interior of the lymphatic red blood-cells accidentally forced from the blood-capillaries into the tissue-spaces. The mode of passage of leucocytes into or out of the lymphatics offers no such difficulties as that of the fluids, for they are able, by ameboid movement, to pass independently through the endothelium—a process first directly observed by Cohnheim.

1. The Extent and Character of Lymphatic Capillaries

The *skin* over the entire surface of the body is richly provided with lymphatic capillaries. They form two sets of plexuses in the dermis, a superficial and a deep. The superficial set sends out blind cul-de-sacs into the dermal papillæ. The richest skin plexuses are found in the scrotum, the palms of the hand and palmer side of the fingers and in the soles of the feet and plantar side of the toes. In the loose *subcutaneous* fascia, according to Teichmann, there are present only the larger collecting vessels, with no lymphatic capillaries. Lymphatic capillaries of the *scrotum* are shown in fig. 587.

The *conjunctiva*, both the sclerotic and corneal, is supplied with a rich plexus of capillaries, which are narrower in the corneal than in the sclerotic portion. At the corneal border the capillaries form a fairly regular ring which has been called by Teichmann a circulus lymphaticus.

.t the various *orifices* of the body, the skin plexuses go over into the mucous plexuses, ing anastomoses with them. Throughout the entire *alimentary tract*, including the nasal .ies, the lymphatic capillaries form extensive plexuses which are in many places divided a superficial plexus in the mucosa and a deeper plexus in the submucosa. In portions pro- d with a peritoneal covering, there is a third rich subserous plexus. In the tongue and the l intestine the plexus in the mucosa sends out blind cul-de-sacs; in the tongue into the rm papillæ; in the small intestine into the villi. Where muscle is present along the ali- tary tract, the lymphatics pass between the muscle bundles, but form no plexuses around a.

The lining of the *tracheal* and *bronchial passages* is supplied with a double plexus of lym- ic capillaries, a mucous and a submucous set, which vary in richness according to the loose- of the tissue. In the smaller bronchi but a single layer of capillaries is present, and, ac- ing to Miller, no capillaries are present around the air cells. Plexuses surround the pul- ary arteries and veins. Under the *pleura* lie rich plexuses which connect with deeper phatics around the veins only in places where the veins reach the surface of the lung. Concerning the arrangement of the lymphatic capillaries in the *glands* derived from the entary tract much remains to be learned. The *salivary glands* have been studied by aard, who has found lymphatic capillaries accompanying the blood-vessels into the interior he lobules, and forming here irregular plexuses.

The *thyroid gland* contains lymphatic plexuses which lie in relation to the colloid-con- ing alveoli. Direct connection between the lymphatics and the alveoli has been described Matsunaga, but this observation needs verification. The lymphatics are apparently erned in the absorption of the colloidal secretion, for traces of it have been found in the phatics draining the gland.

587.—The Lymphatics of the Scrotum. (After Teichmann.) Showing the transition of the capillaries to the vessels with valves (*a*, *a*, *a*).

Concerning the lymphatics of the *parathyroids* nothing is known.

The course of the lymphatics draining the *thymus* has been recently described, but the re of the capillaries in this gland is unknown.

The lymphatic capillaries of the *liver* are of great importance, for the lymph which flows this organ forms a very considerable part of the total lymph which is collected into the atic duct. And yet very little is definitely known about the nature and distribution of the phatic capillaries in the interior of the organ. In the capsule there is a rich plexus, lying er the peritoneum, in which very large widenings have been described (called by Teichmann aphbehälter'). In the interior rich plexuses surround the branches of the hepatic artery portal vein (fig. 589), and plexuses have been described accompanying the branches of the al vein into the lobules. The path from blood-capillary to lymphatic in the perilobular es is more open than has been found in other organs, for Mall has found that if very finely ular masses are used, and are injected through portal vein or hepatic artery under mild sure, the granules pass over into the lymphatics. Moreover, the lymph from the liver is er in proteins—more like the blood serum—than is the lymph from other organs.

The linings of the large *bile-ducts* and the *gall-bladder* are provided with a submucous network mphatics (Sudler and Clermont). The gall-bladder has also a rich subserous plexus.

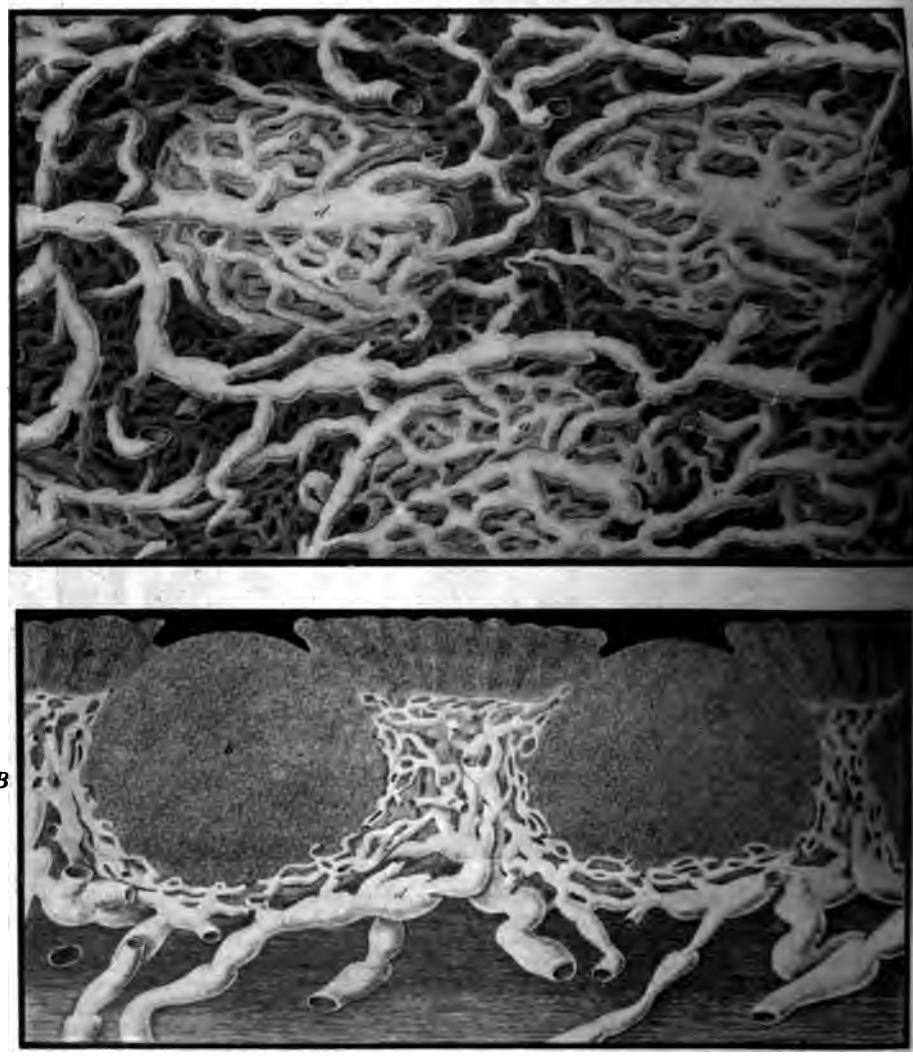
Concerning the lymphatic capillaries of the *pancreas* Bartels notes briefly that they form y branched plexuses in the interlobular connective tissues, which surround larger or smaller s of whole lobules, not the single gland elements.

The mucous lining of the *genitourinary tract*, wherever it has been carefully studied, has found provided with plexuses of lymphatics. In the *bladder* they form a rich plexus of

irregular capillaries which lie immediately under the almost intraepithelial blood-capillaries. They connect, through the muscular layer, with a subserous plexus. The lymphatic plexus of the *urethra* anastomoses with the capillaries of the base of the bladder, and in the male with those of the glans penis. In the *prostate* (Camineti) the lymphatics form rich plexuses surrounding the glands, which connect with a very wide meshed subcapsular plexus, surrounding the entire gland.

In the *testis* there is a rich superficial plexus, lying directly beneath the tunica albuginea. Concerning the deep lymphatics of the testis there has been much dispute. Ludwig and Thomsa found the lymphatic capillaries going over into lacunæ, without endothelium. This has been disputed by Tommasi and Gerster, who find, in the septa, capillaries with endothelial wall, which they consider the beginnings of the lymphatics.

FIG. 588.—SURFACE VIEW AND SECTION OF LYMPH-NODES OF THE INTESTINE. A. Solitary follicle. B. Peyer's patch. (After Teichmann.)



In the female, lymphatic plexuses have been found in the mucosa of *vagina* and *hymen*, anastomosing with those of the vulva. In the *uterus*, capillaries in the mucosa are very difficult to demonstrate. Definite lymphatics, however, have been found passing through the muscularis, and under the peritoneum a rich subserous plexus of capillaries is present. In the pregnant uterus these subserous capillaries are much distended (Schick). The *Fallopian tubes* are provided with lymphatics, but they have not been carefully described.

The *ovary* has a rich superficial lymphatic plexus. In the interior of the gland, according to His, the capillaries form networks in the connective tissue framework. In the tunica externa of the follicles there is a rich plexus.

The *kidney* has two sets of lymphatics, a superficial, capsular set, and a deep set. The capsular set is divided into two layers, one lying directly beneath the peritoneum made up of a wide meshed plexus, and the other in the fibrous capsule of the kidney, with finer capillaries and narrower meshes, which anastomose with the deeper capillaries. The lymphatic capillaries of

ey parenchyma have been described by Kumita. He found rich plexuses in both
ıd medulla, surrounding the straight and convoluted tubules, the loops of Henle and
cting tubules. He also found a plexus surrounding and accompanying the blood-
ıto the interior of the glomeruli.
lymphatic capillaries of the *suprarenal* have also been described by Kumita. His
gree with those of Stilling, who studied the lymphatics of the suprarenal of horse, cow
Like the kidney, the suprarenal possesses a superficial and a deep set. The superficial

vity.
membranes surrounding the *pleural*, *pericardial* and *peritoneal cavities* are richly sup-

plied with lymphatic capillaries, which form here thick plexuses under the mesothelium. These plexuses are usually described with the underlying organ, as the subserous lymphatic capillaries of the intestine, etc. In the central tendon of the diaphragm the subperitoneal lymphatics are extremely rich. They widen out here to form very large endothelial-lined cavities which, in the spaces between the connective tissue bundles, lie directly in contact with the peritoneal epithelium. The existence of open connections between these capillaries and the peritoneal and pleural surfaces (the 'stomata' of von Recklinghausen) has been disproven. The capillaries on the two surfaces of the central tendon communicate freely with one another.

2. *THE LYMPHATIC VESSELS*

The lymph which enters the lymphatic capillaries passes over into collecting vessels, which carry it through the lymph-glands (nodes) to the large veins at the base of the neck. The general course of the lymphatic drainage from any given region is usually very similar to that of the corresponding venous drainage. The lymph-vessels course in the loose subcutaneous tissues, in the connective tissues between muscles and organs, often accompanying the arteries and veins, sometimes forming networks around them. An idea of their arrangement can be best obtained by glancing at the illustrations of the lymphatics of special regions. In general they are made up of numerous long, narrow vessels, rarely more than half or three-fourths of a millimeter in diameter, which occasionally communicate with one another, and which converge toward groups of lymph-glands placed in certain definite regions. In the lymph-glands (fig. 590) the afferent lymph-vessels break up into capillaries, which again collect into efferent vessels. Several of these efferents from each lymph-gland may pass to a second lymph-gland, where they undergo a second widening into capillaries. In this way the lymph, passing through one, two, three or more lymph-nodes in succession, eventually reaches the thoracic duct, or one of the short ducts, all of which empty into the large veins at the base of the neck. The thoracic duct which receives, at its lower end, the lymph from the lower half of the body, is the only lymphatic vessel which attains any considerable size (four to six mm. in diameter) and is usually the only one large enough to be seen readily without injection.

In *structure* the lymphatic vessels much resemble the veins. They possess an intima, a media and an adventitia, although the line of demarcation between the different layers is not sharp. In the thoracic duct, the endothelium of the intima is succeeded by a delicate layer of fibers, mainly elastic; outside of this is the media, made up mainly of circular smooth muscle-cells, interspersed with elastic and connective tissue fibers; then follows a layer of coarse elastic and connective tissue fibers, which is succeeded by the adventitia, containing longitudinal and transverse bundles of smooth muscle-cells, as well as blood-vessels and nerves. The other lymphatic vessels possess the three layers, which, however, toward the capillaries, grow thinner, and eventually reach a stage in which, outside the endothelium, there are found only single muscle-cells, or muscle-cells in groups of two or three.

The lymphatic vessels are characterized by their great richness in valves, which are present throughout their entire course, from their beginnings in the capillary region to their openings into the veins of the neck. The valves are bi- or tri-cuspid, and are always arranged so as to prevent the flow of lymph back to the capillaries. They thus aid indirectly in the *movement of the lymph*, in that any external pressure on the vessels must always force the lymph onward. The pressure of the surrounding organs and skeletal muscles, and the contraction of the smooth muscle in the walls of the lymph vessels, form important secondary factors in the movement of the lymph. The primary force, however, doubtless comes from the secretory or filtration phenomena of the lymphatic capillary walls.

Nerves of lymphatic vessels.—That the thoracic duct and the smaller lymphatic vessels are provided with nerves has been shown by several observers. According to Kytmanoff (in dogs) the nerves to the lymphatics are mainly non-medullated, and are both motor and sensory. They form four sets of plexuses—adventitial, supramuscular, intermuscular, and subendothelial. Sensory nerve-endings are found in adventitia and media, in the form of free-ending threads and bush-like endings. Motor endings are present in connection with the smooth muscle cells of the media. In the intima there is a plexus of extremely fine varicose threads. The physiological action of the nerves supplying the cisterna chyli has been tested by Camus and Gley who found in dogs a dilatation of the cisterna as the result of electrical stimulation of the splanchnic nerve.

3. *THE LYMPHOID ORGANS*

Closely associated with the lymphatic capillaries and vessels is a group of glandular structures known as lymphoid organs. They consist, essentially, of groups of round lymphoid cells, lying in a meshwork of reticulum fibers, and having often a definite relationship to the blood- or lymph-vessels. The group of lymphoid organs includes, in addition to the lymph-glands [lymphoglandulæ] or lymph-nodes, which are particularly related to the lymphatic vessels, the

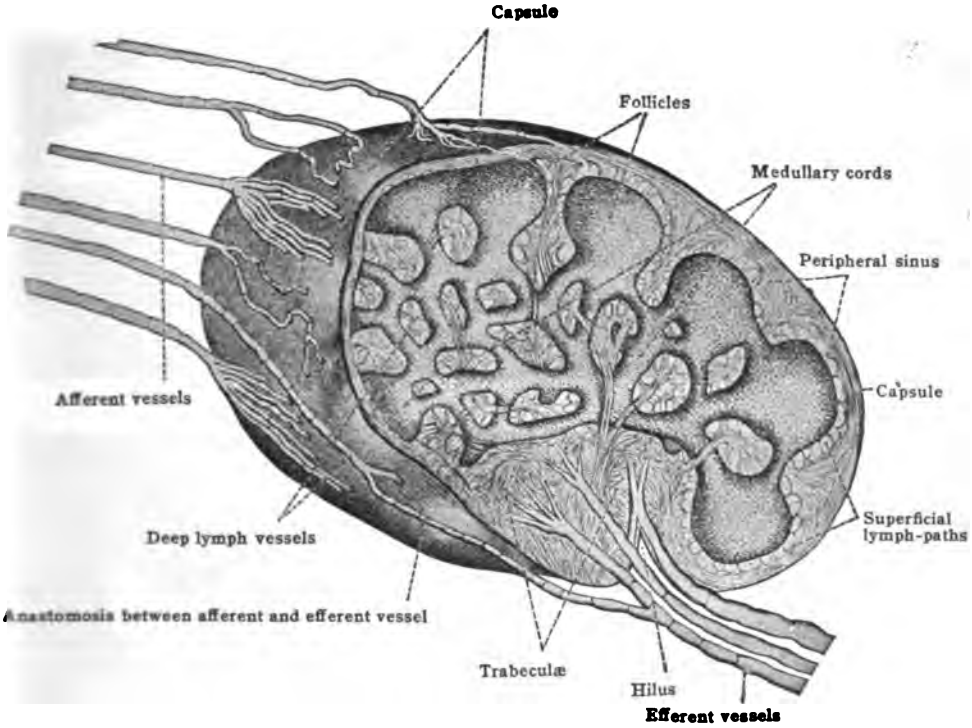
spleen, thymus and (in part) bone-marrow, which are also largely made up of lymphoid tissue. The thymus, however, is considered separately with the GLANDS OF INTERNAL SECRETION.

In their most simple form, the lymphoid organs form mere irregular accumulations or patches of lymphoid cells, which have been termed lymphoid infiltrations. Such patches are frequent in mucous membranes especially along the intestinal tract and the air-passages in the lungs.

Larger accumulations of lymphoid cells produce definite round nodules, which may occur singly, as *solitary follicles* or in groups, as *aggregated follicles* (Peyer's patches) (fig. 588). In the solitary follicle the lymphoid cells are arranged concentrically, with a region in the center where the cells are less closely packed together. This is called the germinal center, and contains numerous cells undergoing mitotic division. The solitary follicle contains blood-capillaries. Lymph-capillaries, however, do not enter the follicle but form a rich plexus about it.

The **lymph-glands** or nodes (fig. 590) are larger lymphoid structures, which are developed along the course of the lymph-vessels. They vary much in size, shape, and color, and may occur singly or in small or large groups. The *size* varies from the size of a pin-head to that of an olive, or larger. In *shape* they may be spherical, oval, or flattened on one or more sides, according to their relations to other organs. Each gland has an indentation or hilus, where the arteries

FIG. 590.—DIAGRAM OF A LYMPH-NODE. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



enter, and where the veins and efferent ducts emerge. Their *color* depends upon position and state of function. The glands along the respiratory tract are black, due to the presence of carbon granules. The mesenteric glands are milk-white during digestion, and other nodes are pale and translucent when their sinuses are filled with fluid, and pink or even red when red-blood cells are present in the sinuses. The lymph-gland is made up of four distinct elements: lymphoid elements, lymphatic capillaries, supporting structures, and blood-vessels.

The *lymphoid elements* (fig. 590) are arranged as follicles and as cell-strings. The follicles lie around the circumference of the gland, and form the cortex [substantia corticalis]. The cell-string or medullary cords are irregular cords of cells which extend from the follicles through the central or medullary portion [substantia medullaris] of the gland. The follicles and medullary cords are made up, as are the solitary follicles, of round lymphoid cells.

The *lymphatic vessels* (figs. 590, 591) enter the lymph-gland as several vasa afferentia, and leave it, at the hilus, as the vasa efferentia. The vasa afferentia spread out in the cortical portion of the gland into an extremely rich plexus of wide capillaries which surround the follicles, forming the peripheral sinus. The capillaries do not enter the follicle. This plexus continues, around the follicles, into the medullary portion where it forms again a rich plexus, the medullary sinus, in the spaces around the medullary cords. The medullary sinuses are broken up by naked reticulum fibers and cells, which are thus exposed directly to the lymph passing through the gland. At the hilus medullary capillaries collect into larger vessels and emerge as the vasa efferentia.

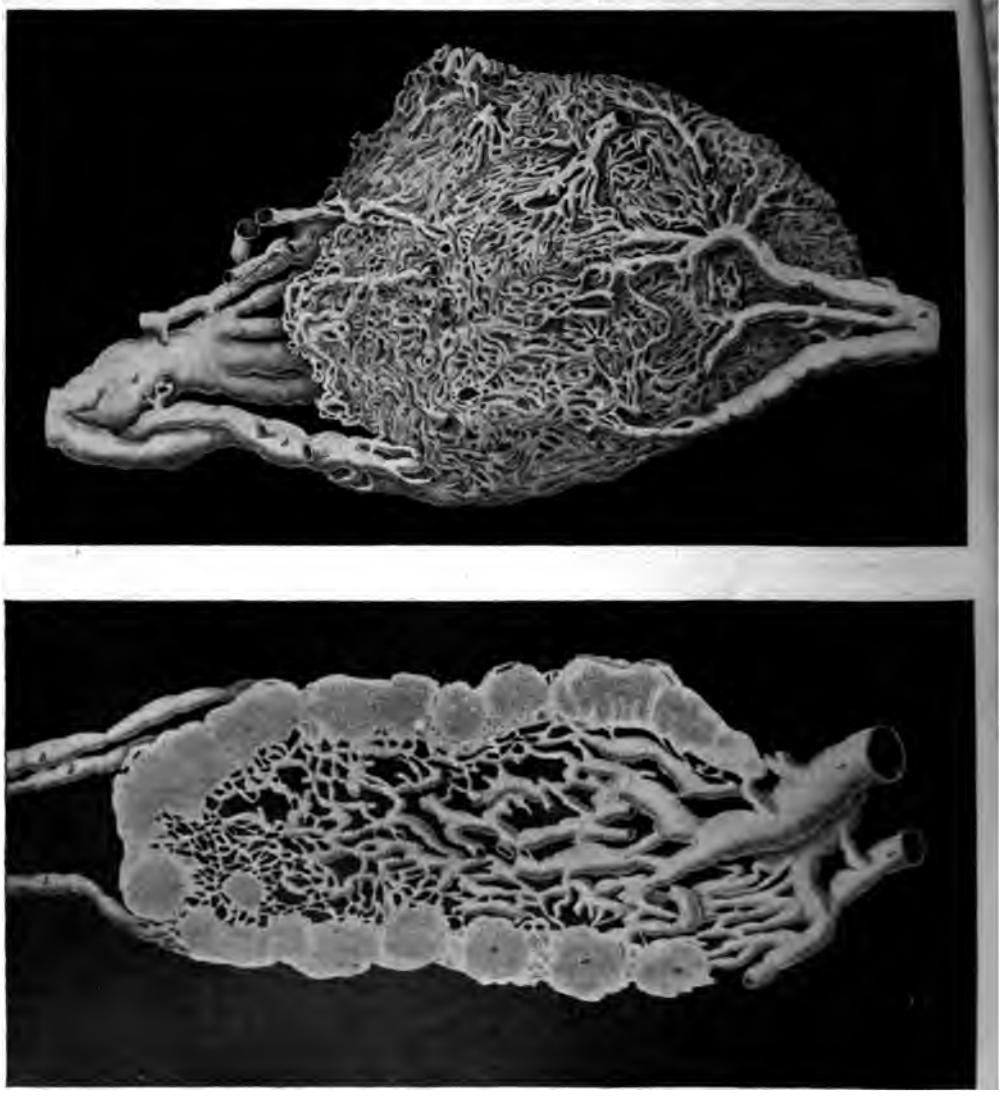
The *supporting structures* consist of a fibrous capsule surrounding the gland, from which

trabeculæ or septa pass in, around and between the follicles and cords. From the septa, a fine reticulum passes into the follicles and cords, where it forms a rich dense meshwork, in the interstices of which lie the lymphoid cells. The capsule and trabeculæ are made up of white fibers, elastic fibers and smooth muscle-fibers.

The *blood-vessels*, which enter and leave at the hilus, send branches into the follicles and into the medullary cords.

The enormous widening of the lymph-stream in the lymph-node from the vasa afferentia to the capillaries—like a brook widening out into a pond—causes a very great diminution in the rate of flow of the lymph. Thus there is present in the gland a very slowly moving stream of lymph, which is separated from the lymphoid tissue outside by a single layer of flattened

FIG. 591.—SURFACE VIEW AND SECTION OF A LYMPH-NODE SHOWING THE PERIPHERAL AND CENTRAL SINUSES. (After Teichmann.)



endothelial cells. There is thus possible an easy interchange of substances, and an opportunity or the passage, through the endothelium, of wandering cells. While the entire mode of functioning of the lymph-gland is not clear, it is known that lymphocytes, formed here, enter the lymph-stream, and that substances such as, for instance, carbon granules, or leucocytes laden with bacteria, are checked in their course by the lymph-gland. It is also known that lymph-glands become swollen as a result of the presence, in the lymph reaching them, of the poisonous products of bacterial action.

Lymphoid tissue is markedly reduced in amount during starvation (Jolly) and increased by rich feeding (Settles). The number of lymphocytes in the blood stream is increased during digestion.

Variations in lymphoid tissue according to age.—Lymphoid tissue—including lymph-glands, palatine and pharyngeal tonsils, aggregated and solitary follicles, the lymphoid portion

spleen and thymus—is much larger in amount in the child than in the adult (cf. p. 36). fact, after an early period of relatively rapid growth there is a steady reduction in size, or ophy, of lymphoid tissue both relative and absolute, which commences before adult life is ched. Miller believes that an exception is furnished by the lymphoid tissue in the lungs, due the continuous irritation produced by carbon particles inhaled, which are taken up mainly lymphoid cells, and deposited largely around lymphoid accumulations.

Arrangement.—The lymph-glands are so arranged throughout the body that all the lymph which enters the lymphatic capillaries must pass through one or more lymph-glands on its way to the veins.

It is possible that this rule may have exceptions, although none have yet been definitely proved. Thus, some of the small lymphatics which join the thoracic duct may enter it without having passed through a gland. Moreover, there is often found (fig. 590) a direct anastomosis between an afferent and an efferent lymphatic vessel.

Most of the glands are collected in certain regions, where they form centers toward which the lymphatic vessels radiate. Such groups are termed regional glands. The glands forming such a group are connected with one another by numerous anastomoses, which are termed lymphatic plexuses. In addition to the regional glands there are many isolated glands which lie along the course of the lymph-vessels, and through which pass the vessels draining a much more limited capillary area. Such glands are termed *intercalated* glands.

4. THE DEVELOPMENT OF THE LYMPHATIC SYSTEM

Our knowledge of the lymphatic system has been very greatly increased during the past twenty years by studies on its mode of development. Previous to 1902 nothing definite was known about the primary development or the mode of growth of the lymphatic system. It was concluded by some (Budge, Gulland and Saxer) that the lymphatics arise from undifferentiated mesenchyme cells; Ranvier believed that they arise from veins by budding of the endothelium; while Sala described them as arising partly from the mesenchyme and partly from venous endothelium. Regarding the mode of growth and spreading of the lymphatics, various theories were likewise held. Kölliker, His, Goethe and, later, Sala held that growth takes place by the successive addition of mesenchyme cells; Langer, Rouget, and Ranvier maintained that growth takes place by sprouting of the endothelium. S. Mayer thought that new lymphatics are derived from transformed blood-capillaries.

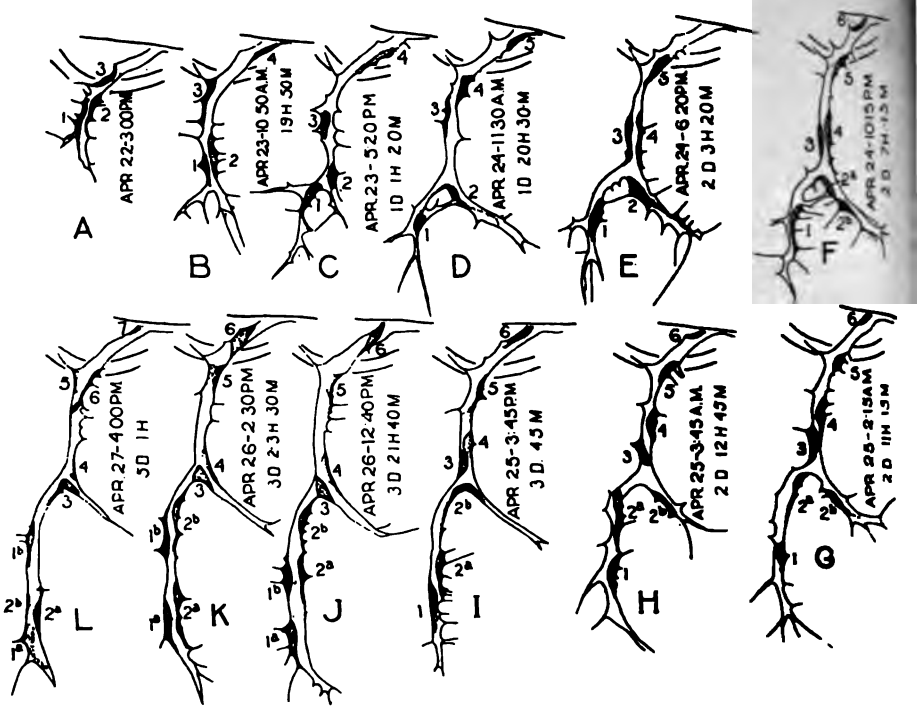
Miss Sabin, in 1902, gave the first clear picture of the mode of origin and growth of the lymphatic system, and our present knowledge has grown largely out of her discoveries. She showed, by injections of pig-embryos, that the lymphatics of the skin appear first in four regions of the body—two on each side at the base of the neck, and two in the inguinal region—in the form of sacs which are connected with the veins and spread out step by step over the skin of the entire body in the form of a richly anastomosing capillary plexus. Numerous studies have since been made on the mode of development of lymphatics, in many different animals, including man. The results of these studies leave many points still matters of controversy, and several divergent views have been developed, particularly as to the primary source of lymphatic endothelium. Miss Sabin first made the obvious conclusion that it is derived from venous endothelium by a process of sprouting, a view maintained by Hoyer and his pupils and by Kampmeier. F. T. Lewis described the first lymphatics as forming by the actual transformation of veins into lymphatics—a view which Miss Sabin later concurred in. Huntington and McClure at first also agreed with this view, but later gave it up in favor of the view that all lymphatic endothelium is derived from mesenchyme cells. This view has been supported chiefly by their pupils—Stromsten, Miller and West. E. R. and E. L. Clark failed to find any evidence for the transformation of blood-capillaries into lymphatics. There is pretty general agreement that the earliest lymphatic endothelium differentiates in certain definite regions, in the neighborhood of the veins. A recent study of the early lymphatics in chick-embryos, however, casts doubt upon the validity of this view. It was found that, in chick-embryos, if regions such as the posterior body-wall and the base of the posterior limb-bud are experimentally isolated from their supposed source of lymphatic supply, lymphatics develop *in loco*—but whether from blood-vessels or mesenchyme cells the authors were unable to determine. However, it has been found by all investigators that lymphatics have numerous connections with the veins, at early stages, particularly in certain regions, and that the number of connections is rapidly reduced, as the separated lymphatics grow together and anastomose, until, in most higher vertebrates, the only connections which persist are those at the right and left jugulosubclavian angles. The exact mode of origin is still in dispute and uncertain, largely on account of difficulties in technique.

The method by which lymphatics extend after their primary differentiation is also a matter of dispute. According to Huntington and McClure, lymphatic endothelium spreads chiefly by the continued differentiation of the indifferent mesenchyme cell into lymphatic endothelium. S. Mayer thought that spreading occurred by the continuous transformation of blood-vessels into lymphatics, although E. R. Clark, working on the same material, showed conclusively that he was in error. A similar view has been tentatively proposed by F. T. Lewis. Another group including Ranvier, MacCallum, Sabin, Hoyer, Clark, etc., hold that the spreading takes place by sprouting—that after the primary differentiation new lymphatic endothelium is derived exclusively from old. This has been observed in the transparent tails of living frog-

larvæ (fig. 592). Studies of very early lymphatics in pig- and chick-embryos indicate clearly growth by sprouting (fig. 593). There is therefore solid basis for the view that lymphatic endothelium, after its primary differentiation (the exact extent of which in time and place has not yet been entirely cleared up), becomes a specific, independent tissue, from which all lymphatic endothelium is derived.

The *lymphatic nodes* do not make their appearance until the system of vessels is well established. They are at first represented by masses of lymphoid tissue in the meshes of a lymphatic network. Later the lymphoid mass breaks up into smaller portions, into which the blood-vessels and branches from the surrounding network penetrate; and each mass, together with the portions of the network surrounding it, becomes enclosed in a connective tissue capsule. The original lymphoid tissue becomes transformed into the medullary cords and cortical nodules of the node, while the enclosing lymphatic capillaries form its peripheral lymph-sinus.

FIG. 592.—THE GROWTH OF A LYMPHATIC CAPILLARY, AS SEEN IN THE TRANSPARENT TAIL OF A LIVING FROG-LARVA. Nuclear areas are dotted, and corresponding areas are numbered. (After E. R. Clark.)



The earliest nodes appear in the places occupied by the primary lymphatic plexuses and sacs (Miss Sabin, F. T. Lewis, Jolly), and have been termed the 'primary nodes' (Miss Sabin). Secondary and tertiary sets of nodes develop later at places of confluence of many lymphatics (cf. A. H. Clark.)

Regeneration and new growth of lymphatic vessels and glands.—While blood-vessels are known to possess throughout life the capacity for regeneration and new growth, this process in lymph-vessels has been very little studied. Yet enough has been learned from the work of Coffin and Evans to justify the statement that lymphatic vessels also possess the capacity for new growth.

The question as to whether lymph-glands may form anew is not yet entirely settled. The study of the problem is extremely difficult, because very small lymph-nodes may be normally present in a certain region, yet they may escape observation until they become hypertrophied under certain conditions. A. W. Meyer in a careful experimental study found no evidence for new-formation of lymph glands. On the other hand, there is considerable evidence for the new formation of lymph-glands under pathological conditions.

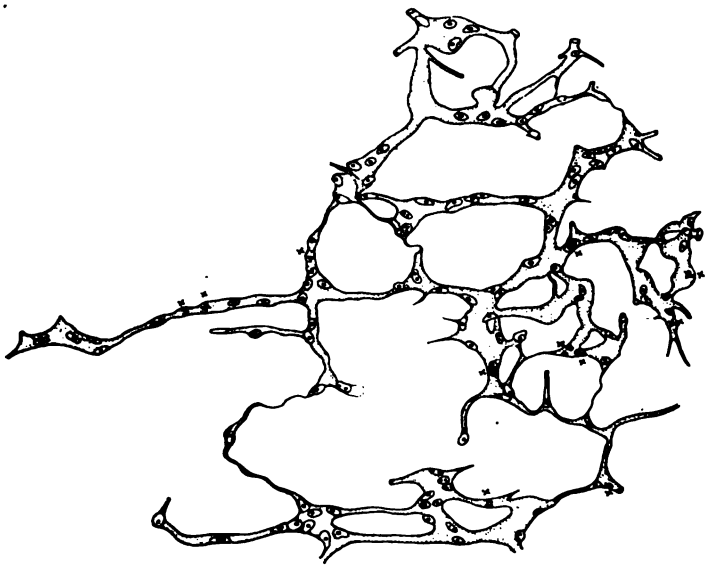
The Hemal nodes.—In addition to the lymph-nodes, there are present in certain animals (bovines, sheep and goats), and probably in man, a set of nodes somewhat similar to lymph-nodes in size, but related to the blood-vascular system, and without any connections with lymphatic vessels—the *hemal nodes*. Their structure resembles that of lymph-nodes, in that there are accumulations of lymphoid tissue, with peripheral and central sinuses, but the sinuses are filled with blood instead of lymph, thus giving them a red color. There is considerable resemblance, histologically, between hemal nodes and accessory spleens, and without doubt the two have frequently been confused. There is still some question as to the precise relationship between the sinuses and the arteries and veins. Some observers hold that arteries supply and veins drain the sinuses, others that the vascular connections of the sinuses are purely venous. Their function is unknown.

Their distribution is variable. In sheep (A. W. Meyer) they may be found anywhere near the viscera, from the base of the skull to the rectum, with a tendency to the following groupings: pararectal, lumbar or prevertebral, mediastinal, and cervical. The total number in sheep averages between thirty and forty. In bovines there is a variable number (2–36) of subcutaneous hemal glands, located mainly over the back in neck, shoulder and hip-regions. There are probably no hemal glands in cat, dog, pig, guinea-pig, rat and rabbit.

A much disputed point has been the question as to whether there is a type of gland, intermediate between the hemal gland and the lymph-gland. Several observers have described such glands. However, A. W. Meyer, who has made the most thorough studies of hemal glands, is very strongly of the opinion that there is no intermediary type—that the hemal glands are definite and distinct structures, and that the term 'hemolymph' gland should be discarded.

Comparative.—Lymphatics are present in all vertebrates, excepting possibly the lower fishes. In amphibia, there are several longitudinal vessels, two of which connect with a variable number of segmental veins. There is also an important connection at the junction of the anterior and posterior cardinal veins. At the points of connection of the

FIG. 593.—PORTION OF EARLY SUBCUTANEOUS LYMPHATIC PLEXUS. From the hip region of a chick embryo of 5 days, 7½ hrs. incubation, showing the character of the primitive plexus and the frequency of mitoses (marked X.) (After E. R. and E. L. Clark.)



lymph-vessels with the veins, lymph-hearts (in variable number, over 100 in Gymnophonia) are found, which pump the lymph into the veins. In reptiles, there is but a single pair of lymph-hearts (posterior). In certain birds, chiefly aquatic, a pair of posterior lymph-hearts persists throughout life, while in others, such as the chick, a pair is present and active until the time of hatching, after which it atrophies and disappears. No lymph-hearts are present in mammals. In the frog there are found large subcutaneous lymph-sacs, which are drained by lymphatic vessels.

The thoracic duct is double in lower vertebrates, and in early embryonic stages of mammals. In adult mammals it is normally single. The number of persistent connections of the lymph-vessels with the veins shows a reduction from lower to higher vertebrates. In reptiles, there are two pairs, in birds, one or two pairs, in mammals (typically) one pair.

No lymph-glands have been found in fishes, amphibia or reptiles. In birds (Jolly) lymph-glands are present in some of the lamellirosters—swan, duck and goose—but are absent in hen and pigeon. In mammals, all of which have more extensive sets of lymph-glands, the first to develop arise out of the primary lymph-sacs and correspond in location to the lymph-glands found in birds.

II. SPECIAL ANATOMY OF THE LYMPHATIC SYSTEM

The lymphatic system will be considered by regions as follows: A, head and neck; B, upper extremity; C, thorax; D, abdomen and pelvis; E, lower extremity.

A. THE LYMPHATICS OF THE HEAD AND NECK

The lymphatics of the head and neck may be divided into two sets. One set is superficial, draining the entire skin-surface, and has its nodes, for the most part, in the neck, the principal group lying along the external jugular vein. The other

set is deeper and drains the mucous membrane of the upper part of the digestive and respiratory tracts, together with the deep organs, such as the thyroid gland, and the tendons of the muscles. The nodes of this set are deeply placed being situated along the carotid arteries, with outlying retropharyngeal nodes.

1. THE SUPERFICIAL NODES OF THE HEAD AND NECK

Lymph-nodes appear first in the neck in the process of development. In the pig the first node to appear develops from the lymph-sac, which is in the supraclavicular triangle behind the sternocleidomastoid muscle. From here vessels grow across the muscle and give rise to a chain of nodes along the external jugular vein. This chain is to be considered as the main chain of superficial nodes in the neck. From it lymphatic vessels grow over the back of the head, the side of the head, the face, and the front of the neck, and in their course groups of secondary nodes develop. The nodes of the main chain are known as the superficial cervical nodes, and are from four to six in number. The secondary groups are—(1) the occipital; (2) the posterior auricular; (3) the anterior auricular; (4) the parotid; (5) the submaxillary, with the facial as a tertiary set, and (6) the submental.

1. **The occipital nodes** [lymphoglandulæ occipitales].—The lymphatics of the scalp of the back of the head collect into a few trunks that either empty into from one to three small nodes near the occipital insertion of the semispinalis capitis muscle, or pass by the secondary group and empty directly into the upper nodes of the main superficial cervical chain (figs. 594, 596).

2. The **posterior auricular nodes.**—A portion of the temporal part of the scalp, together with the posterior surface of the auricle, except the lobule, and the posterior surface of the external auditory meatus, drain into two small nodes on the insertion of the sternocleidomastoid muscle. The efferent vessels of these nodes pass to the upper part of the superficial cervical chain (fig. 594).

3. The **anterior auricular nodes** are few in number—from one to three—and are situated immediately in front of the tragus. They receive vessels from the anterior surface of the auricle and the external auditory meatus, from the integument of the temporal region and the lateral portion of the eyelids. Their efferents pass to the parotid and superior deep cervical nodes (fig. 596).

4. **The parotid nodes.**—The parotid group of nodes (figs. 595, 596, 600) is considerably larger than the two preceding, containing from ten to sixteen nodes, and the group drains a more complex area. It receives vessels from the adjacent surface of the external ear, the external auditory meatus, the skin of the temporal and frontal regions, and the eyelids and nose. The deeper nodes of this set receive vessels from the parotid gland.

In the embryo these nodes lie in the pathway of the lymph-vessels that grow to the scalp; many of these vessels, however, pass the parotid group and empty into the superficial cervical chain. The nodes of the parotid group lie embedded in the substance of the parotid gland, and their efferents pass to the submaxillary and the superior superficial and deep cervical nodes.

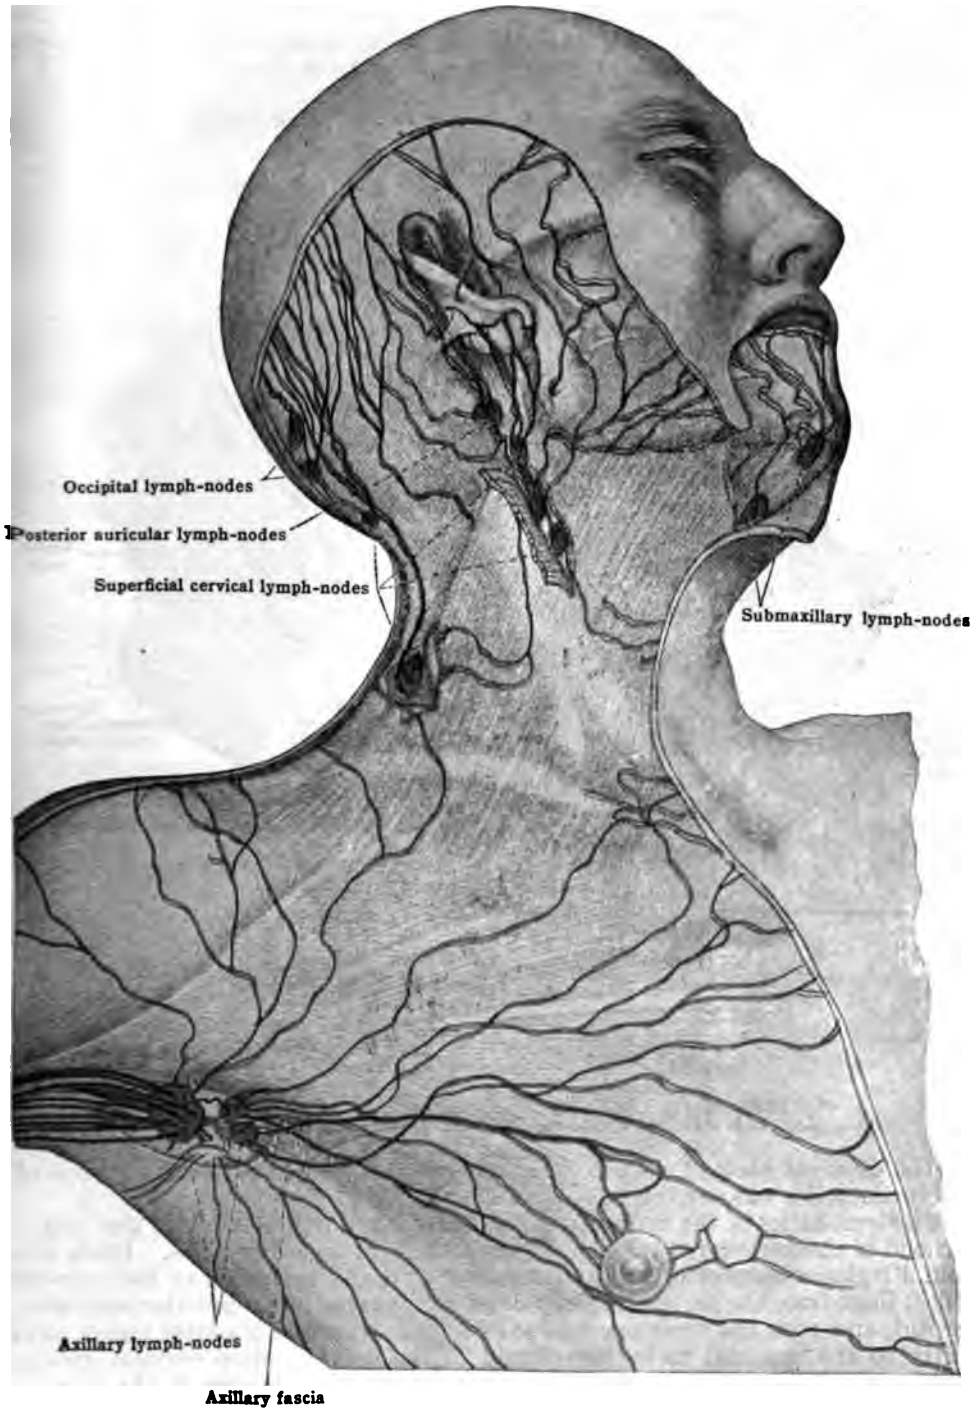
As 'inferior auricular nodes' (fig. 596), Bartels designates one or two small glands of the parotid group which lie below the ear, and receive afferent vessels from its lower part.

5. **The submaxillary and facial** [lgl. faciales profundæ] **nodes.—The submaxillary** (or 'mandibular') group (figs. 595, 596, 600) consists of a chain of from three to six nodes, resting on the submaxillary (salivary) gland, along the inferior border of the mandible. They lie usually on the submaxillary gland, but may extend from the insertion of the anterior belly of the digastric to the angle of the jaw. They are about 5 mm. in diameter, and the largest is near the point where the external maxillary (facial) artery crosses the mandible. The submaxillary nodes, together with the next group, the facial, drain a complex area, including not only skin, but mucous membrane. They receive lymph-vessels from the nose, cheek, upper lip, the lateral part of the lower lip, together with almost all those from the gums and teeth and from the anterior third of the lateral portions of the tongue. In agreement with the fact that these nodes, though lying superficially and draining the skin, drain also the mucous membrane, their vessels empty not only into the superficial cervical chain, but also into the deep cervical chain.

The facial nodes (figs. 595, 597) are evidently outlying nodes of the submaxillary group. They are in two main sets—(1) the **supramaxillary set,** which consists of from one to thirteen nodes, resting on the mandible near the point

where it is crossed by the external maxillary (facial) artery; (2) the **buccinator set,** lying on the line connecting the lower margin of the ear and the angle of the jaw.

FIG. 594.—THE LYMPHATICS OF THE HEAD AND NECK. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)

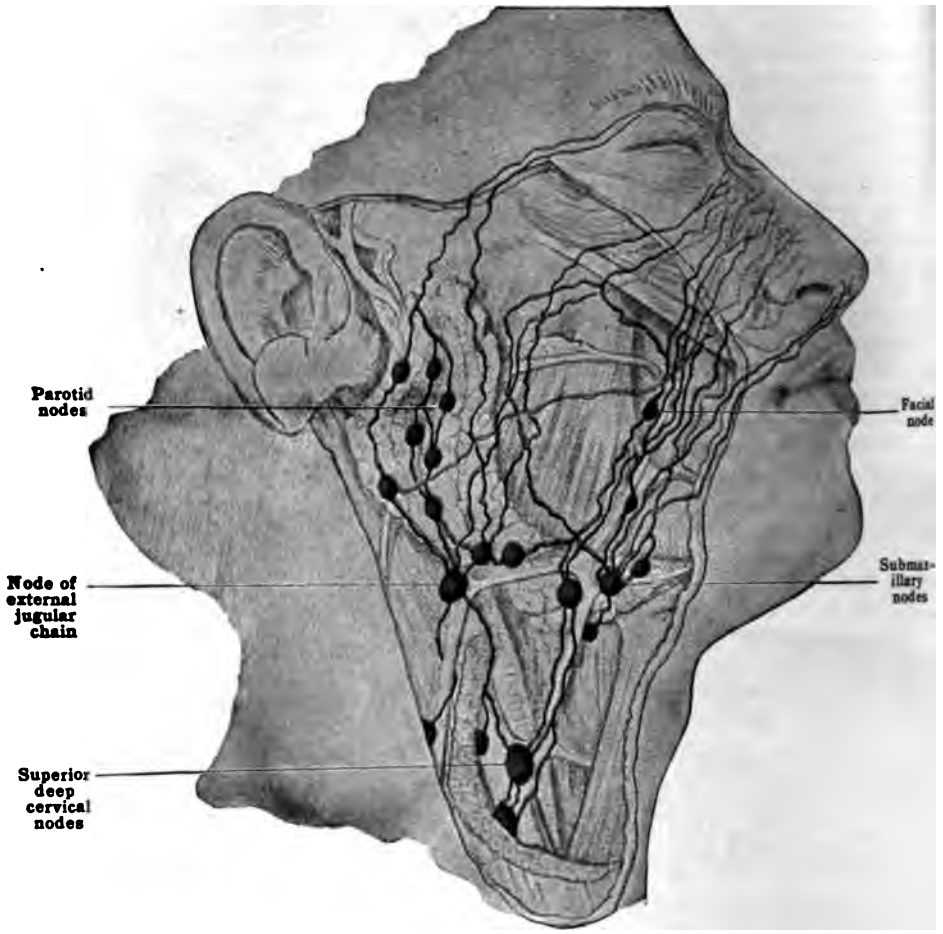


Of these latter nodes, some lie near the point where the parotid duct perforates the buccinator muscle; the others are further forward, between the external maxillary artery and the **anterior facial** vein. Additional nodes belonging to the group may occur near the nose and in the **suborbital region.** These facial nodes receive afferents from the outer surface of the nose,

the lips, eyelids, cheek, temporal part of the face, the mucosa of the mouth, the teeth of the upper jaw, the gums, the tonsils, and the parotid gland. Their efferents pass to the submaxillary and parotid nodes.

6. The **submental nodes,** usually two in number, lie in the triangle bounded by the anterior bellies of the two digastric muscles and the hyoid bone (figs. 594, 598, 602). They are usually near the median line, and drain the skin of the chin, the skin and corresponding mucous membrane of the central part of the lower lip and jaw, the floor of the mouth, and the tip of the tongue. The efferent vessels pass either to the submaxillary nodes or to the deep cervical chain.

FIG. 595.—LYMPHATICS OF THE FACE. (After Küttner.)



2. THE LYMPHATIC VESSELS OF THE FACE

The different parts of the face and their lymphatic relation to these groups of superficial nodes will now be considered.

The **lymphatics of the scalp** (figs. 594, 600) form a rich network in the neighborhood of the vertex, from which vessels pass in various directions. From the frontal region a number of vessels pass downward and backward to the parotid nodes; those from the parietal and temporal regions pass to the anterior auricular, parotid, and posterior auricular nodes; and those from the occipital region pass partly to the occipital nodes and partly to the superior deep cervical group, while a single large vessel descends along the posterior border of the sternomastoid muscle to terminate in one of the inferior deep cervical nodes.

The lymphatics of the eyelids and conjunctiva.—The capillary plexus of the eyelids and the conjunctiva is an abundant one, and at the free border of the eyelids becomes extremely close. The lymphatics from the lateral three-fourths

e lids pass to the anterior auricular and parotid groups of nodes, while those the medial one-fourth pass obliquely across the cheek with the facial vein to inate in the facial and submaxillary nodes (figs. 595, 596, 600).

. 596.—Lymphatic Nodes and Vessels of the Ear, Eyelids, Nose and Lips. New-hild. P, parotid. M, submaxillary gland. B, buccal fat ('sucking pad'). The dorsal ervical lymph nodes are not labelled. (After Bartels.)

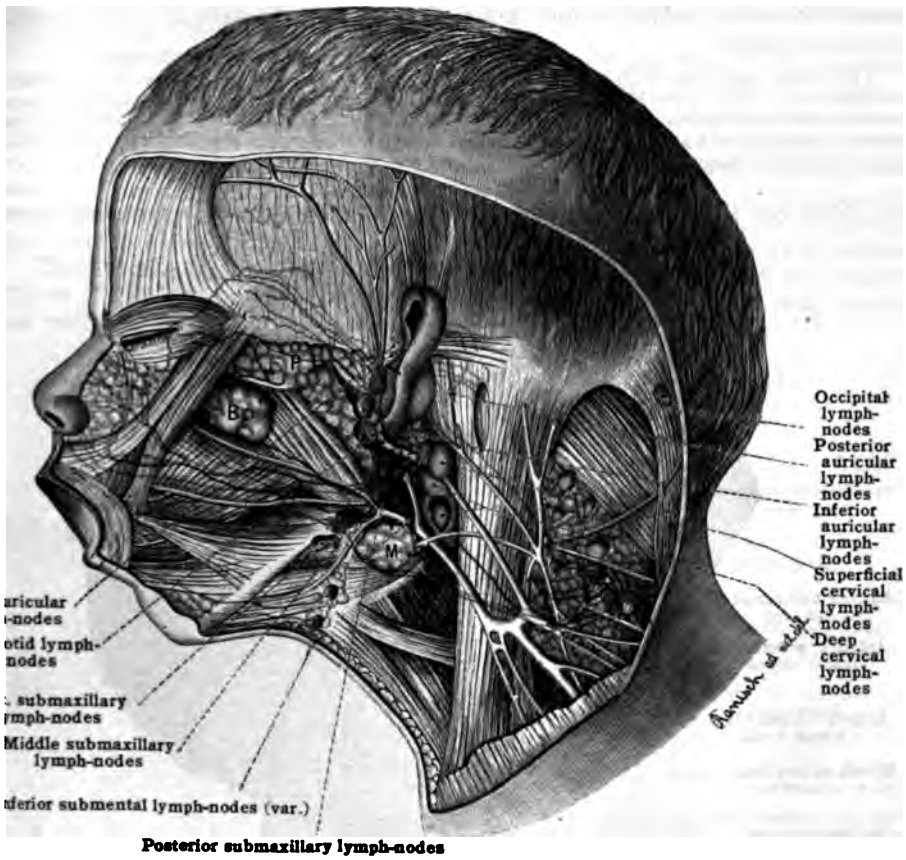


Fig. 597.—The Facial Nodes. (After Buchbinder.)

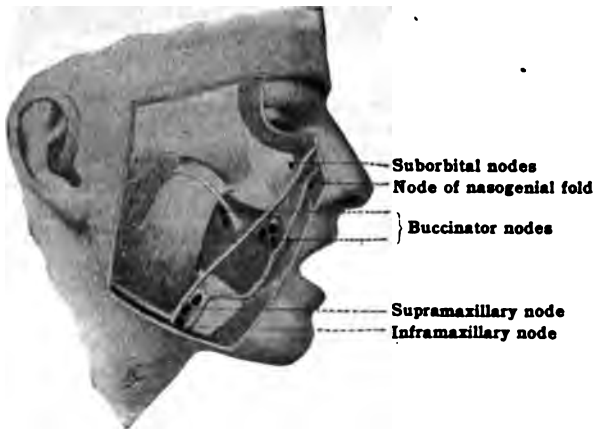


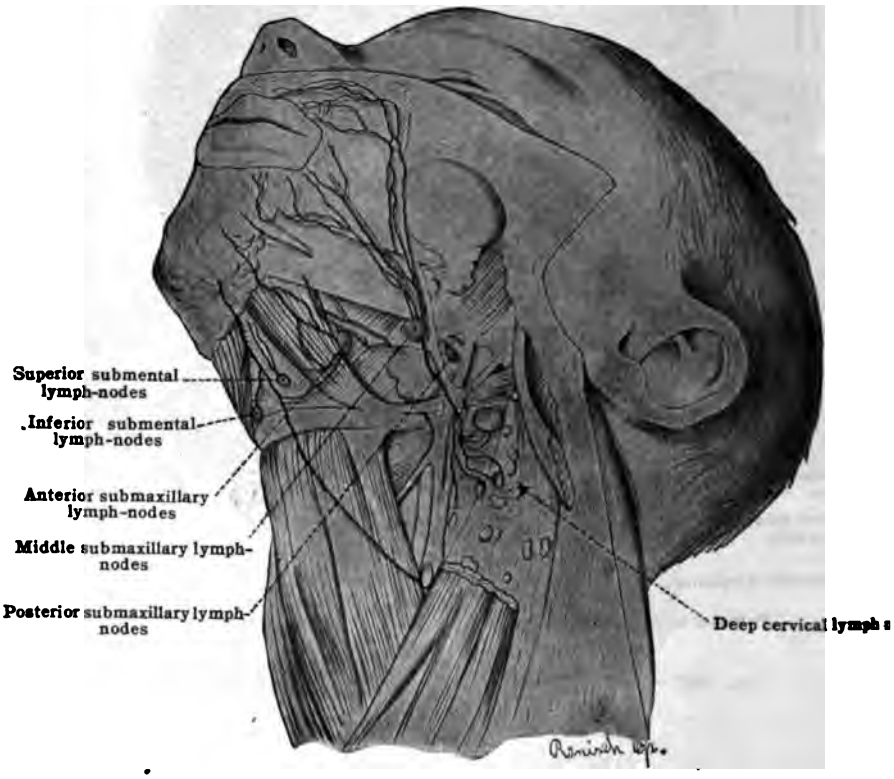
he lymphatics of the nose.—The lymphatics of the nose (figs. 595, 596) form a **ork** which is coarse at the root of the organ, but dense over the alar region. **vessels** run in three sets—(1) one set passing over the eye to the parotid nodes; **set passing** under the eye to the same nodes; and (3) the most important

group, consisting of from six to ten trunks, passing to the facial and submaxil nodes. There are some anastomoses between the capillaries of the skin and t of the mucous membrane of the nose.

The lymphatics of the lips (figs. 598, 600).—The capillary plexuses of the and mucous membrane are continuous at the free border of the lips. The ve of the upper lip, of which there are about four on each side, pass to the maxillary nodes. From the lower lip the trunks from near the angle of the m pass to the submaxillary nodes, while those from the center of the lip pass to submental nodes.

There are from two to four subcutaneous vessels and from two to three submucous v on either side. The collecting trunks passing to the submaxillary nodes do not anastomos the same is true of the submucous vessels of the lower lip. On the other hand, the subcuta vessels passing to the submental nodes anastomose freely, an important fact in connection the extension of cancer of the lower lip.

FIG. 598.—THE LYMPHATICS OF THE LIPS. Newborn child. (From Bartels after Dore



The lymphatics of the auricle and external auditory meatus.—The lym plexus in the auricle, external auditory meatus, and the outer side of the ty membrane is an abundant one. An anastomosis has been described bet scanty plexus on the inner side of the tympanic membrane and the plexus outside. The collecting vessels pass to three sets of nodes:—(1) those fr external and internal surface of the auricle and the posterior part of the e auditory meatus pass to the posterior auricular nodes; (2) those from the the helix, a part of the concha and the outer portion of the external auditor tus pass to the inferior auricular and superficial cervical chain; some of the from the first and second areas also run to the deep cervical group; (3) an a group from the tragus and part of the external auditory meatus consisting o four to six trunks, pass to the anterior auricular nodes, which are connecte the parotid nodes.

3. THE DEEP LYMPHATIC NODES OF THE HEAD AND NE

The **deep cervical chain** (figs. 595, 596, 598–600) is the largest mass of in the neck. It consists of from fifteen to thirty nodes, which lie along the

course of the carotid artery and internal jugular vein. This chain receives vessels from all the superficial nodes, also directly from the skin, as well as from the entire mucous membrane of the respiratory and alimentary tracts in the head and neck. Thus it drains both the superficial and the deep structures.

For convenience of description this long chain, though usually continuous, is divided into two groups—(1) a superior group, lying above the level at which the omohyoid muscle crosses the carotid artery, and (2) an inferior or supraclavicular group, lying below that level.

(1) **The superior deep cervical nodes** extend from the tip of the mastoid process to the level at which the omohyoid muscle crosses the common carotid artery. The **dorsal** and smaller nodes of the chain lie on the splenius, levator scapulæ, and scalene muscles (fig. 596). They drain the skin of the back part of the head, both indirectly and directly, and receive (1) efferents from the occipital and posterior auricular nodes, (2) a large vessel from the skin of the occipital part of the scalp, (3) some trunks from the auricle, and (4) cutaneous and muscular vessels from the neck. The **ventral nodes** of the chain lie on the internal jugular vein. They drain the face both directly and indirectly, as well as the deeper structures of the head and neck. They show especially well in fig. 602 in connection with the tongue.

FIG. 599.—THE DEEP CERVICAL CHAIN. (After Poirier.)

(2) The **inferior deep cervical** or supraclavicular nodes lie in the supraclavicular triangle (fig. 600). In the upper part of the triangle the nodes rest on the splenius, the levator scapulæ, and the scalene muscles, while at the base of the triangle they are related to the subclavian artery and the nerves of the brachial plexus. They drain a wide area, receiving vessels from the head, neck, arm, and thoracic wall. They are connected with the superior deep cervical chain, and receive afferents from the axillary nodes, and, in addition, they receive vessels directly from the back of the scalp, from the skin of the arm, and from the pectoral region. Thus it will be seen that a large part of the lymph of the head and neck, as well as some from the arm and thorax, passes through these nodes. Their efferents unite to form the jugular trunk, which ends at the junction of the internal jugular and subclavian veins.

In the descriptions of the deep lymphatic vessels certain additional groups of nodes will be considered, which may be regarded as outlying groups from the deep cervical chain.

4. THE DEEP LYMPHATIC VESSELS OF THE HEAD AND NECK

The lymphatics of the brain.—It is now recognized that there are no lymphatics in the brain and cord, so that the function of absorption must be accom-

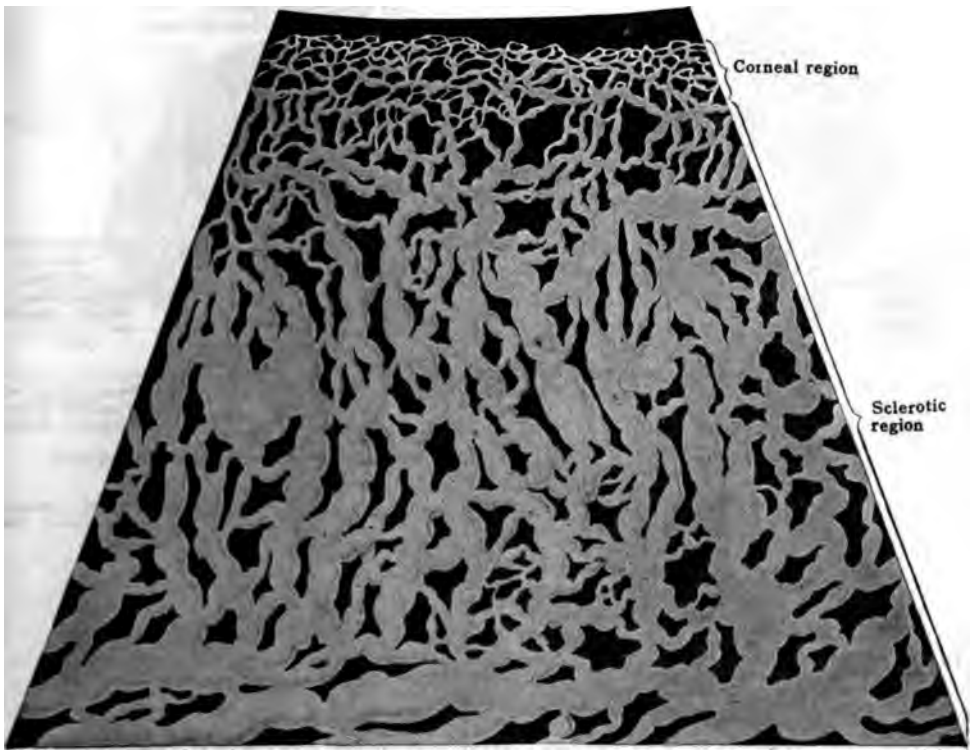
There is a continuous renewal of the fluid in the cerebral ventricle, chiefly derived from the choroid plexus. It passes into the subarachnoid spaces through the three foramina in the roof and at the sides of the fourth ventricle. Fluid is removed from the subarachnoid spaces chiefly by passing through the arachnoidal villi into the venous sinuses of the cranium.

The lymphatics of the eye.—No lymphatic vessels have as yet been discovered either in the eyeball or in the orbit. In both, however, there are abundant tissue-spaces, the most noteworthy of the orbit being the **interfascial space (space of Tenon)**, which communicates by a space between the optic nerve and its sheath with the subarachnoid spaces of the cranial cavity.

In the eyeball the tissue-spaces are abundant, aside from the vitreous and aqueous chambers. Numerous spaces exist in the choroid coat, especially in the lamina suprachoroidea, and in the sclerotic, both sets communicating by perivascular spaces surrounding the venæ vorticosæ with the interfascial space. In the cornea there are abundant lacunæ, united by their anastomosing canaliculi, to form a network of lymph-spaces which come into close relation with the conjunctival lymphatics at the corneal margin.

FIG. 601.—THE LYMPHATICS OF THE CONJUNCTIVA, SURFACE VIEW. (After Teichmann.)



The conjunctiva, however, being a portion of the integument, does possess **lymphatic vessels** (fig. 601), arranged in a double network whose collecting vessels **accompany those of the eyelids**, and terminate with them in the submaxillary, **anterior auricular**, and parotid nodes.

THE LYMPHATICS OF THE DIGESTIVE TRACT IN THE HEAD AND NECK

The lymphatics of the gums.—The lymphatics from the mucous membrane **of the gums pass to the** submaxillary nodes. The capillary plexus is abundant; **the collecting vessels arise** from it on the inner surface of the gum, and pass **between the teeth to reach** a common semicircular collecting vessel on the outer **surface.** Lymphatics **have** been demonstrated in the pulp of the tooth (Schweitzer).

The lymphatics of the tongue (fig. 602).—There is a rich lymphatic plexus **throughout the entire** extent of the submucosa of the tongue, but **that portion lying in the basal part** of the tongue seems to be more or less independent of the **rest. According to Aagaard** the tongue muscles are provided with lymphatics

which are drained by the vessels from the submucosal plexuses. There a groups of collecting vessels—(1) apical, (2) marginal, (3) basal, and (4) cen

(1) The *apical vessels* are usually four in number, two on each side. One pair pe the mylohyoid muscle and ends in a suprahyoid median node, while the other pair pa deep cervical chain. The latter are long, slender vessels, which run along the frenu tongue to the surface of the mylohyoid muscle, cross the hyoid bone just behind th of the digastric and then run downward in the neck to a node of the deep cervical ch above the omohyoid. It will be noted in fig. 602 that the most anterior vessels en lowest nodes, while those from the back of the tongue end in higher nodes.

(2) The *marginal vessels* are from eight to twelve in number. They all pass to the deep cervical nodes, a part of them passing external to the sublingual gland, while t number pass internal to it. There is one large and constant node at the point where the muscle crosses the jugular vein, to which a large number of the vessels converge.

(3) The *basal vessels* are seven or eight in number, and drain the basal portion of t Some end in the large node just mentioned, while others run backward close to t line, where they anastomose, as far as the glossoepiglottidean fold, when they sep join the tonsillar vessels to pass outward to the superior deep cervical nodes.

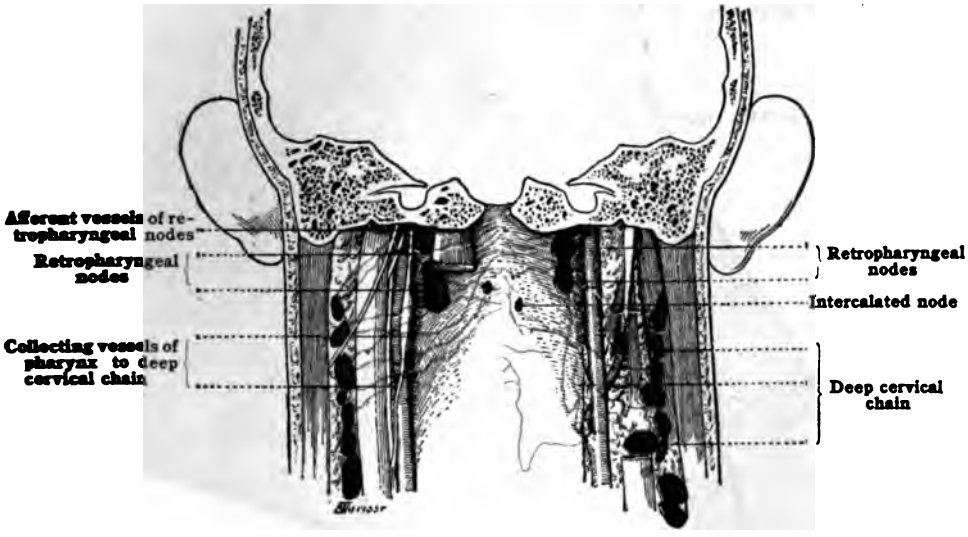
(4) The *central vessels*, arising from the central portion of the tongue, pass ba the median line on the ventral surface of the tongue. They lie upon the mylohoyo cross the hyoid bone, and end in the superior deep cervical chain.

The lymphatics of the palate.—The lymphatics from the palate pa deep cervical chain. The trunks from the hard palate run in the submuc as the last molar tooth, where they pass in front of the anterior palatine arc and end in the superior deep cervical nodes beneath the digastric mu the soft palate the capillary plexus is very rich, reaching a maximum in t

From the inferior surface of the soft palate and the palatine arches vessels pass directly to the superior deep cervical chain, but some of the vessels from the upper surface of the soft palate run forward with the pharyngeal vessels and end in the *retropharyngeal nodes*. It will be seen from fig. 603 that the retropharyngeal nodes are simply outlying nodes from the deep cervical chain.

The lymphatics of the pharynx.—As has just been stated, there are certain outlying nodes of the deep cervical chain which lie behind the pharynx. They receive some of the vessels from the submucosa of the roof of the pharynx, but many of the pharyngeal vessels pass by these nodes and end directly in the superior deep chain. The tonsil is especially rich in lymphatics, and its efferents, together with those from the middle and inferior portions of the pharynx, end in the superior deep cervical chain. The lymphatics of the Eustachian tube run to the lateral retropharyngeal lymph-nodes or, passing these, to the deep cervical nodes.

FIG. 603.—THE LYMPHATICS OF THE PHARYNX. (After Poirier and Cunéo.)



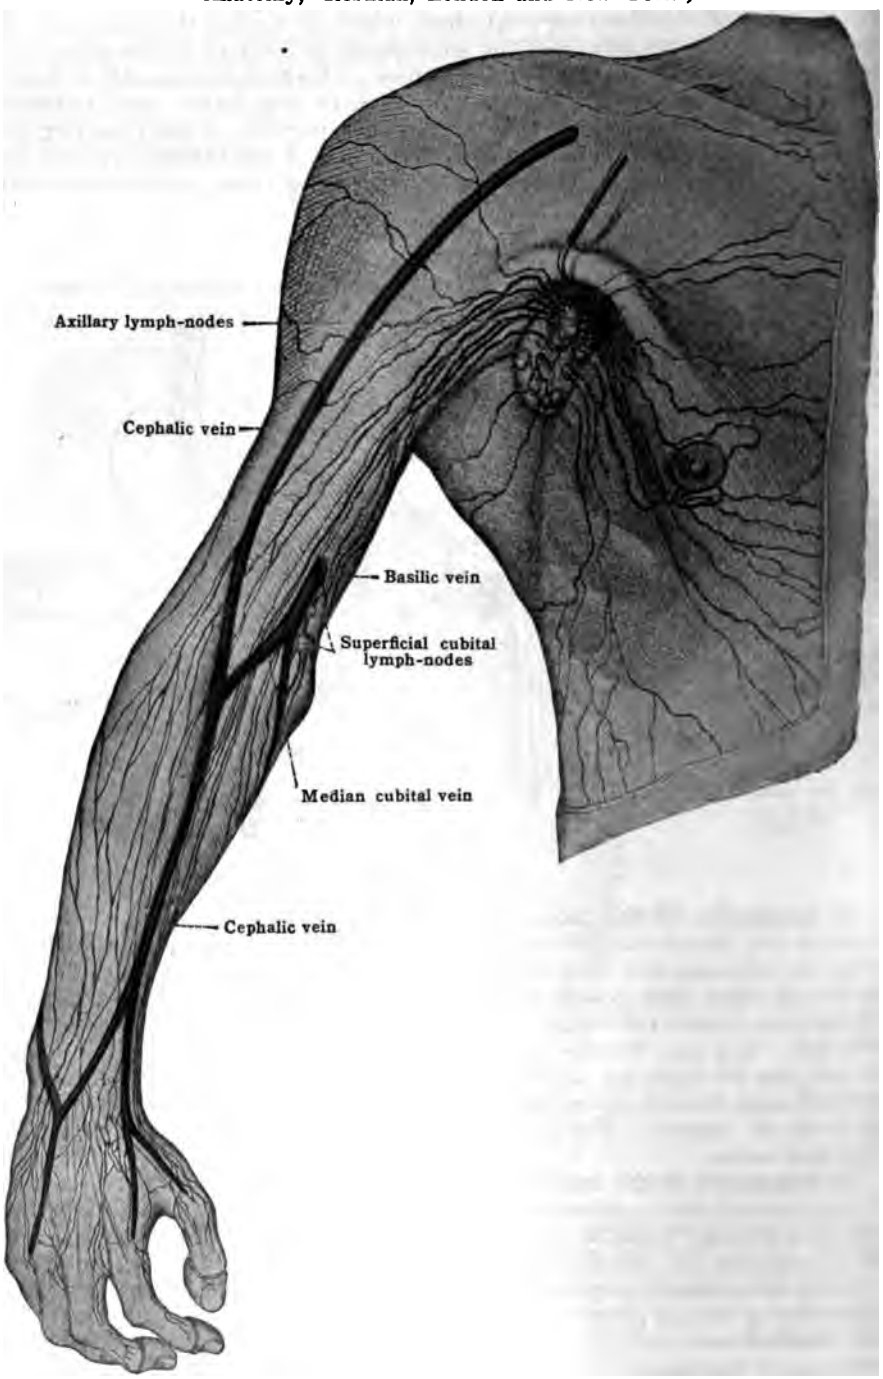
The lymphatics of the nasal cavities.—The mucous membrane of the nose contains a rich lymphatic plexus whose main trunks pass to the retropharyngeal nodes. An anterior set, however, anastomoses with the subcutaneous vessels, and through these their lymph is conveyed to the facial and submaxillary nodes. The posterior vessels run either to the deep cervical chain or to the retropharyngeal nodes. Key and Retzius have shown that an injection of the lymphatics of the nose may be made by injecting the subarachnoid spaces at the base of the brain, although there is presumably no direct connection between the spaces and the lymphatic vessels. The lymphatics of the nasal sinuses end in the retropharyngeal nodes.

The lymphatics of the larynx.—The larynx is, for the most part, drained by the deep cervical nodes, although its lymph may also pass through certain outlying nodes situated upon its ventral surface. The mucous membrane is divided into two zones by the ventricular folds, the mucous membrane of these structures possessing but a scanty lymphatic plexus. The vessels from the upper part of the larynx, four or five in number, pass to the nodes of the superior deep cervical chain, situated near the digastric muscle; those from the lower part pass to the lower nodes of the same chain, some even descending as far as the supraclavicular nodes. The lymphatics of the trachea pass, on each side, to the paratracheal and inferior deep cervical nodes.

The lymphatics of the thyroid gland.—The lymphatics of the thyroid gland pass either to the small nodes situated in front of the larynx and trachea, or to nodes of the deep cervical chain, a part of them ascending and a part descending.

It will thus have been seen that the lymphatics of the mucous membrane of the head and neck all end in the deep cervical chain of nodes or in its outlying nodes. Some of the vessels pass by the outlying nodes, but since the nodes

FIG. 604.—THE LYMPHATICS OF THE UPPER EXTREMITY. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



of the chain are so closely connected, the lymph must pass through several nodes before entering the veins. The palatine tonsils, the numerous lingual and pharyngeal tonsils, together with small lymph-follicles in the submucosa of the respiratory tract, represent lymph-nodes in the capillary zone.

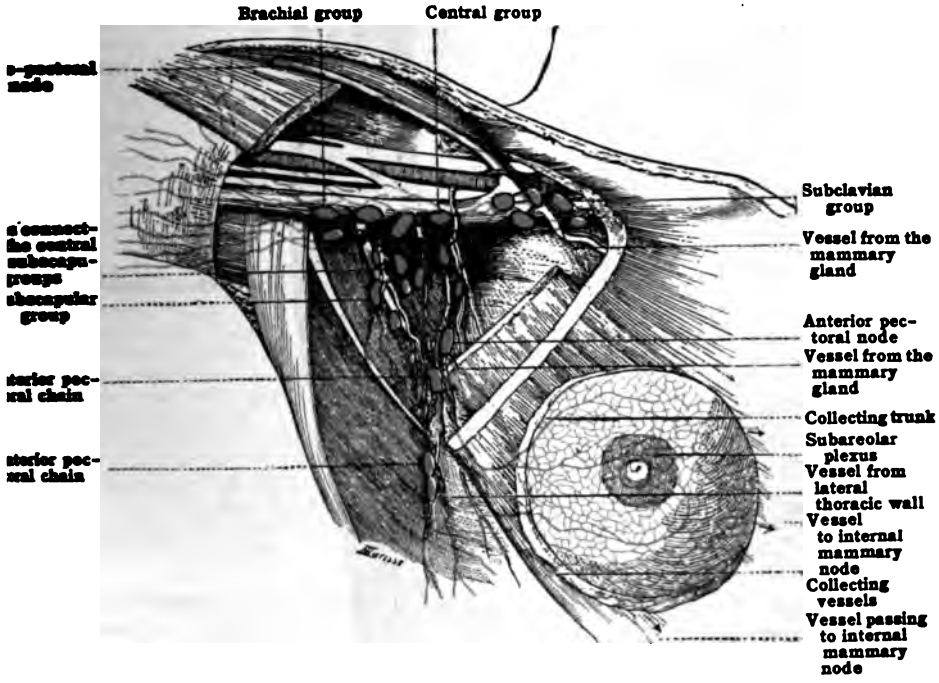
B. THE LYMPHATICS OF THE UPPER EXTREMITY

1. THE LYMPHATIC NODES OF THE UPPER EXTREMITY

The lymph-nodes of the arm lie, for the most part, in the axilla, where there is rge group of nodes which receive almost the entire drainage of the arm and thoracic wall. In addition, there is in the arm a set of outlying superficial es, the superficial cubital (supratrochlear), while small isolated nodes are often rcalated along the course of the deep lymphatic vessels which accompany the ial, ulnar, anterior interosseus and brachial arteries, the cephalic vein, and the p cubital vessels.

(1) **The antibrachial nodes** are very small nodes (size of pin-head) intercalated ng the deep lymphatics which accompany the radial, ulnar, anterior and pos- ior interosseus arteries.

FIG. 605.—THE AXILLARY LYMPH-NODES. (After Poirier and Cunéo.)



(2) The **deep cubital nodes** are also very small nodes, one or two in number, ercalated along the lymphatic vessels, near the deep vessels at the bend of the ow.

(3) The **superficial cubital** (or supratrochlear) **node** is situated three or four - above the medial epicondyle of the humerus. It lies in the superficial fascia the medial side of the basilic vein near the place where it passes through the p fascia. It is usually single, but may be absent or represented by a chain of n two to five nodes. Its efferents follow the basilic vein.

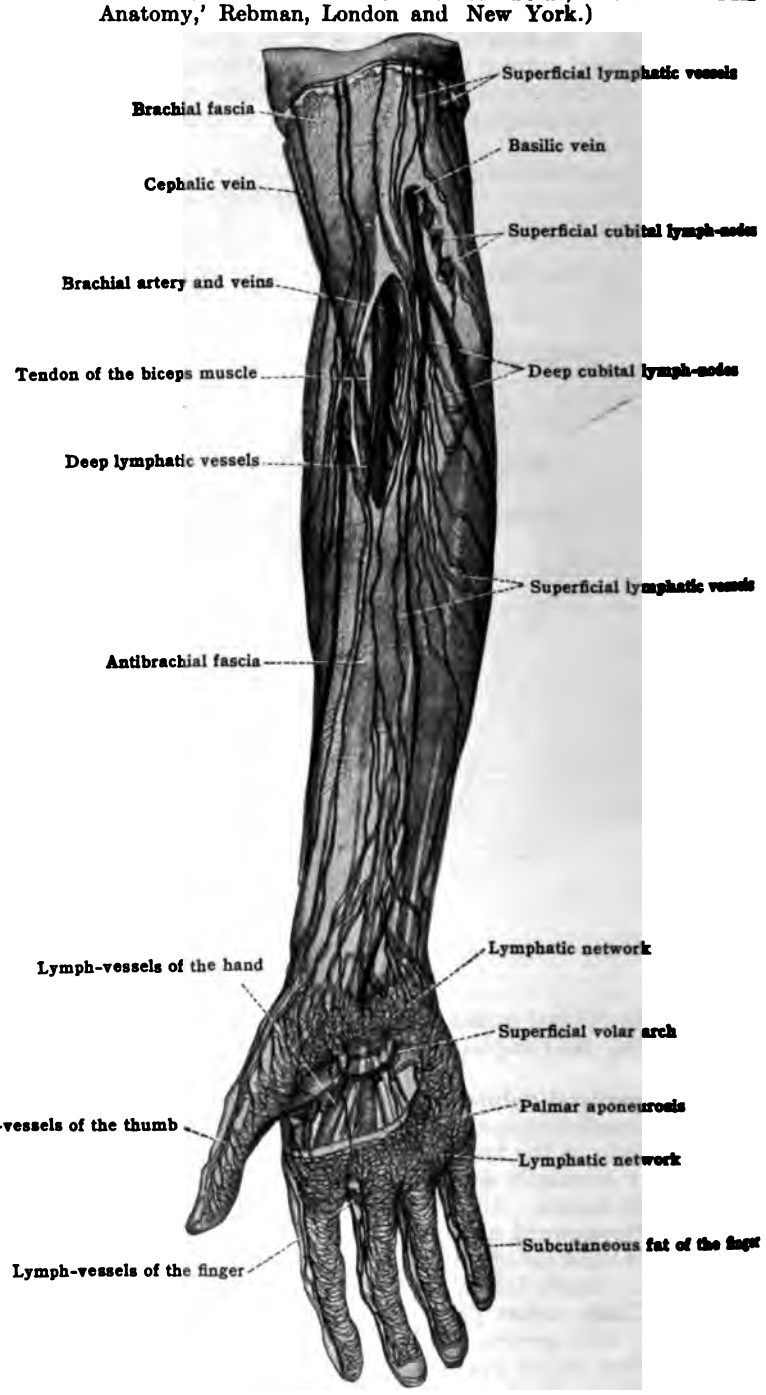
(4) The **deltopectoral nodes** are very small intercalated nodes, from one to e in number, and are situated in the groove between the deltoid and pectoral scles. Their vessels follow the cephalic vein.

(5) The **axillary nodes** [lgl. axillares], from twelve to thirty-six in number, y be divided into groups according to the areas which they drain (figs. 604,). In addition to the upper extremity, they receive lymphatic drainage from thoracic walls, including dorsal, lateral and ventral (mammary) regions.

(a) The *subclavian group* consists of four or five nodes, situated in the apex of the axillary a. They receive the efferent vessels of all the other groups, and their efferent vessels in turn te to form a single trunk, the subclavian, which empties into the thoracic duct on the left e and on the right side either into the vein directly or else after uniting with the jugular nk. (See pp. 758–760.)

(*b*) *The central group.* A little lower along the axillary artery is a group of three to f nodes, which makes a second center for the vessels of the other groups, and sends its effe to the subclavian group. It will be clear from fig. 605 that the separation of groups 1 and arbitrary.

FIG. 606.—THE LYMPHATICS OF THE FOREARM. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



(*c*) *The brachial group.*—This consists of four or five nodes, and, as its position towa the junction of the axillary and brachial arteries indicates, is the main station for the lymphat of the arm proper. It receives almost all the superficial and deep lymphatics of the arm, a its efferents pass to the central and subclavian groups, although a few pass directly to suprascapular group. Small, outlying nodes of this group may be intercalated along vessels following the brachial artery throughout its course.

(*d*) *The subscapular group.*—In this group are six or seven nodes, which follow the subular artery and its branch, the circumflex (dorsal) scapular. Belonging to it there are usually or three small nodes on the dorsal surface of the scapula, in the groove which separates the s major and minor. This group receives vessels from the dorsal surface of the thorax, as as from the arm, and its efferents pass to the brachial group.

(*e*) *The anterior pectoral group.*—This group consists of four or five nodes which lie along the er border of the pectoralis major and drain the mammary gland and front of the chest. ir efferent vessels pass to the central and subclavian groups.

(*f*) The *posterior pectoral group* consists of small nodes situated on the inner wall of the la, along the course of the long thoracic artery. They receive afferents from the lateral gument of the thorax and drain into the nodes of the central group.

2. THE LYMPHATIC VESSELS OF THE UPPER EXTREMITY

The lymphatic vessels of the upper extremity are divided into two sets—a perficial and a deep set.

The superficial vessels.—The superficial lymphatic vessels of the arm course two layers, the one quite subcutaneous, the other next to the deep fascia, with quent anastomoses between the two sets. The majority of these vessels main superficial throughout the arm, but some of them pass through the deep scia in the upper arm especially where the basilic vein pierces the deep fascia, join the deep lymphatics accompanying the brachial artery. The general stribution of the superficial lymphatics and their relations with the lymph-des are shown in figs. 604 and 606.

The capillary plexus is most dense in the volar surfaces of the fingers, where the meshes e so fine that they can only be seen with a lens. On the dorsal surface of the fingers and hand e plexus is less dense. From the plexus on the palmar side of the fingers vessels come together the base of the fingers where they pass dorsally to be joined by the dorsal vessels of the ger. They now follow two rather distinct curves: (1) those from the thumb and index ger and a part of the middle finger pass upward along the radial side of the forearm, course edially over the lower part of the biceps muscle, and empty into the axillary lymph-nodes. ne or two vessels follow the cephalic vein and, after traversing the deltopectoral node, pierce e costocoracoid membrane to enter the subclavian nodes, or pass over the clavicle into the ferior deep cervical nodes. (2) Those from the rest of the fingers course for a short stretch the dorsum of the forearm, when they turn toward the ulnar side, wind around to the volar le and either continue superficially along the upper arm to the axillary nodes, or pass into superficial cubital node, or, joining the efferents from these nodes, pass through the deep cia to unite with the deep lymphatics. (3) A set of vessels from the palm of the hand passes ward along the volar side of the forearm. Anastomoses are frequent between these groups of mphatic vessels, particularly in the cubital region.

It will thus be seen that the superficial cubital nodes receive lymph from the ulnar digits l from the palm of the hand, but not from the thumb and forefinger.

The superficial lymphatics from the rest of the arm join these three main groups at various els.

The deep vessels.—The deep lymphatic vessels of the upper extremity drain e joint-capsules, periosteum, tendons, and (if the work of Aagaard is correct) e muscles. They collect into vessels which, in general, accompany the arteries; the forearm, the radial, ulnar, anterior and posterior interosseous, and in the m the brachial. Above the elbow they are joined by numerous superficial mphatic vessels including efferents from the superficial cubital nodes. Along eir course in the forearm are intercalated small nodes (pin-head size), radial, lnar, anterior and posterior interosseous (Mouchet) and deep cubital; and, the arm, small brachial intercalated nodes. The deep vessels in the main enter he brachial group of axillary lymph-glands which lie behind the large vessels nd nerves, the efferents from which nodes pass either into the lower deep cer-ical lymph-nodes or directly into the subclavian trunk.

The lymphatics of the *shoulder-joint* have been described by Tananesco. He finds a ring f lymphatics in the joint capsule, whose efferents, in the main, following the arteries, run to e central and subclavian groups of axillary nodes.

C. THE LYMPHATICS OF THE THORAX

The lymphatics of the thorax will be considered under the following divisions: he superficial vessels, the deep nodes, and the deep vessels.

1. THE SUPERFICIAL LYMPHATIC VESSELS OF THE THORAX

The superficial lymphatics of the thorax pass almost exclusively to the axillary odes, and may be regarded as forming three sets, a ventral, a lateral, and a

dorsal. The **ventral set** drains the thoracic integument, which extends from the median line and the clavicle over to the lateral border of the chest, and includes the vessels of the mammary gland, which will, however, be described separately. The majority of the vessels from this area end in the anterior pectoral group of axillary nodes, a few, which arise beneath the clavicle, passing to the supraclavicular nodes, and a few perforating the intercostal spaces and ending in the chain of nodes along the internal mammary artery.

It has been shown that an injection into the subcutaneous plexus near the median line passes to the opposite side, and that, in addition to the anastomosis between the networks of the two sides of the thorax which this result manifests, there may also be a few collecting trunks crossing the median line, and, furthermore, anastomoses occur between the superficial networks of the anterior thoracic and abdominal walls. Thus while the main channel of lymphatic drainage is through the axilla, there are minor accessory channels (1) to the supraclavicular nodes, (2) to the axilla of the opposite side, (3) to the internal mammary chain, and (4) in isolated cases even to the inguinal nodes. These accessory channels may become more open in cases of obstruction to the main channels.

The **lateral set** of superficial thoracic lymphatics is much less extensive than the anterior, and its collecting vessels pass upward to open chiefly into the posterior pectoral group of axillary nodes.

The **dorsal set,** which occupies the subcutaneous tissue of the dorsal thoracic wall, sends its vessels to the subscapular group of axillary nodes.

The Lymphatics of the Mammary Gland (Figs. 605, 607)

The lymphatic network over the peripheral portions of the mammary gland is like that of the rest of the thoracic wall. In the areola, however, the capillaries are far more abundant, forming a double subareolar plexus. The superficial plexus is so dense that its meshes can be seen only with a lens. The deeper plexus not only drains the superficial plexus, but receives the vessels from the mammary gland itself, and from it arise usually two large trunks, one from the inferior and one from the superior part of the plexus. These two vessels pass to one or two of the nodes belonging to the anterior pectoral group of axillary nodes. In addition there may be—(1) one or two vessels passing to the nodes along the axillary artery; (2) in rare cases a vessel passing directly to the subclavian nodes. There is also a definite channel from the medial margin of the gland to the internal mammary nodes, the trunks following the perforating branches of the internal mammary vessels. It may also be noted that the crossed anastomosis and that with the abdominal network, mentioned in connection with the superficial thoracic vessels, may occasionally serve as channels for the mammary drainage.

There is also clinical evidence indicating that lymphatic vessels from the lower and medial aspect of the mammary gland may pass through the abdominal wall in the angle between the xiphoid process and the costal cartilages, establishing a communication with the lymphatics of the abdomen in the diaphragmatic region.

Lymphatics of the thoracic muscles.—The studies of Aagaard make it probable that muscles are provided with lymphatics. It is unquestioned that lymphatic vessels course through the pectoral muscles—some passing to the axillary, others to the subclavian, and still others to the internal mammary chain of nodes. This would suffice to explain the fact that cancer of the breast may extend into and through the pectoral muscles.

2. THE DEEP LYMPHATIC NODES OF THE THORAX

The lymphatic nodes of the thoracic cavity may be divided into the parietal and the visceral. The **parietal nodes** are arranged in two sets, the sternal and the intercostal nodes. Along the internal mammary artery are from four to six small **sternal nodes** which receive trunks from the anterior thoracic and the upper part of the abdominal walls, from the anterior diaphragmatic nodes which drain the liver, and from the medial edge of the mammary gland. The efferent vessels usually unite with the vessels of the anterior mediastinal and bronchial nodes, to form the bronchomediastinal trunk, which may join the thoracic duct on the left and the jugular or subclavian trunk on the right or may empty separately into the subclavian vein on either side or both.

The **intercostal nodes** (fig. 609) lie along the intercostal vessels, near the heads of the ribs. There are usually one or two in each space. They receive afferents from the deeper part of the thoracic wall and costal pleura. Their efferents enter the thoracic duct, those from the nodes of the lower four or five

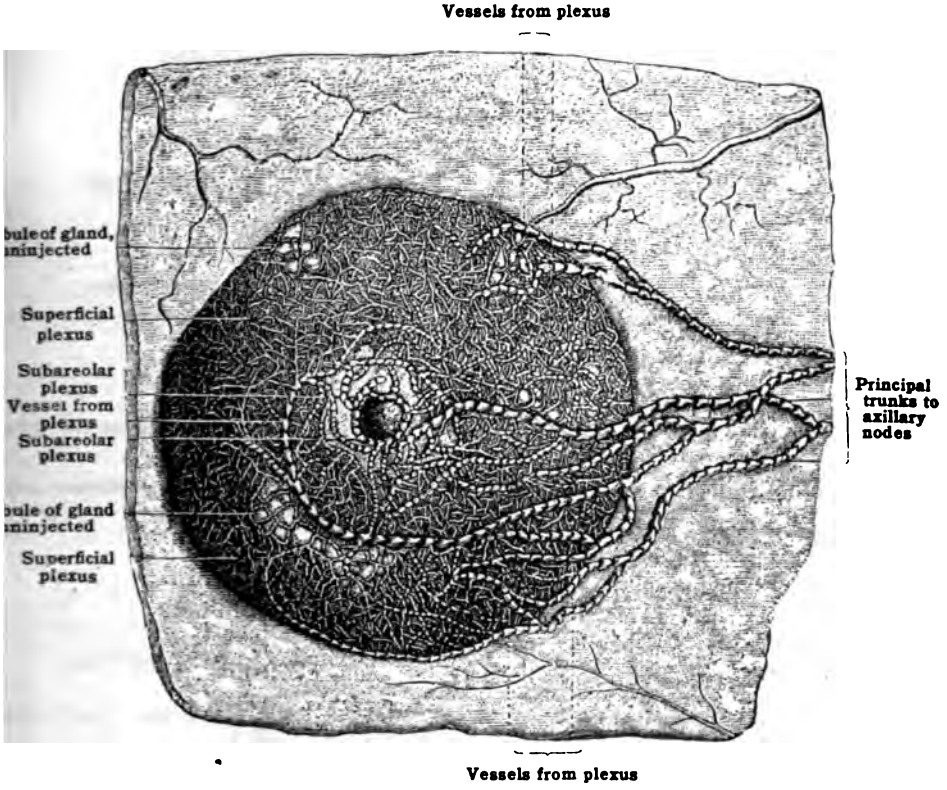
terspaces uniting usually to form a common trunk on each side, but more rked on the left side, which descends to the cisterna chyli.

The efferent lymph-vessels from the upper intercostal nodes often unite into common nks which drain several interspaces, and which may pass through a large gland near the racic duct before emptying into it. Occasionally such collecting vessels from the right side s the midline behind the aorta to reach a large gland to the left of the aorta.

The **visceral nodes** of the thorax are arranged in three groups:

1. The **anterior mediastinal nodes** are situated, as their name indicates, in the terior mediastinum, and are arranged in an upper and a lower set. The upper (superior mediastinal group) is situated along the arch of the aorta, and con- ts of eight or ten nodes, which receive afferents from the pericardium and the mains of the thymus gland. Their efferent vessels pass upward to join the onchomediastinal trunk. The lower set consists of from three to six nodes,

FIG. 607.—LYMPHATICS OF THE SUBAREOLAR PLEXUS OF THE BREAST. (After Sappey.)



uated in the lower part of the anterior mediastinum. They receive afferent icts from the diaphragm (for which reason they are sometimes termed the **aphragmatic nodes**) and also from the upper surface of the liver. Their ferents pass upward to open into the upper anterior mediastinal nodes.

2. The **posterior mediastinal nodes** eight or ten in number, are situated along e thoracic aorta, and receive vessels from the mediastinal tissue and from the oracic portion of the esophagus. Their efferents open directly into the thoracic ct.

3. The **tracheal** and **bronchial nodes** (fig. 608) form an extensive group lying ong the sides of the lower part of the trachea, and along the bronchi as far as the lus of each lung. According to their position they are termed tracheal (para- acheal), lateral tracheobronchial, inferior tracheobronchial (nodes of the bifur- tion), and pulmonary nodes. The latter occur within the lung, at the bifurca- on of the bronchial tubes. These groups receive the drainage of the lower part the trachea, the bronchi, the lungs, part of the esophagus, and, to a small tent, the heart. Their efferent vessels unite with those from the upper anterior ediastinal and internal mammary nodes to form the bronchomediastinal trunk.

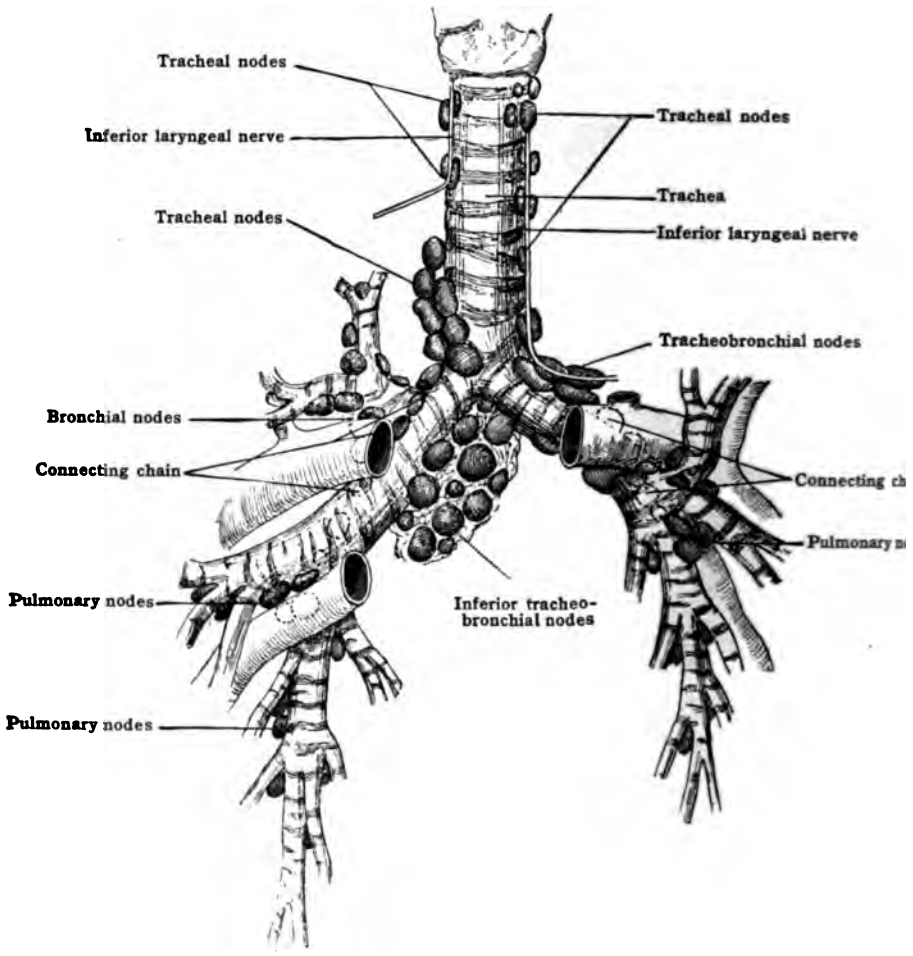
3. THE DEEP LYMPHATIC VESSELS OF THE THORAX

The deep lymphatics of the thorax will be taken up in the following ord the thoracic duct; the right terminal collecting trunks; the parietal vessels; a the visceral vessels.

The Thoracic Duct

The **thoracic duct** [ductus thoracicus] (fig. 609), which is the main collecti trunk of the lymphatic system, extends from the second lumbar vertebra al the spinal column and course of the aorta to the junction of the left internal ju lar and subclavian veins. It receives all the lymphatics below the diaphrag

Fig. 608.—The Tracheal and Bronchial Nodes. (Sukiennikow.)



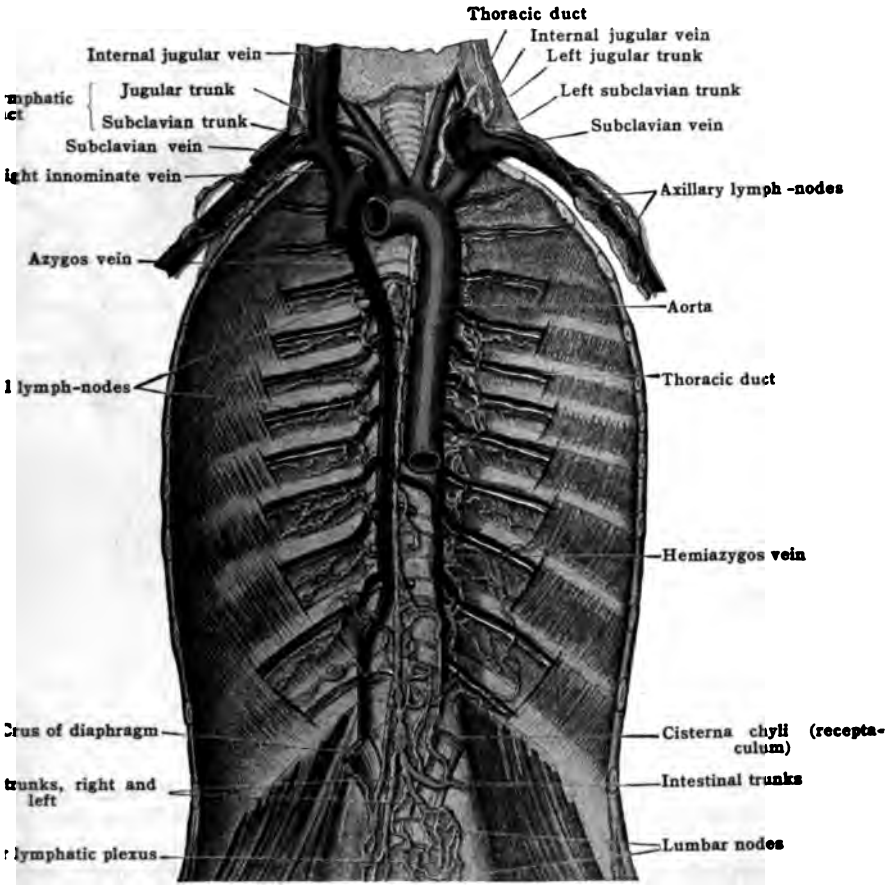
the deep lymphatics from the dorsal half of the chest wall; and also, when jo by the left bronchomediastinal, subclavian and jugular trunks, from the remai of the left half of the body, above the diaphragm. At the caudal end the du formed usually by the union of three collecting trunks, one from each of the bar groups of nodes, and an unpaired intestinal trunk. At its origin the frequently a dilated portion known as the **cisterna chyli** (or receptaculum ch This usually ends opposite the body of the eleventh thoracic vertebra, and here on the duct is from 4 to 6 mm. in diameter, until near its termination, w it is again wider.

In its caudal part, the duct lies dorsal to the aorta in the median line; it p through the aortic opening in the diaphragm, and then inclines to the right passes upward between the aorta and the azygos vein to about the fourth, fif

ıoracic vertebra, where it bends to the left and passes, continuing upward, .e apex of the left lung to the medial side of the left subclavian artery, and t of the root of the left vertebral artery and vein, and then curves down- o open into the left subclavian vein, close to its junction with the left .l jugular. The duct runs in the wall of the vein a short distance before

ıtions.—There is a wide range of variation from this usual course. The duct is fre- double throughout a part of its course, the two branches being connected by cross ıoses, and finally uniting into a single trunk before joining the veins. It may be ; or a single trunk may pass in front of the aorta instead of behind. In a few instances

)9.—The Thoracic Duct. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



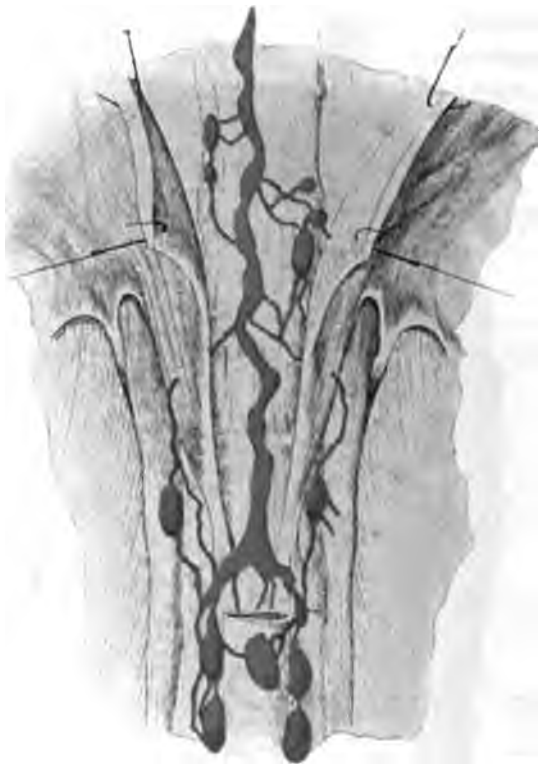
een found emptying into the right instead of the left subclavian vein. There is also a ıge of variation in the height to which the duct ascends in the neck before curving down- the vein. As regards the termination of the thoracic duct, variations are also frequent; bifurcate and end as two ducts. It often connects with the lowermost part of the jugular, or the beginning of the innominate. According to Henle, there is one un- l case reported of a thoracic duct ending in the azygos vein near the sixth thoracic a, the duct being obliterated above this point. At the terminal bend the thoracic duct the jugular trunk from the neck; it may also receive the subclavian and the broncho- inal trunks, but it is more usual for these last two to open either separately or together subclavian.

ations are extremely numerous in the region of the cisterna chyli. Several observers at, in the majority of cases in man, no definite receptaculum exists (cf. fig. 610). Bartels ne in only 25 per cent. of the cases studied. Instead, there is present a widening of each wo lumbar trunks, with several anastomoses between them (55 per cent., Bartels), or a g of these two stems without anastomosis (5 per cent.), or a much elongated widening from the growing together of the two lumbar trunks (10 per cent.). In cases where the trunks remain separate, the intestinal trunk joins the left one. One case has been d in which the thoracic duct ended at the level of the ninth thoracic vertebra. The

lymphatics from the body below this point collected into a duct which became superficial just below the termination of the left saphena magna vein, passed cranialward in the subcutaneous tissue of the left body wall, passed through the axilla, and joined the venous system at the usual place. (E. R. Clark.)

Development.—While the exact mode of its development is still in dispute, enough is agreed upon by the various investigators to explain most of the variations in the thoracic duct. As stated above, it is known that the lymphatics start in the neck in the form of a number of outgrowths from the veins in the region of the junction between the later internal jugular and subclavian veins. A variable number of these connections disappear, while the various combinations of one, two, three or four which are retained furnish the numerous variations in number and position of the ducts which empty into the vein in the adult. Thus the thoracic duct may have one, two or even three openings into the veins, while the jugular, subclavian and bronchomediastinal trunks may join the thoracic duct or may enter the veins separately or in various combinations.

FIG. 610.—ABDOMINAL PORTION OF THE THORACIC DUCT. (Poirier and Cunéo.)



The cisterna develops in connection with branches of veins in the upper lumbar region. All connections with the veins here are soon lost. Around the aorta there develops a plexus, which forms a connection between the anterior plexus and the cisterna. In this plexus two main vessels soon differentiate—the right and left thoracic ducts, which anastomose frequently with one another, and which join, respectively, the right and the left jugulosubclavian angle. Usually the cephalic part of the right and the caudal part of the left duct disappear, leaving the permanent vessel to the right of the aorta for the major part of its course but emptying into the left vein. However, the anterior part of the left duct may disappear, leaving the permanent duct to join the vein on the right side.

Most of the other variations—the frequent presence of longer or shorter doublings of the duct with anastomoses between the two parts and the numerous variations in the region of the cisterna chyli—are easily explained by the fact that they pass through a stage in development in which they form richly anastomosing plexuses around the aorta.

THE RIGHT TERMINAL COLLECTING TRUNKS

On the right side the jugular, subclavian, and bronchomediastinal trunks usually open separately into the subclavian vein, the orifices of the first two being near together. When the jugular and subclavian trunks unite, the common trunk is termed the right lymphatic duct. This is a rare form, and it is still

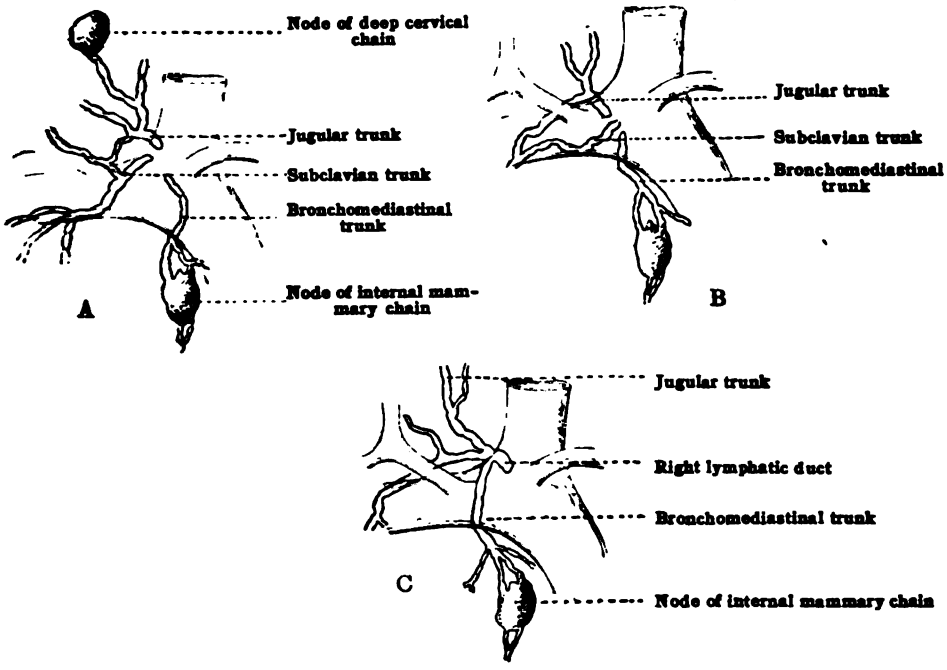
more rare for the three ducts to unite to form a common stem (fig. 611). These variations have the same explanation, embryologically, as was given for the corresponding variations on the left side.

The Deep Lymphatic Vessels

As with the nodes, the deep lymphatic vessels of the thorax may be divided into a parietal and a visceral group. To the former group may be assigned the lymphatics of the intercostal spaces and those of the diaphragm.

The intercostal lymphatics form plexuses in each intercostal space, which receive lymph from the periosteum of the ribs and from the parietal pleura, and from which the drainage is either ventral or dorsal. From the dorsal half of each space the drainage is to the intercostal nodes (fig. 609), while from the ventral half it is toward the internal mammary nodes.

Fig. 611.—Terminal Collecting Trunks on the Right Side. (Poirier and Cunéo.)



The lymphatics of the diaphragm.—There is an exceedingly rich plexus of capillaries both on the thoracic and on the abdominal surface of the diaphragm, especially in the region of the central tendon. These plexuses lie in the subserous layer and are freely connected by vessels which perforate the muscle. There is, however, only slight communication between the plexuses of the right and left sides of the diaphragm. The vessels lie between the coarse muscle-bundles, forming a very characteristic picture, in which the lymphatics stream outward radially, like the spokes of a wheel. The collecting vessels empty into three groups of small nodes on the convex thoracic surface.

The *ventral group* lies ventral to the central tendon. Two or three nodes in the center of this group receive afferents from the liver and none from the diaphragm, but the rest receive vessels from the ventral portion of the diaphragm and the efferents of all pass to the lower set of anterior mediastinal nodes.

The *middle group* consists of from three to six nodes, which lie, on the left side, near the point where the phrenic nerve enters the diaphragm; and on the right side, near the vena cava.

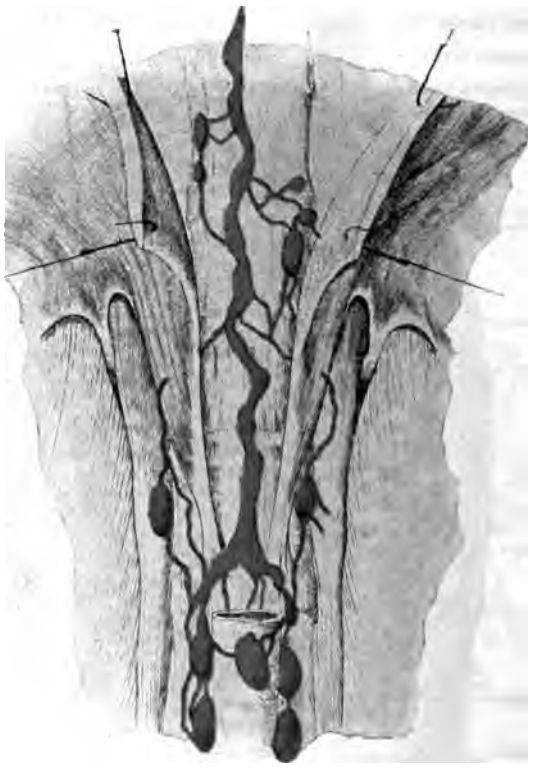
The *dorsal group* of four or five nodes is placed between the crura of the diaphragm. The vessels from the middle and dorsal groups pass to the posterior mediastinal nodes, and also to the upper celiac nodes, which likewise receive the drainage from the dorsal part of the abdominal surface of the diaphragm.

To the visceral group of thoracic lymphatics belong the vessels of the thymus, the lungs, the heart, and the esophagus.

lymphatics from the body below this point collected into a duct which became superficial just below the termination of the left saphena magna vein, passed cranialward in the subcutaneous tissue of the left body wall, passed through the axilla, and joined the venous system at the usual place. (E. R. Clark.)

Development.—While the exact mode of its development is still in dispute, enough is agreed upon by the various investigators to explain most of the variations in the thoracic duct. As stated above, it is known that the lymphatics start in the neck in the form of a number of outgrowths from the veins in the region of the junction between the later internal jugular and subclavian veins. A variable number of these connections disappear, while the various combinations of one, two, three or four which are retained furnish the numerous variations in number and position of the ducts which empty into the vein in the adult. Thus the thoracic duct may have one, two or even three openings into the veins, while the jugular, subclavian and bronchomediastinal trunks may join the thoracic duct or may enter the veins separately or in various combinations.

FIG. 610.—ABDOMINAL PORTION OF THE THORACIC DUCT. (Poirier and Cunéo.)



The cisterna develops in connection with branches of veins in the upper lumbar region. All connections with the veins here are soon lost. Around the aorta there develops a plexus, which forms a connection between the anterior plexus and the cisterna. In this plexus two main vessels soon differentiate—the right and left thoracic ducts, which anastomose frequently with one another, and which join, respectively, the right and the left jugulosubclavian angle. Usually the cephalic part of the right and the caudal part of the left duct disappear, leaving the permanent vessel to the right of the aorta for the major part of its course but emptying into the left vein. However, the anterior part of the left duct may disappear, leaving the permanent duct to join the vein on the right side.

Most of the other variations—the frequent presence of longer or shorter doublings of the duct with anastomoses between the two parts and the numerous variations in the region of the cisterna chyli—are easily explained by the fact that they pass through a stage in development in which they form richly anastomosing plexuses around the aorta.

THE RIGHT TERMINAL COLLECTING TRUNKS

On the right side the jugular, subclavian, and bronchomediastinal trunks usually open separately into the subclavian vein, the orifices of the first two being near together. When the jugular and subclavian trunks unite, the common trunk is termed the right lymphatic duct. This is a rare form, and it is still

growths from the thoracic ducts, those to the posterior third are outgrowths from the retroperitoneal sac, and that there is persistent drainage of this portion of the lung into preaortic nodes and cisterna chyli. No such line of drainage has been found in man.

Lymphatics of the heart.—The superficial (subepicardial) lymphatics of the heart collect to two main stems which accompany the main coronary vessels. The right stem accompanies the right coronary artery to its origin, passes on over the arch of the aorta and empties into one of the anterior mediastinal lymph-nodes. The left stem, formed by two stems accompanying the circumflex and anterior descending branches of the coronary vein, passes behind the arch of the aorta to an anterior mediastinal lymph-gland. Two small subepicardial intercalated nodes have been described along these trunks.

Subendocardial lymphatics have been described, which connect by vessels passing through the musculature with the superficial lymphatics. Parenchymatous lymphatics have been demonstrated by Bock. The course of their efferent vessels has not yet been described.

The lymphatic vessels of the esophagus may be divided into three sets, of which the uppermost pass to outlying nodes belonging to the deep cervical chain, those from the thoracic portion of the tube pass to the bronchial and posterior mediastinal nodes, while those from its lowermost part pass to the superior gastric nodes (fig. 612).

D. THE LYMPHATICS OF THE ABDOMEN AND PELVIS

In the following section there will be described successively the lymphatic nodes of the abdomen and pelvis, the lymphatic vessels of the abdominal walls, and the visceral lymphatic vessels.

1. The Lymphatic Nodes of the Abdomen and Pelvis

The lymphatics which connect directly with the thoracic duct, though complicated, may be described briefly by saying that they follow the aorta and its branches. In the abdomen there are four main chains along the aorta—(1) the left lumbar chain; (2) the right lumbar chain; (3) the preaortic chain; and (4) the postaortic chain.

The right and left lumbar nodes [lgl. lumbales], form an almost continuous chain along the abdominal aorta (fig. 613), resting upon the psoas muscles, some of those on the right side being ventral and some dorsal to the inferior vena cava. They receive: (1) the efferent lymphatics of the common iliac nodes, and hence drain the lower limb and external genitalia; (2) the efferent lymphatics that follow the lumbar arteries and thus drain the abdominal wall; (3) the efferents that follow the paired visceral aortic branches, namely, those from the kidneys, suprarenal, and internal reproductive organs. On the right side, the lymphatics from the reproductive organs pass to the nodes ventral to the vena cava; those of the abdominal walls pass to the dorsal set, while those from the kidney pass to both sets. The efferent vessels of the lower lumbar nodes pass to higher ones and so on up the chain, the vessels from the uppermost nodes uniting to form a single **lumbar trunk** on each side. These trunks pass to the thoracic duct, forming two of the so-called trunks of origin of that vessel (fig. 609).

The **preaortic nodes** (cf. fig. 615) of the lumbar chain are arranged in three groups at the root of each of the three unpaired visceral branches of the aorta—the celiac, the superior mesenteric, and the inferior mesenteric arteries. The **celiac nodes** are from one to three in number, and are in reality parts of chains of nodes extending along the branches of the artery and constituting the **hepatic, gastric,** and **splenic** nodes. They drain the stomach, duodenum, liver, pancreas, and spleen.

The **superior mesenteric** group is larger, and is continuous with the **mesenteric nodes** lying in the root of the mesentery. This group drains the remainder of the small intestine, the cecum and appendix, the ascending and transverse colons, and the pancreas.

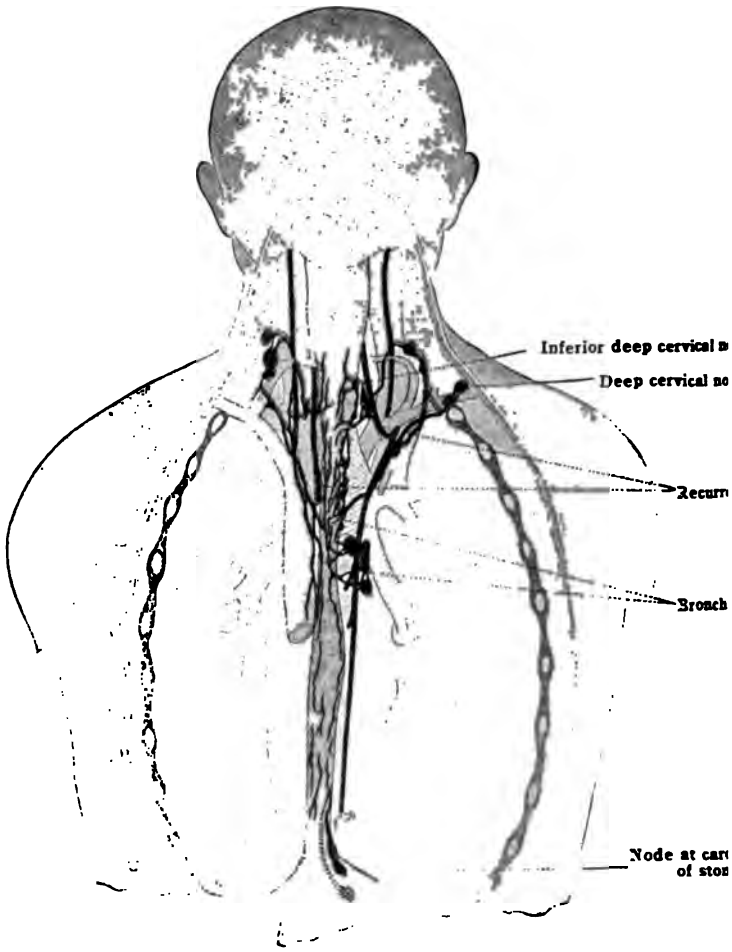
The **inferior mesenteric** group (fig. 613) usually has two nodes, one on either side of the artery. It drains the rectum and descending and sigmoid colons. All the nodes in the mesentery and intestinal walls may be considered as outlying

The **lymphatics of the thymus,** according to Severeanu, drain into thr of nodes, an anterior, a ventral and a dorsal group.

The *anterior* set, one gland on each side, lies lateral to the cephalic end of the thym drains into the jugular or subclavian trunk. The *ventral* set includes 4–6 of the anteri astinal lymph-glands. The *dorsal* set, 2 on each side, is made up of anterior mediastina lying between the thymus and the pericardium.

The **lymphatics of the lungs** are arranged in two sets, deep and sup The *deep lymphatics* fall into three groups: the lymphatics of (1) the b (2) the arteries; (3) the veins.

FIG. 612.—THE LYMPHATICS OF THE ESOPHAGUS. (After Sakata.)



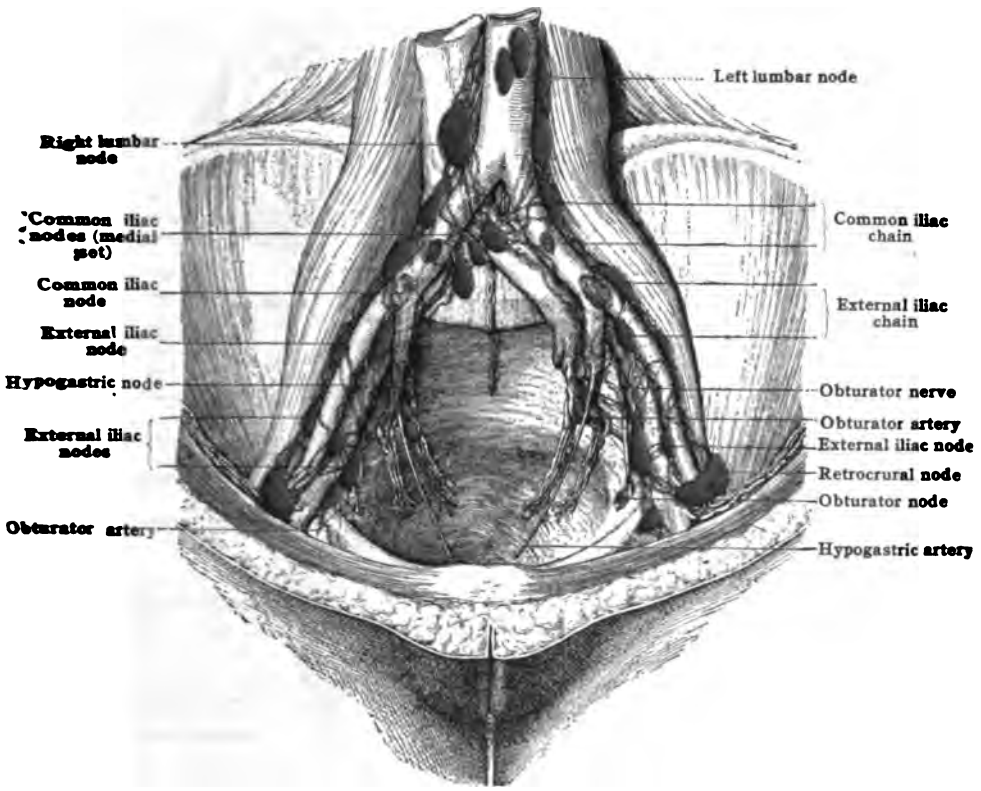
(1) The lymphatics of the bronchi take origin in plexuses which surround the bro bronchioles, and accompany the bronchi to the hilus, communicating with the bronc (fig. 608). (2) The lymphatics of the arteries originate from the lymphatics of the bronchus. Two branches, with numerous anastomoses, usually accompany each art The lymphatics of the veins have an origin similar to that of the arteries, from the lymphatics, at the point where the smaller bronchioles divide. They accompany th the hilus. An additional set of lymphatics, which have a deep origin, pass to the l company with the veins which go to the surface. There are no lymphatic capillaries ing the alveoli.

The *superficial lymphatics* consist of a rich plexus of vessels lying on the of the lung, beneath the pleura. They receive vessels from the deeper aties, and are drained by vessels which pass directly, and independently other sets, to the lymph-nodes of the hilus (W. S. Miller).

In studying the development of the lymphatics to the lung, R. S. Cunningham h that, in the pig, while the lymphatics to the anterior two-thirds of the lung are forme

The *intermediate* chain consists of two or three nodes behind the artery. When there are three, the lowest ('retrocrural') is likewise near the femoral ring. It receives vessels from the bladder, prostate, neck of the uterus, and upper portion of the vagina. The *medial* chain consists of three or four nodes, and is the continuation of the deep inguinal nodes. Its lowest nodes are likewise near the femoral ring, while the next node is large and constant, and usually lies within the pelvis. This chain receives many vessels: (1) from the superficial and deep inguinal nodes; (2) from the glans and clitoris through the femoral canal; (3) from the abdominal wall; (4) from the neighborhood of the obturator vessels; (5) from the neck of the bladder, the prostate, and membranous part of the urethra; (6) from the hypogastric chain.

FIG. 614—ILIAC AND HYPOGASTRIC NODES. (Cunéo and Marcille.)



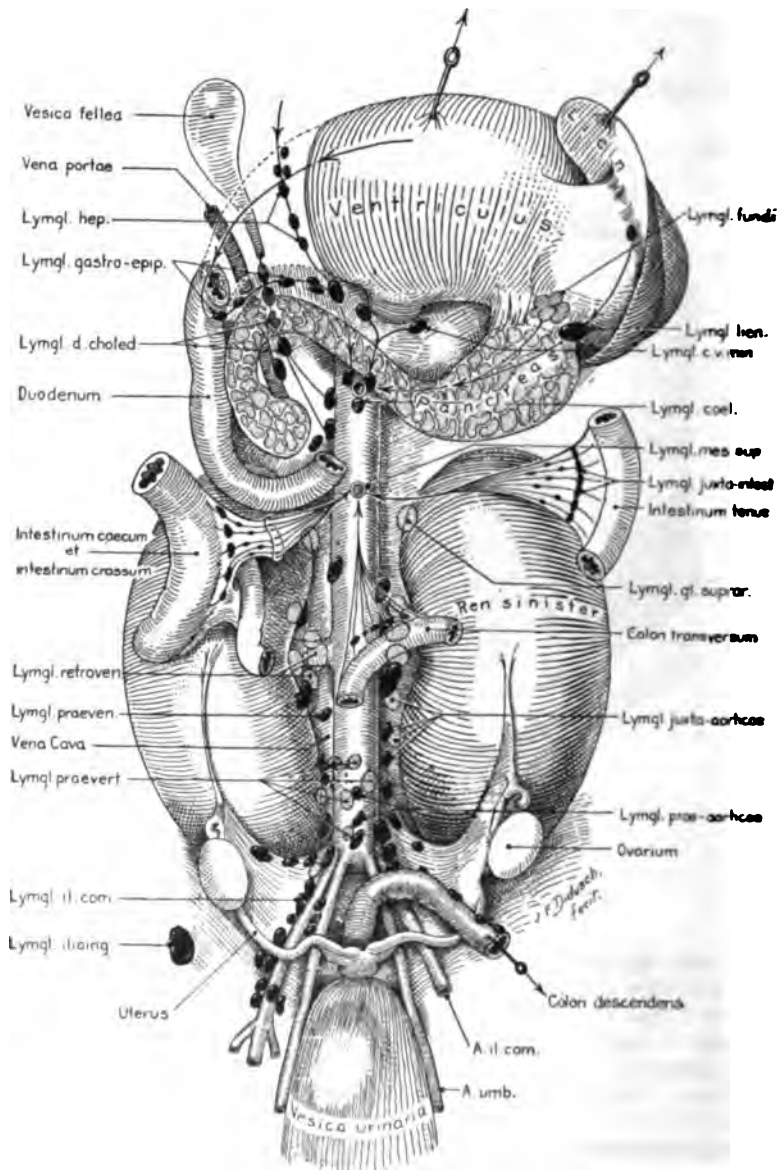
Thus, to sum up the nodes of the external iliac chains, they are a part of a chain which includes the lumbar, common iliac, external iliac, and inguinal nodes. It will be noted that this extensive chain stops, for the most part, with the deep inguinal group. The external iliac nodes receive the efferents of the superficial and deep inguinal nodes; the intermediate and medial groups receive vessels from the pelvis. The efferent vessels of all the nodes in the chain pass to the higher nodes.

The **hypogastric nodes** (figs. 614, 622–625).—These nodes are in groups near the origin of the branches of the hypogastric (internal iliac) artery. Thus they occur near the origin of the obturator, the uterine, or prostatic, the trunk of the inferior gluteal (sciatic) and pudic, the middle hemorrhoidal, and the lateral sacral arteries. All the nodes are beneath the pelvic fascia, and are connected by numerous anastomoses. They receive lymphatics from the structures supplied by the corresponding arteries, namely, from the pelvic viscera, the perineum, and the posterior surface of the thigh and gluteal region. Their efferent vessels pass partly to the middle group of the common iliac nodes, and partly to the posterior nodes of the same chain.

The sacral nodes.—These nodes, 5 or 6 in number, lie in the hollow of the sacrum, in or near the mid-line. They receive afferent vessels from rectum and prostate, and their efferents pass to the hypogastric and lumbar nodes.

Development—Miss Sabin and Reichert have shown, in the pig, that the primary lymph-glands of the abdomen develop out of the primary lymph-sacs, in two fundamental groups (1) the group of glands, ventral to the aorta, extending from the celiac artery to the bifurcation

FIG. 615.—ABDOMINAL LYMPH-NODES OF A 20 CM. PIG FETUS. Solid black: derivatives of the retroperitoneal sac; stippled: derivatives of the iliac sac. (After Reichert.)



of the aorta, which form from the retroperitoneal sac, and (2) the groups of glands dorsal and dorsolateral to the aorta, extending from the level of the suprarenals to the bifurcation of the aorta, with extensions along the iliacs, which develop from the paired iliac sacs. In general, the ventral group receives the drainage from the structures situated within the abdominal cavity, while the dorsal and dorsolateral groups drain organs and structures outside the abdominal cavity, including body-wall and lower extremities. There is, however, an intermediate group of organs—diaphragm, kidney, suprarenal, ureter, and ducts of sex glands—which drain into both sets. Secondary sets, such as the mesenteric, gastric and hepatic glands, develop at a distance from the primary sets (cf. fig. 615).

ermediate chain consists of two or three nodes behind the artery. When hree, the lowest ('retrocrural') is likewise near the femoral ring. It ssels from the bladder, prostate, neck of the uterus, and upper portion ina. The *medial* chain consists of three or four nodes, and is the on of the deep inguinal nodes. Its lowest nodes are likewise near the g, while the next node is large and constant, and usually lies within . This chain receives many vessels: (1) from the superficial and nal nodes; (2) from the glans and clitoris through the femoral canal; e abdominal wall; (4) from the neighborhood of the obturator vessels; he neck of the bladder, the prostate, and membranous part of the) from the hypogastric chain.

THE LYMPHATIC VESSELS OF THE ABDOMINAL WALLS

e lymphatic vessels of the abdominal walls are arranged in two sets, one of is subcutaneous and the other deep or aponeurotic. The **subcutaneous** s form a rich network through all the subcutaneous tissue of the abdomen, mosing above with the subcutaneous plexus of the thorax, which drains pper part of the anterior abdominal wall. The vessels chiefly converge d the inguinal region, those from the posterior wall curving forward along est of the ilium, and terminate in the superficial inguinal nodes (fig. 629). e **deep** vessels drain along four principal lines. (1) A set of collecting s follows the line of the deep epigastric artery to terminate in the lower al iliac nodes; (2) a second set follows the deep circumflex iliac vessels to me nodes; and (3) a third set follows the lumbar vessels to terminate in the of the lumbar chain; (4) the upper part of the anterior abdominal wall into the sternal nodes, following the superior epigastric vessels.

oup of small **epigastric nodes,** which may be regarded as offsets from the iliac chain, on the lymph-vessels which accompany the deep epigastric vessels, not far from their ation, and a second less constant group of usually three small **umbilical nodes** occurs in inity of the umbilicus in the network covering the posterior layer of the sheath of the abdominis muscle.

IE VISCERAL LYMPHATICS OF THE ABDOMEN AND PELVIS

he lymphatics to the viscera follow along the course of the blood-vessels. e point where the artery of an organ branches from the aorta there is a of nodes which represents the main regional group, and a second chain of extends along the artery. The final arrangement of nodes and vessels with each organ. The lymphatics (vessels and nodes) of the alimentary suprarenal gland, urinary and reproductive tracts will be successively dered.

almost all organs there is a peripheral or capsular lymphatic plexus, which anastomoses he parietal lymphatics, these anastomoses being particularly well developed in the case liver. In addition there are one or two deep plexuses in the great majority of the organs drain partly directly to their regional nodes and partly by way of the peripheral plexus.

THE LYMPHATICS OF THE ALIMENTARY TRACT

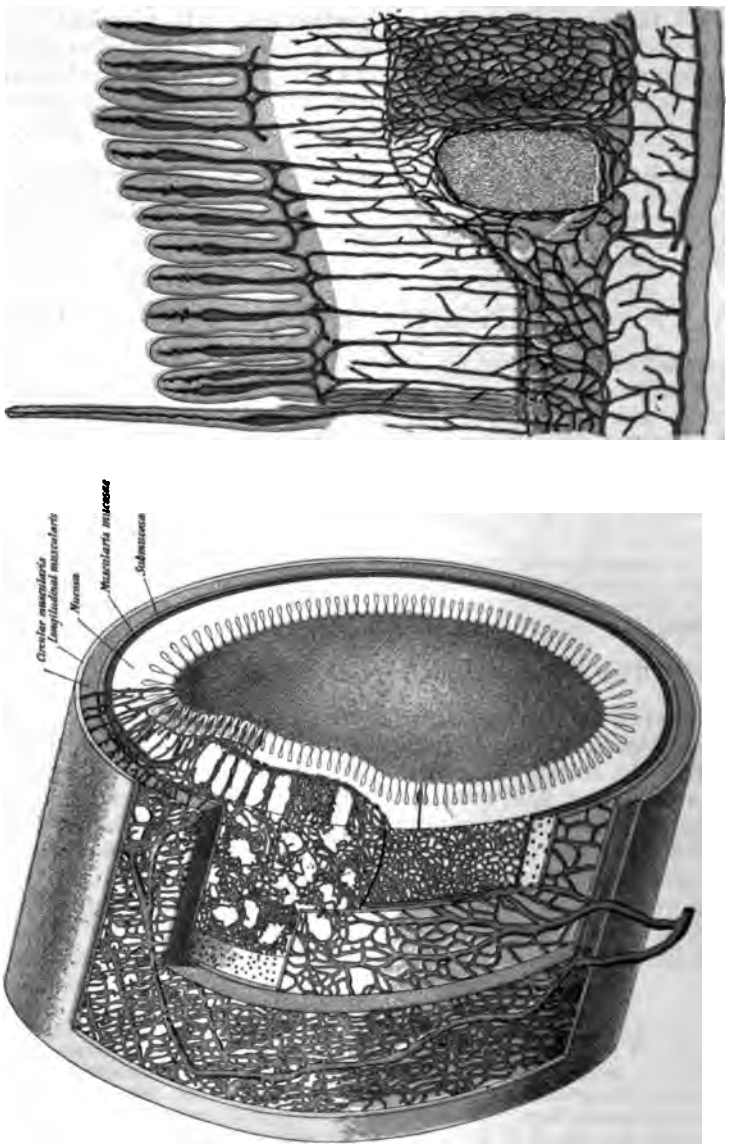
he lymphatics of the mouth, pharynx, and esophagus have already been ibed (pp. 749, 763). In general, throughout the abdominal part of the ali- ary canal, the distribution of nodes is as follows: (1) There are primary nal nodes situated at the roots of the arteries (celiac and the superior and or mesenteric arteries); these nodes drain large segments of the intestine; roups of definite and constant nodes placed along the branches of the arteries n the mesentery; these drain a definite smaller segment of the intestine; hains of nodes along the anastomotic loops of the arteries, close to the in- al wall; these are of the type called 'intercalated nodes'; (4) solitary or ound follicles, situated within the submucosa or capillary zone of the hatics.

hat may be taken as the typical arrangement of the lymphatic vessels in the intestine may n in fig. 616. There are three zones in which the capillary plexuses are spread out, namely, subserosa, the submucosa, and the mucosa. There is an abundant plexus of large cap- just beneath the serosa; in the submucosa the plexus is also formed by large capillaries, the mucosal plexus is finer. The lymph-follicles lie in the zone of the mucosal plexus, and om this that the central chyle vessels of the villi arise. The spiral tips of the central ls shown in fig. 616 are probably artefacts. The collecting vessels are formed by the union els from the submucous and subserous plexuses. They traverse the three sets of nodes scribed.

he lymphatics of the stomach (fig. 617).—The stomach differs from the rest alimentary canal in its blood-supply in having a ventral anastomotic loop, **ly,** that along the lesser curvature. Along this loop is the **superior gastric** [lgl. gastricæ superiores] of nodes, lying between the folds of the lesser **tum,** some of them being on the posterior surface of the stomach. This is ost important group of nodes draining the stomach, and it has been shown he lymph-vessels from the pylorus run obliquely across the stomach to the

main mass of nodes near the cardia, an important point in the surgery of pylorus. The efferent vessels of the chain pass to the celiac nodes. The ve of the greater curvature pass to a group of **inferior gastric nodes** [lgl. gast inferiores], situated along the right gastroepiploic artery, while those of the fu follow the short gastric and left gastroepiploic vessels to the nodes whic along the splenic artery [lgl. pancreaticolienales], both these sets of nodes draining to the celiac group. There is a zone half-way between the lesser

FIG. 616.—THE LYMPHATIC VESSELS OF THE INTESTINE. (After Mall.)

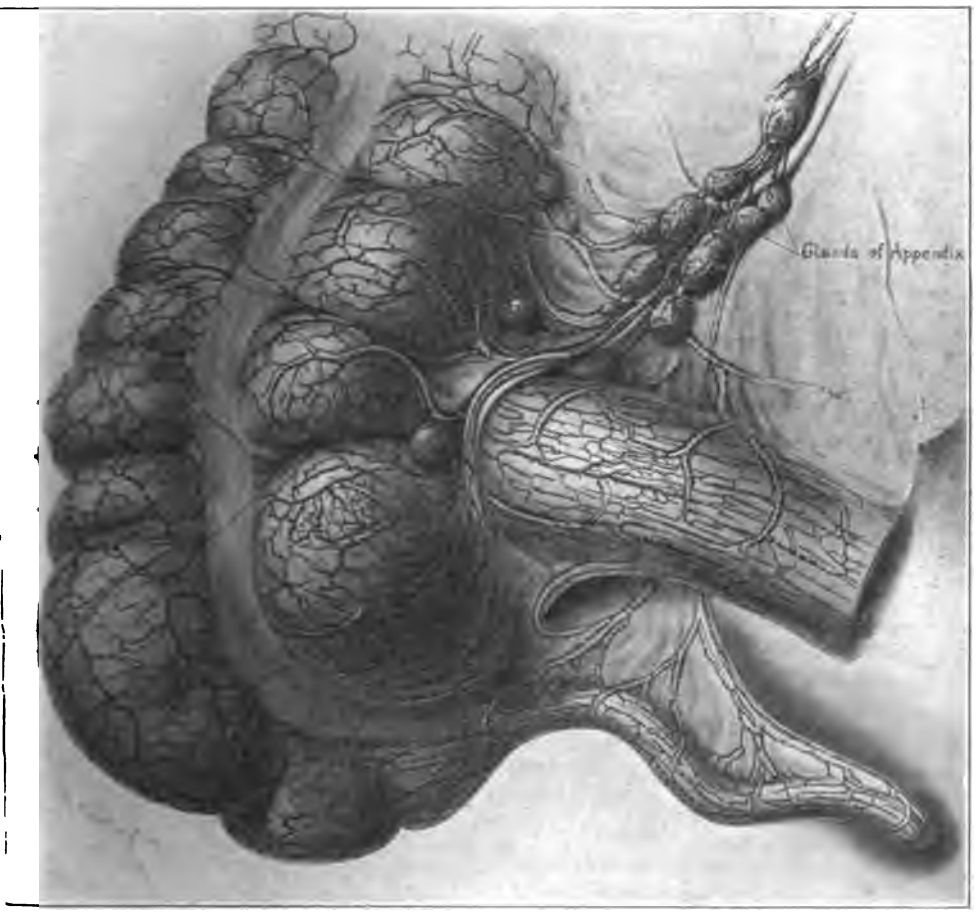


greater curvatures, in which the lymphatics are scanty. **The lymphatics** cardia connect with those of the esophagus, and **the mucosal plexus of the p** is continuous with that of the duodenum.

The lymphatics of the duodenum.—The lymphatics of the duodenum somewhat from the type, owing to its relations with **the pancreas and th** ducts. The collecting vessels end: (1) in nodes **ventral to the pancreas,** follow the pancreaticoduodenal artery to the hepatic **chain; (2) in nodes do** the pancreas, which follow the superior mesenteric **artery to the superior** teric nodes. There are anastomoses between the **lymphatics of the duo**

The superficial lymph-vessels of the liver have been studied by Sappey. Those from the superior surface include three sets. From the dorsal part vessels pass through the diaphragm with the vena cava, and end in the adjacent posterior mediastinal nodes. Some of these vessels from the right lobe pass in the coronary ligament to the celiac nodes, and some from the left lobe to the superior gastric nodes. The second set of vessels from the superior surface runs over the ventral border to the hepatic nodes situated in the portal fissure. The third and most important set arises near the falciform ligament, and passes partly dorsalward to the anterior mediastinal group of nodes on the upper surface of the diaphragm, and to the nodes around the vena cava, and partly ventralward to the hepatic nodes of the portal fissure.

FIG. 619.—THE LYMPHATICS OF THE ILEOCECAL REGION, ANTERIOR VIEW. (After Kelly.)



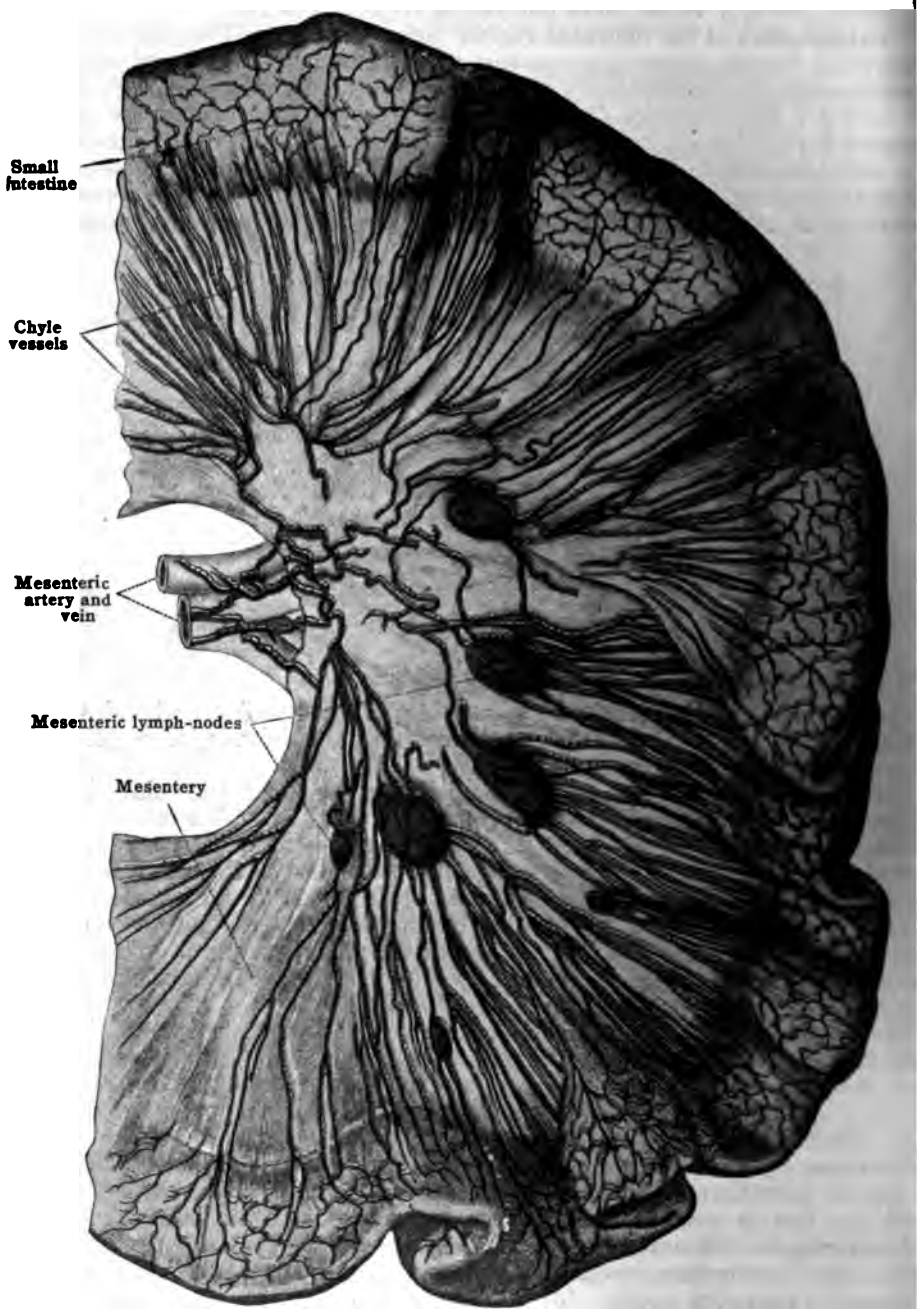
The collecting vessels of the inferior surface of the liver pass to the nodes situated in the portal fissure, either along the artery or the bile-ducts.

The lymphatics of the **gall-bladder** join the hepatic nodes along the cystic and common bile-ducts, and also the superior pancreatic nodes.

Lymphatics of the pancreas.—The lymph-vessels which drain the pancreas fall, according to Bartels, into four groups: left, anterior (upper), right and posterior (lower). (1) The left group drain the tail of the pancreas and pass to the splenic lymph-nodes, at the hilus of the spleen. (2) Anteriorly lymphatics pass to the superior pancreatic, superior gastric and hepatic nodes. (3) To the right, lymphatics pass to the pancreaticoduodenal lymph-nodes. (4) Posteriorly lymphatics pass to the aortic, mesenteric, mesocolic, and inferior pancreatic nodes. The splenic, superior pancreatic, inferior pancreatic, and pancreaticoduodenal nodes form a closely associated group [lymphoglandulæ pancreatico-

ondary group of three to six **hepatic nodes,** situated along the hepatic artery. Some of these nodes are along the hocizontal part of the artery, parallel to the superior border of the pancreas, while the rest follow the artery in its vertical course along with the portal vein, and become continuous at the portal fissure

FIG. 618.—LYMPHATICS OF THE SMALL INTESTINE. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



with two distinct chains of nodes, one of which follows the hepatic artery i portal vein, and the other the cystic and common bile-ducts. These nodes variable, but one constant node is at the junction of the cystic and hepatic du A part of the drainage of the liver is also through the diaphragmatic no of the anterior and posterior mediastinal groups.

superficial lymph-vessels of the liver have been studied by Sappey. m the superior surface include three sets. ollecting vessels of the inferior surface of the liver pass to the nodes n the portal fissure, either along the artery or the bile-ducts.
ymphatics of the **gall-bladder** join the hepatic nodes along the cystic and bile-ducts, and also the superior pancreatic nodes.
hatics of the pancreas.—The lymph-vessels which drain the pancreas rding to Bartels, into four groups: left, anterior (upper), right and (lower). (1) The left group drain the tail of the pancreas and pass to ic lymph-nodes, at the hilus of the spleen. (2) Anteriorly lymphatics he superior pancreatic, superior gastric and hepatic nodes. (3) To the phatics pass to the pancreaticoduodenal lymph-nodes. (4) Posteriorly cs pass to the aortic, mesenteric, mesocolic, and inferior pancreatic The splenic, superior pancreatic, inferior pancreatic, and pancreaticonodes form a closely associated group [lymphoglandulæ pancreatico-

lienales]. Anastomoses exist between the lymphatics of the pancreas and of the duodenum.

The **lymphatics of the spleen** form a subcapsular plexus from which v pass through the hilus to the **splenic nodes** (of the pancreaticolienal group). nodes are variable in number and are situated along the course of the s vessels. In addition to the spleen, they drain the fundus of the stomach part of the pancreas.

FIG. 620.—THE LYMPHATICS OF THE ILEOCECAL REGION, POSTERIOR VIEW. (After

THE LYMPHATICS OF THE SUPRARENAL GLAND AND OF THE URINARY

The lymphatics of the suprarenal gland.—The lymphatic vessels comi the capsular and parenchymatous plexuses pass, on the right side, into three anterior para-aortic nodes, and a small retrovenous gland, near the cru diaphragm; on the left side, into para-aortic nodes, and, in part, throu diaphragm, in company with the splanchnic nerve, to a posterior med gland, lying between the ninth thoracic vertebra and the aorta. Anast occur with the lymphatics of the kidney.

In addition to the capsular lymphatics proper, Kumita describes a subserous plexu is present over both kidney and suprarenal, which anastomoses with the lymphati liver and diaphragm. The efferents of this plexus collect, on the right side, to a glar

FIG. 621.—LYMPHATICS OF THE KIDNEY. (After Poirier and Cunéo.)

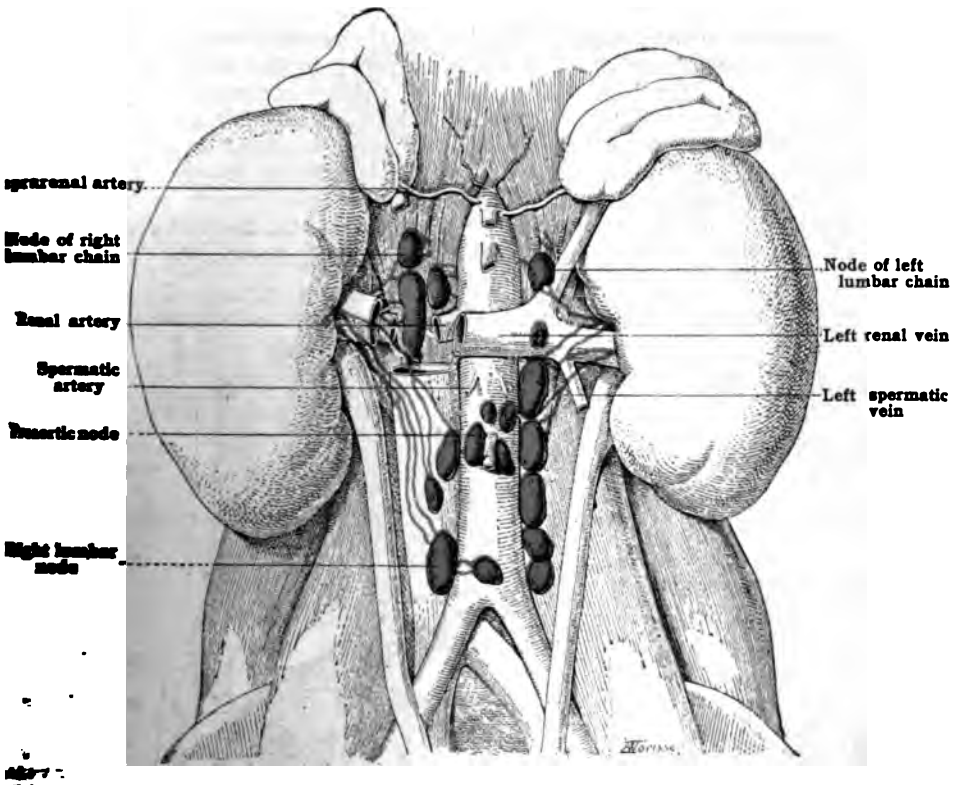

FIG. 622.—LYMPHATICS OF THE BLADDER. (After Cunéo and Marcille.)

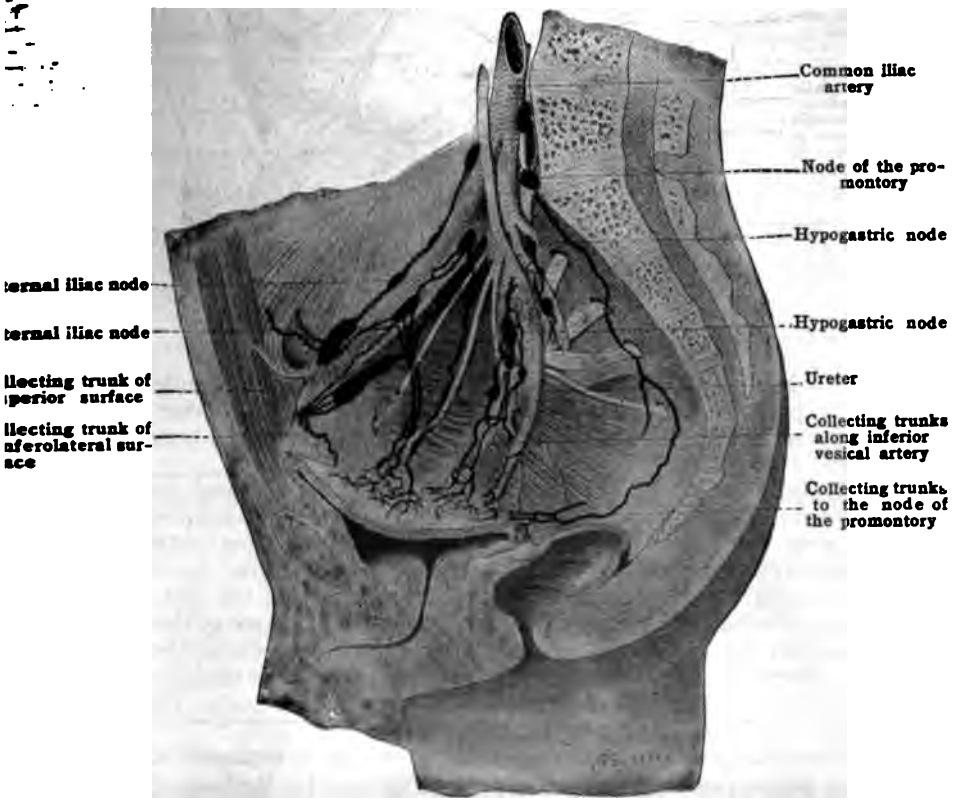
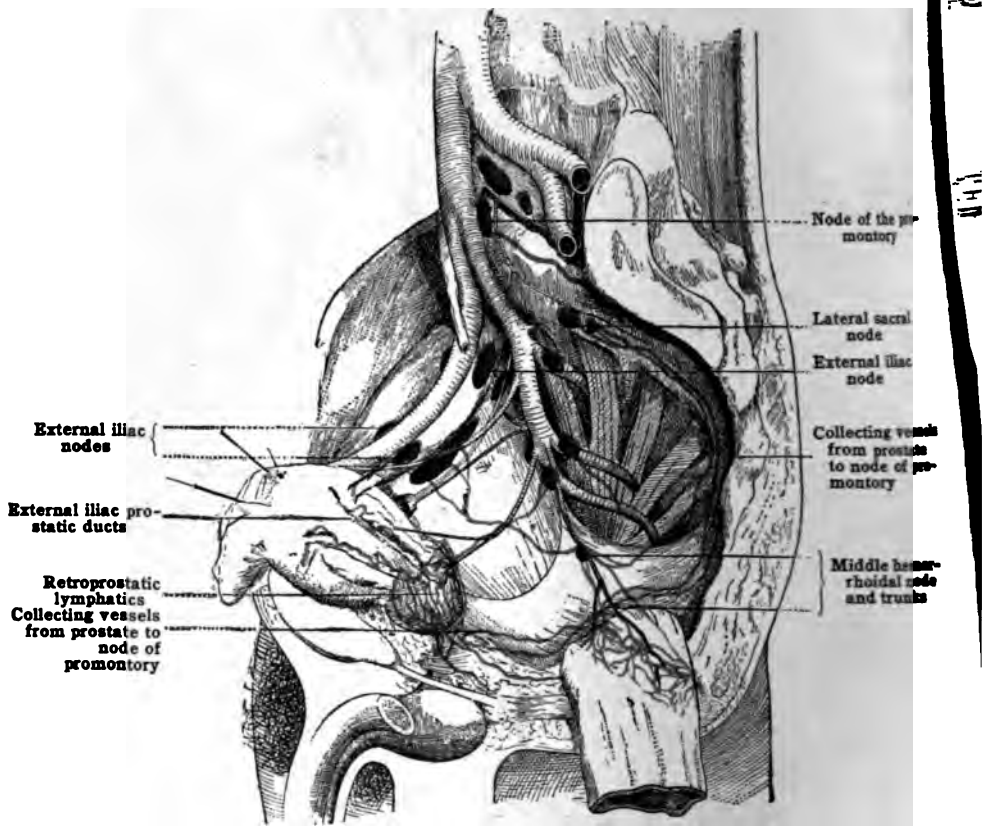


to the right of the inferior vena cava, anterior to the right renal vein, and on the left side to a gland anterior to the left renal vein.

The lymphatics of the kidney.—The lymphatic vessels from the deep capsular and parenchymatous lymphatics of the kidney run to the nodes of the lumbar chain (fig. 621). On the right side, part of the nodes concerned lie ventral and part dorsal to the renal vein; one of the nodes lies as far caudalward as the bifurcation of the aorta; and one or two vessels may pass to preaortic nodes. On the left side the vessels end in four or five nodes of the lumbar group. The efferents of these nodes end in the thoracic duct.

The lymphatics of the ureter.—According to Sakata, the lymphatics of the ureter fall into three groups: (1) An anterior (upper) group, which run to the

FIG. 623.—THE LYMPHATICS OF THE PROSTATE. (After Cunéo and Marcille.)



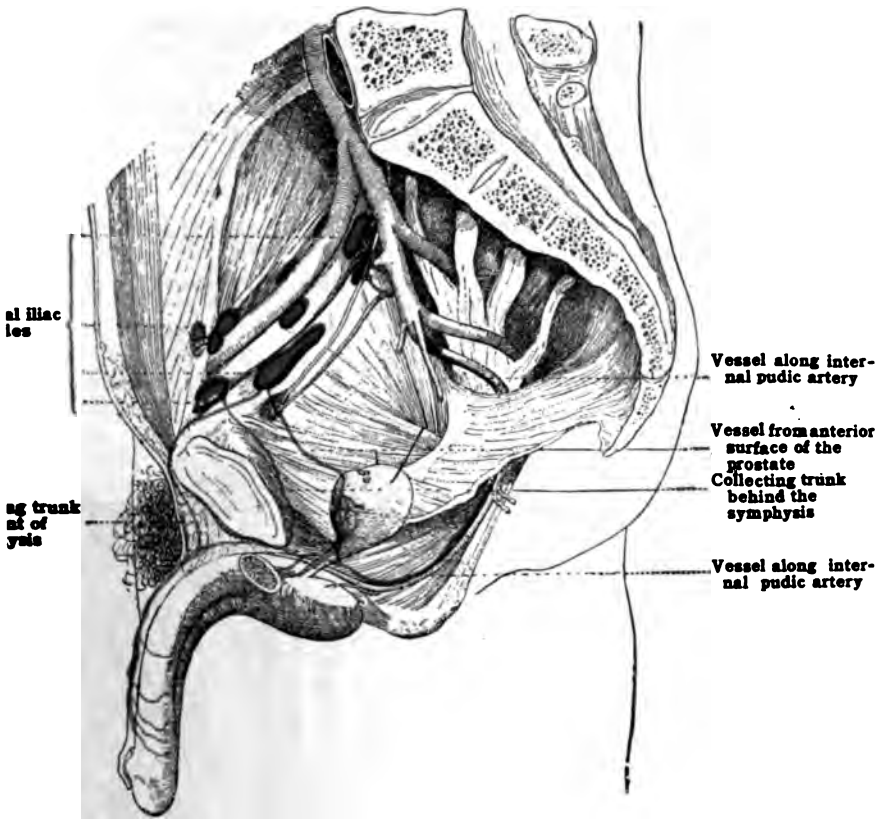
Node of the promontory
Lateral sacral node
External iliac node
External iliac nodes
Collecting vessels from prostate to node of promontory
External iliac prostatic ducts
Middle hemorrhoidal node and trunks
Retroprostatic lymphatics
Collecting vessels from prostate to node of promontory

anterior lumbar nodes, or join the renal lymphatics; (2) a middle group which pass to the posterior lumbar and interiliac nodes; (3) a posterior (lower) group which pass to hypogastric nodes and which anastomose with lymphatics of the bladder.

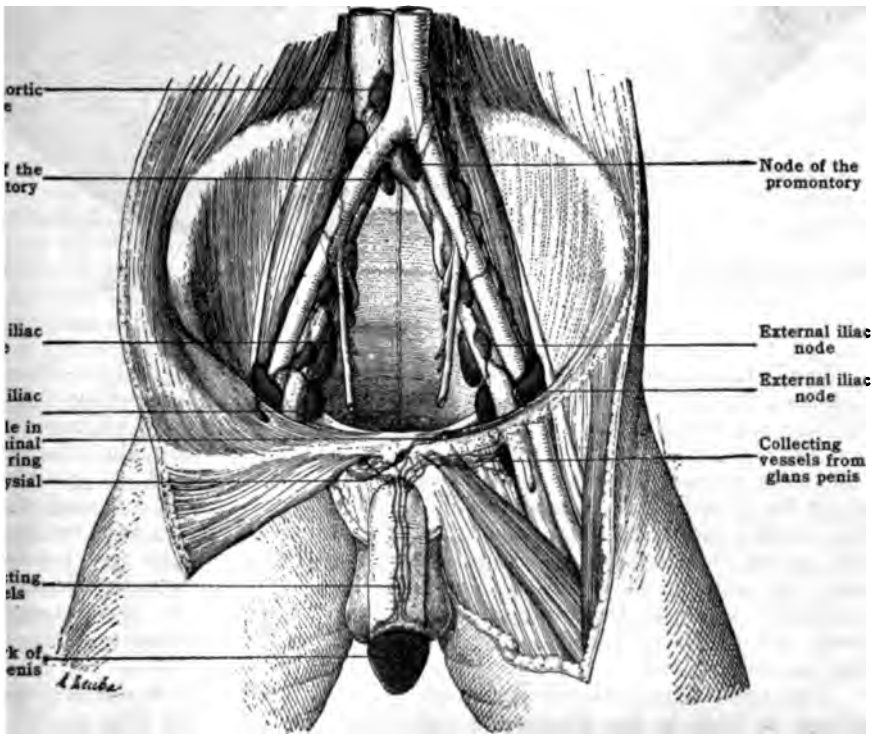
The lymphatics of the bladder (fig. 622).—The collecting vessels from the anterior part of the inferolateral surface pass to a node of the external iliac group, situated near the femoral ring; those from the upper part of the inferolateral surface and anterior part of the superior surface pass to the middle node of the middle group of the external iliac chain; and those from the rest of the superior surface and the base of the bladder pass either to the hypogastric nodes or beyond these to the nodes at the bifurcation of the aorta (nodes of the promontory). In this latter group end also the vessels from the neck of the bladder. Along some of the lymphatics of the bladder are intercalated lymph-nodes, which have been termed anterior and lateral vesical nodes.

The lymphatics of the prostate (fig. 623).—The lymphatics of the prostate have been studied in the dog by Walker and in man by Bruhns. The collecting

:.—Lymphatics of the Cavernous and Membranous Portions of the Urethra (After Cunéo and Marcille.)



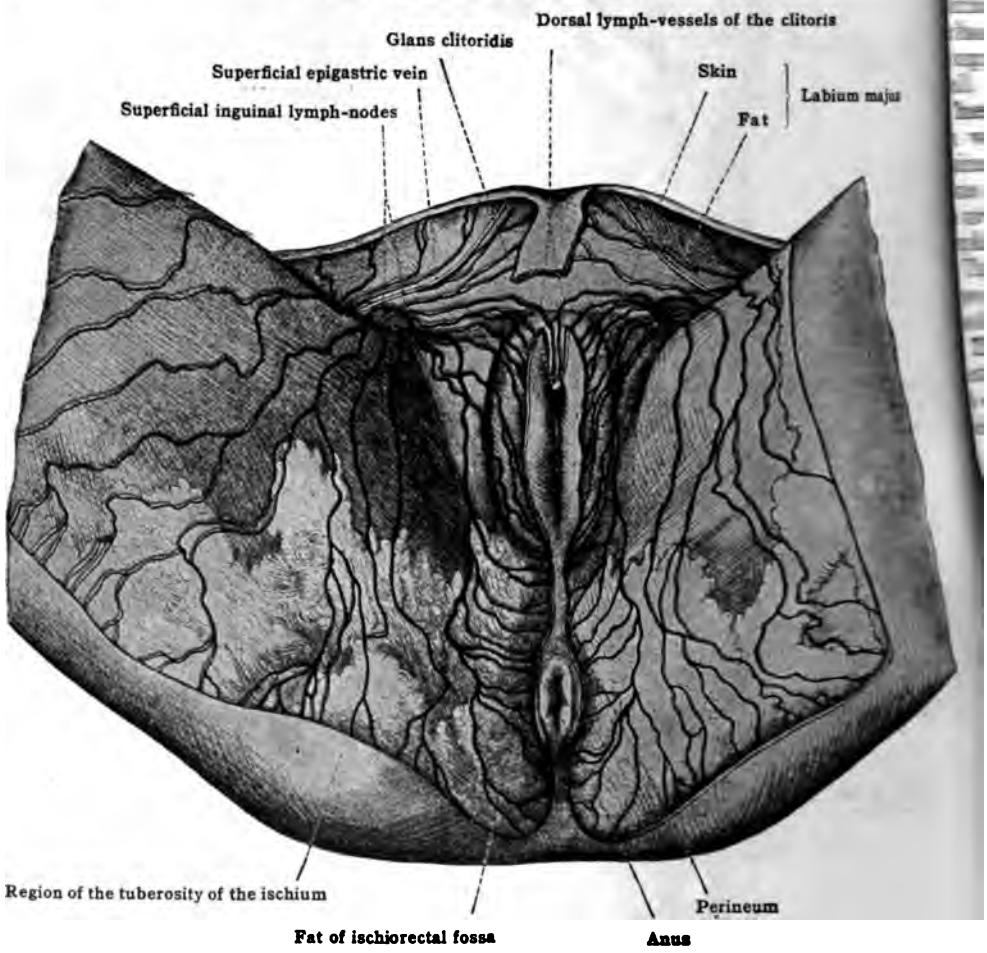
.—Lymphatics of the Glans Penis in a New-born Child. (Cunéo and Marcille.)



vessels, six to eight on each side, pass along the prostatic artery to the nodes along the hypogastric artery.

These nodes are connected with those along the external and common iliac arteries, and it is possible, from an injection of the prostate, to fill the entire chain of nodes as far as the renal artery. A trunk from the posterior surface runs up over the bladder and curves outward to the middle node of the middle group of the external iliac chain, and still other vessels from the posterior surface run first downward, pass around the rectum, and then ascend to the lateral sacral nodes. From the anterior surface a descending trunk may follow the deep artery of the penis, and the internal pudic to the hypogastric nodes (fig. 623). The lymphatics of the prostate anastomose with those of the bladder, ductus deferens and rectum.

FIG. 626.—LYMPHATICS OF THE PERINEUM. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



The lymphatics of the urethra.—1. *In the Male* (figs. 624, 625).—The capillary plexus of the urethra is in the mucous membrane. The collecting vessels from the mucous membrane of the glans follow the dorsal vein. Those from the cavernous and membranous portions of the urethra start from the inferior surface and curve around the corpora cavernosa, as seen in fig. 624, to join the others along the dorsal vein. These vessels run with the vein to the symphysis, where they form a plexus in which there may be some small intercalated nodes. From this plexus vessels pass in various directions: Three or four vessels pass to the deep inguinal and external iliac nodes, and one vessel enters the inguinal canal and ends in one of the external iliac nodes. There is also a communication, along the dorsal vein of the penis, with the prostatic plexus and the external iliac nodes (fig. 624).

The vessels from the membranous portion either follow the internal pudic artery, or pass to the symphysis and end in the external iliac nodes, or pass

the surface of the bladder and thence to the external iliac chain. The hatics of the prostatic urethra run with the prostatic vessels. The lymics of the urethra anastomose with those of the bladder and those of the glans. *In the female* the lymphatic vessels of the urethra end in the external iliac hypogastric nodes.

Lymphatics of the Reproductive Organs

In the Male (Figs. 623–625)

he lymphatics of the external genitalia will be first described and then those e internal organs.

he lymphatics of the scrotum form a rich plexus which has been pictured by hmann (fig. 587). The collecting vessels, ten to fifteen on either side, arise the raphe and pass to the root of the penis, where some curve lateralward to superior medial superficial inguinal nodes; while others, coming from the al surface of the scrotum, pass to the corresponding inferior nodes.

he lymphatics of the penis.—(1) The cutaneous lymphatics form a plexus which collecting vessels follow the dorsal vein and end in the superficial inal nodes. (2) The lymphatics of the glans form an exceedingly rich us from which vessels follow the dorsal vein of the penis, as described under urethra, and end in the deep inguinal and external iliac nodes. (3) The hatics of the erectile structures are little known.

he lymphatics of the testis are both superficial and deep, the latter being edingly hard to inject. The collecting vessels follow the spermatic cord and d-vessels to end in the lumbar nodes.

he lymphatics of the ductus deferens and vesiculæ seminales.—In the us deferens only a superficial set has been injected, and its vessels pass to external iliac nodes. The plexus of the vesiculæ seminales is double, super- and deep, and its vessels pass to the external iliac and hypogastric nodes.

Lymphatics in the Female (Figs. 626–628)

he lymphatics of the vulva.—Throughout the vulva there is an exceedingly superficial lymphatic plexus, from which collecting vessels pass to the symis and there turn lateralward to the medial superficial inguinal nodes (fig. The fact that the capillary plexus is continuous from side to side and that is a plexus of the vessels in front of the symphysis makes the nodes of both liable to infection from a unilateral lesion.

he lymphatics of the clitoris.—The lymphatics of the glans of the clitoris an abundant network from which collecting vessels pass toward the symphyubis, and thence principally to the deep inguinal nodes, one or two, however, ng through the inguinal canal to terminate in the lower external iliac nodes.

he lymphatics of the ovary.—The ovary has a remarkably rich lymphatic s, from which from four to six vessels leave the hilus and follow the ovarian l-vessels to the lumbar nodes. One vessel may run in the broad ligament to the internal iliac group.

he lymphatics of the uterine (Fallopian) tube form three capillary networks which collecting vessels run in part with those of the ovary, and in part with terine lymph-vessels.

he lymphatics of the uterus.—According to Poirier, the lymphatics of the s arise from three capillary plexuses, a mucous, a muscular, and a peritoneal. collecting vessels from the *body of the uterus* (fig. 627) are in three sets: Those from the fundus, consisting of four or five vessels, run lateralward gh the broad ligament and the suspensory ligament of the ovary and follow varian vessels to the lumbar and preaortic nodes. They anastomose with ymphatics from the ovary opposite the fifth lumbar vertebra; (2) some small ls from the fundus follow the round ligament of the uterus and terminate e inguinal nodes; and (3) others from the body of the uterus pass laterally the uterine vessels and terminate in the iliac nodes.

he collecting vessels from the *cervix* (figs. 627, 628), five to eight in number, a large lymphatic plexus just after leaving the cervix. From this plexus run

FIG. 627.—LYMPHATICS OF THE INTERNAL GENITAL ORGANS IN THE FEMALE. (After Poirier.)

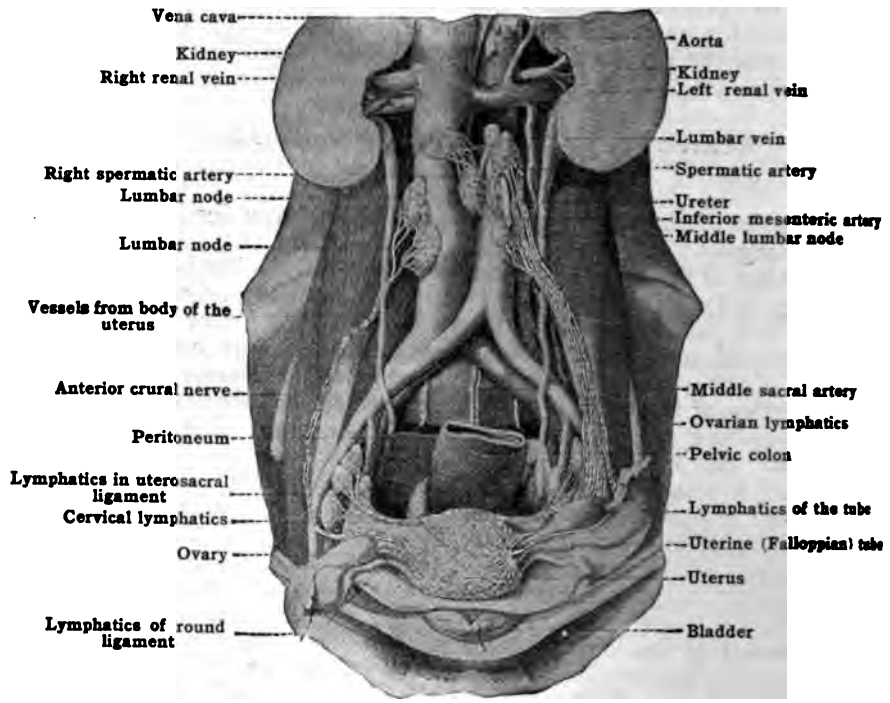


FIG. 628.—LYMPHATICS OF THE VAGINA. (After Poirier.)

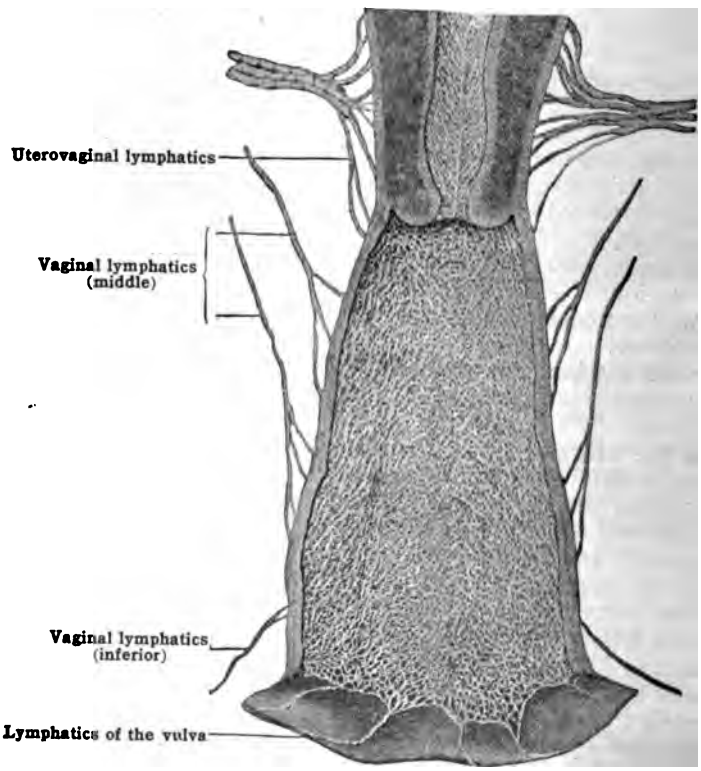


three sets of vessels. Two or three vessels pass lateralward with the uterine artery in front of the ureter, and end in the external iliac nodes; a second set passes behind the ureter and ends in a node of the hypogastric group; and a third set from the posterior surface runs downward over the vagina and then backward and upward to end in the lateral sacral nodes and node of the promontory of the sacrum.

The lymphatics of the vagina (fig. 628).—There are two lymphatic plexuses in the vagina, a superficial and deep—the latter, the mucosal plexus, being exceedingly rich. The collecting vessels are in three groups. The superior set (uterovaginal) drains the upper third of the vagina and takes the same course as those from the lower cervical portion of the uterus; the middle set follows the vaginal artery to the hypogastric nodes; and the inferior set runs to the lateral sacral nodes and to those of the promontory. The capillary network of the lower part of the vagina is continuous with the plexus of the vulva, which drains to the inguinal nodes.

E. THE LYMPHATICS OF THE LOWER EXTREMITY

1. THE LYMPHATIC NODES OF THE LOWER EXTREMITY

The principal group of nodes of the lower extremity is situated in the inguinal region, and hence is known as the **inguinal group** (figs. 629, 630). It is in many respects similar to the axillary group, although it is not quite equivalent to it developmentally. The nodes composing it are divisible into a superficial and a deep group, the former containing many more and larger nodes than the latter. Furthermore, it is convenient to divide each of these groups into an upper and a lower set, the dividing line being an arbitrary line drawn horizontally through the point where the saphenous vein pierces the fascia of the fossa ovalis. The nodes above this line are termed collectively the **inguinal nodes** [lgl. inguinales], while those below it are known as the **subinguinal nodes** [lgl. subinguinales).

The superficial inguinal nodes lie along the base of the femoral trigone immediately below Poupart's ligament, superficial to the fascia lata. Their number varies from ten to twenty. They receive the subcutaneous drainage of the anterior and lateral abdominal walls, the gluteal region, the external genitalia and the perineal region. Their efferents descend to the fossa ovalis, which they perforate along with the saphenous vein and terminate in the lower external iliac nodes.

The **superficial subinguinal nodes** occupy the lower part of the femoral trigone and receive the entire superficial drainage of the lower extremity, as well as a few vessels from the gluteal region and from the perineum. Their efferents pierce the fossa ovalis and pass partly to the deep subinguinal nodes and partly directly to the lower external iliac nodes.

The deep inguinal nodes.—The deep nodes are small, and vary from one to three. They lie medial to the femoral vein, the highest one (node of Cloquet or of Rosenmüller) being placed in the femoral ring and being of especial surgical interest in that, when enlarged, it may simulate a strangulated hernia. The lowest node is below the point where the great saphenous joins the femoral vein. These deep nodes receive the deep lymphatics of the lower extremity, also vessels from the glans penis or clitoris, and some of the vessels from the superficial subinguinal nodes. Their efferent vessels enter the external iliac nodes.

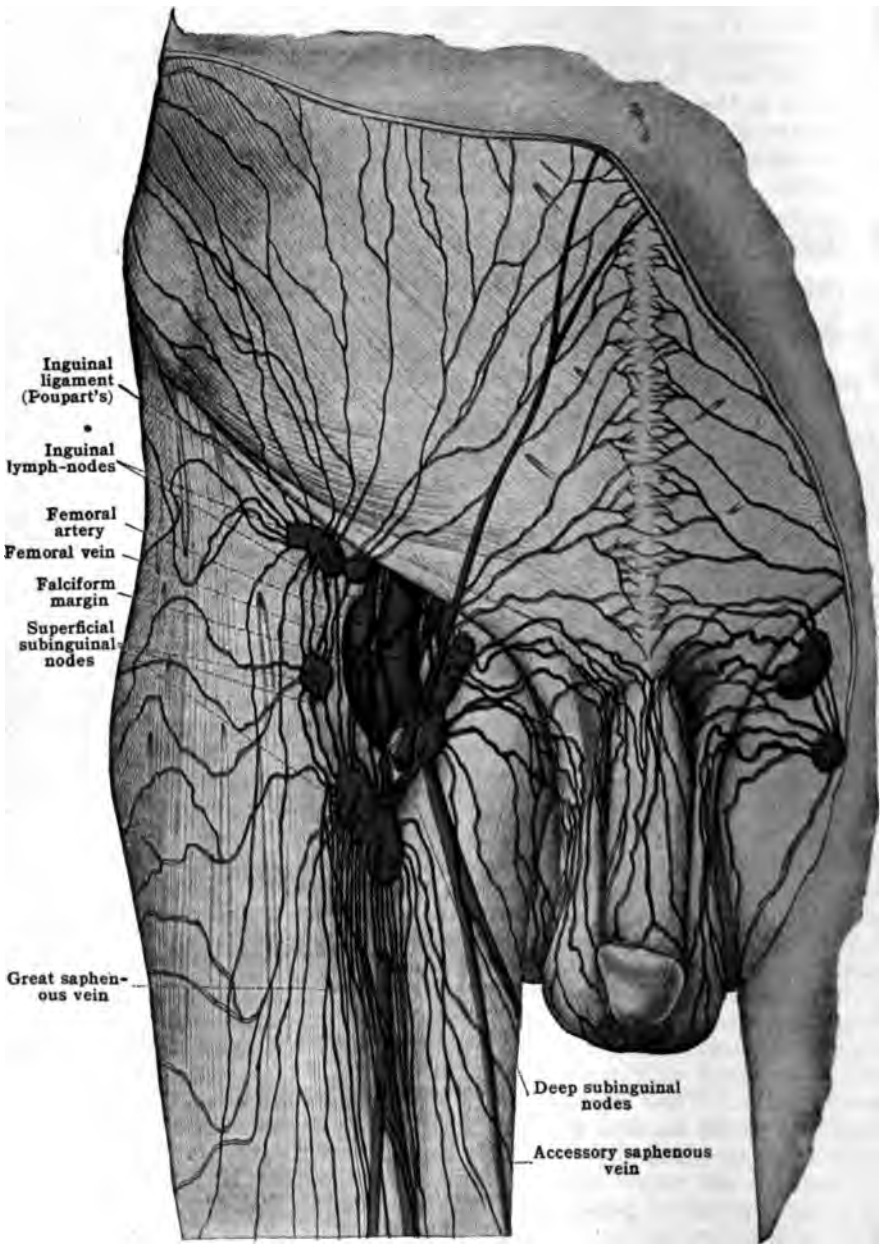
In addition to the inguinal group of nodes there are some other nodes in the lower limb situated along the course of the deep vessels. Thus there is an inconstant node in the course of the anterior tibial vessels below the knee, and there is a small group of **popliteal nodes** [lgl. popliteæ], in the popliteal space (fig. 631), which receive the lymphatics accompanying the lesser saphenous vein, also those which accompany the posterior tibial and peroneal vessels, and those which drain the knee-joint.

2. THE LYMPHATIC VESSELS OF THE LOWER EXTREMITY

As in the upper extremity, the subcutaneous capillary plexus of the lower varies greatly in complexity, being most abundant in the soles of the feet. The collecting vessels form two main groups. The medial, larger group (fig. 630) follows the great saphenous vein, and ends in the superficial subinguinal nodes,

while the lateral group curves around to join the medial, partly in the leg and partly in the thigh. Two or three vessels from the heel follow the lesser saphenous vein to the popliteal space. The vessels from the upper and dorsal part of the thigh curve around on both sides to reach the superficial inguinal nodes. The vessels of the anus and perineum, as well as those from the external genitalia,

FIG. 629.—THE SUPERFICIAL INGUINAL NODES. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



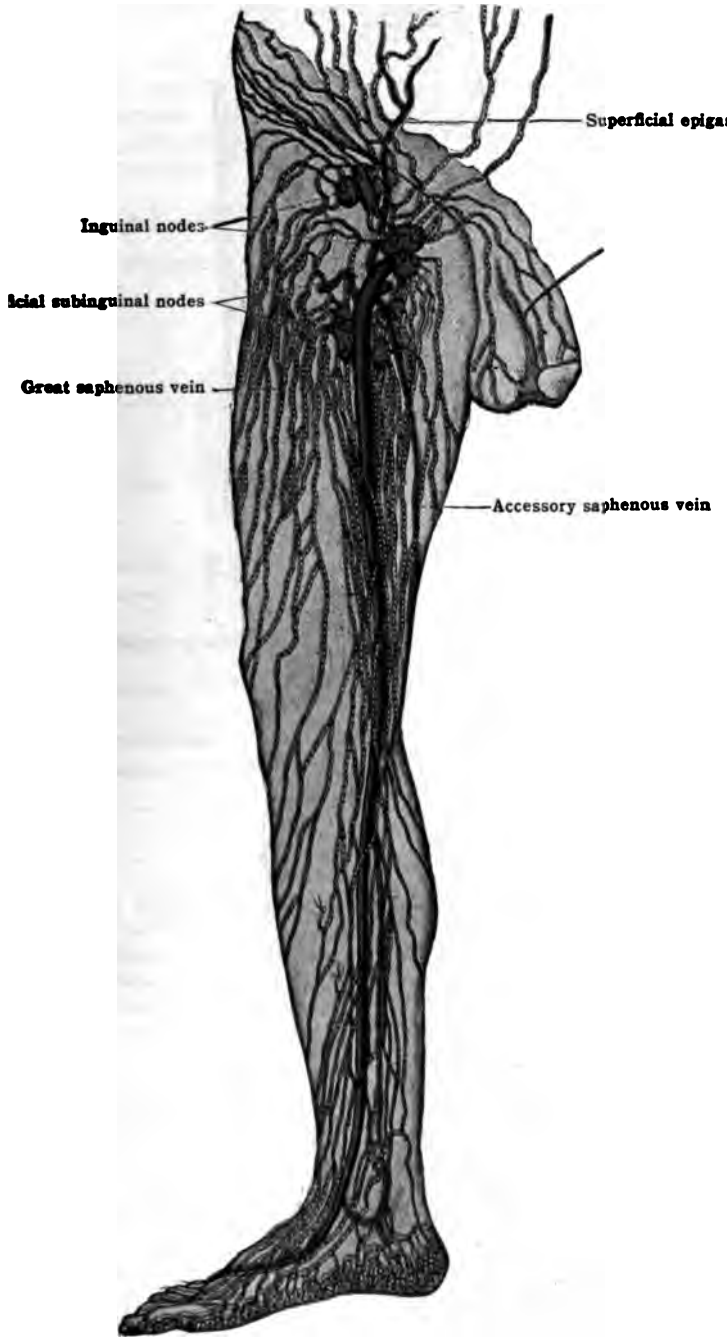
except from the glans penis or the clitoris, pass to the medial nodes of the superficial inguinal group.

The deep vessels follow the course of the arteries of the lower extremity, t accompanying the dorsalis pedis and anterior tibial arteries coming into rel with the anterior tibial node (when present), and then passing backward to the vessels which accompany the posterior tibial and peroneal arteries. T terminate in the popliteal nodes, from which efferents follow the course of femoral artery and terminate in the deep inguinal nodes. The deep lymp

ɔmpanying the gluteal and obturator arteries pass to the hypogastric

cs of the hip-joint.—According to Clermont, they accompany, in the main, the ıt the joint. (1) Satellites of the anterior circumflex artery, draining almost the l surface, pass to the lateral inferior external iliac node. (2) Satellites of the pos-

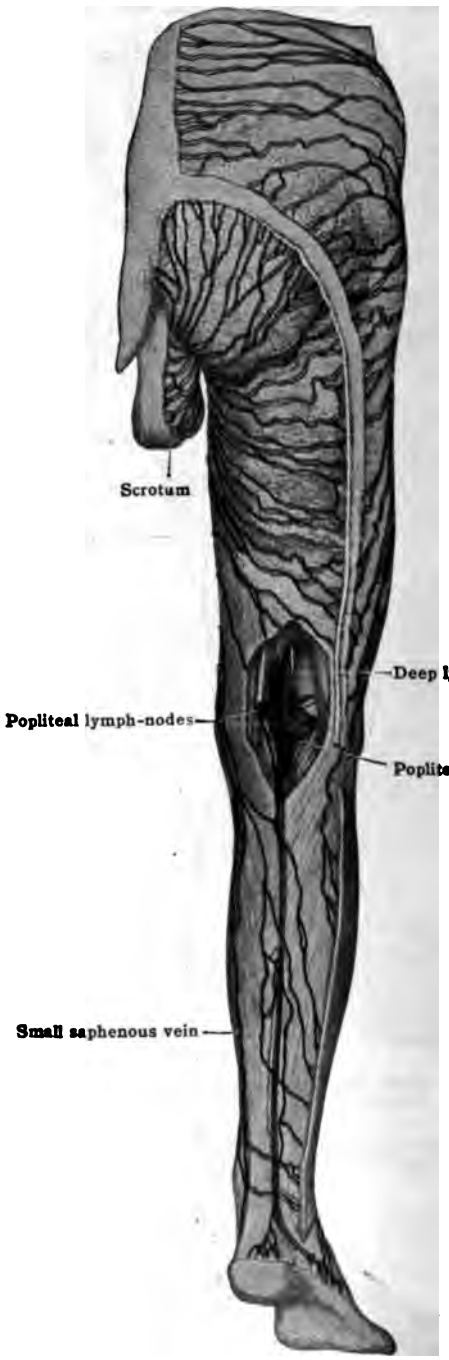
'HE SUPERFICIAL LYMPHATICS OF THE LOWER EXTREMITY. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



ıflex artery, draining the dorsal and medial surfaces, empty into the medial inferior e node, occasionally into one of the deep inguinal nodes. (3) Satellites of the sel, draining the round ligament, empty into the obturator or hypogastric nodes. s of the inferior gluteal vessels, draining the dorsal surface, empty into three small

nodes along the internal pudic and inferior gluteal arteries. Less important ('acce vessels are: satellites of the superior gluteal artery leading to a gluteal node; vessels fr dorsal surface which cross the lateral border of the pectineus to reach the medial i external iliac node; and vessels from the ventral surface, crossing parallel to the cotyloid passing under the psoas to the lateral inferior external iliac or one of the deep inguinal

FIG. 631.—THE LYMPHATICS OF THE BACK OF THE LOWER EXTREMITY. (After Toldt, 'A Human Anatomy,' Rebman, London and New York.)

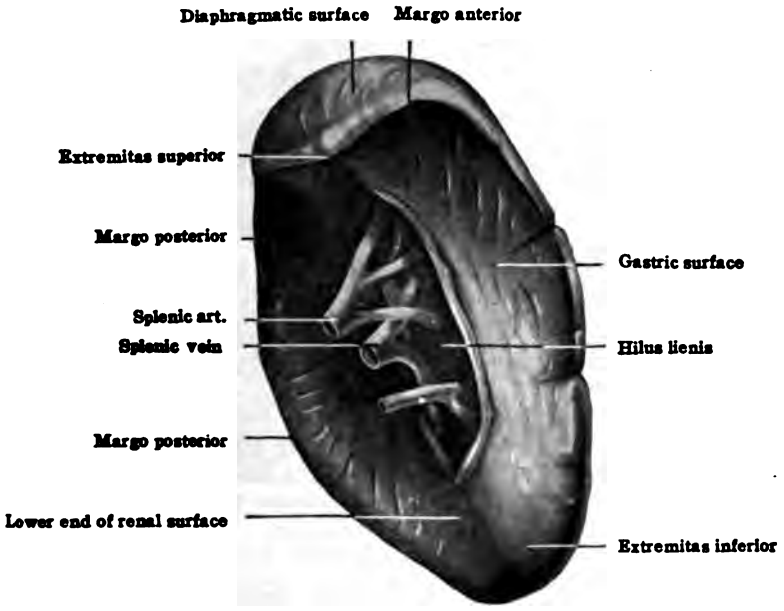


Lymphatics of the knee-joint.—According to Tanasesco the lymphatics draining tl tures around the knee-joint in the main follow the arteries about the joint and pass la the more deeply placed of the popliteal nodes. Some (superficial) follow the great sa vein to the subinguinal nodes, and sometimes deep vessels pass the popliteal nodes companying the femoral artery, run to the deep inguinal or inferior external iliac.

SPLEEN

The spleen [lien] has approximately the shape of an elongated, ovoid body, **hat** of a slightly curved wedge (figs. 632, 633), with three (or four) surfaces, **l** three rounded borders. Its largest surface is the convex, **diaphragmatic face** [facies diaphragmatica], posterolaterally facing the curve of the dia-**agm** (figs. 635, 636). The latter separates the spleen from the pleural cavity **l** ribs. The deeply concave, **gastric surface** [facies gastrica] rests ventro-**dially** against the fundus of the stomach. It includes the **hilus,** which re-**ves** the splenic vessels, and behind which the spleen is in contact with the **l** of the pancreas (fig. 635). The slightly concave, **renal surface** [facies renalis] **ts** posteromedially against the convex, anterior surfaces of the left kidney **g.** 636) and suprarenal. The more caudal portion of this area touches to a **riable** extent the left colic flexure. An enlarged basal or **colic surface** often **es** the spleen a more tetrahedral shape.

FIG. 632.—WEDGE-SHAPED SPLEEN, VISCERAL SURFACE.



The spleen has an anterior and a posterior border. The anterior border **argo anterior**] forms a rather sharp, considerably convex line, on which some-**es** slight serrations (lobulations) are noticeable. The posterior or dorsal **der** [margo posterior] is almost straight and more rounded than the anterior **rgin.** The anterior border touches the fundus of the stomach, the posterior **l** lumbar region of the diaphragm. In the tetrahedral spleen, an **inferior der** separates the colic from the diaphragmatic surface. The spleen also shows **uperior extremity** and an **inferior extremity,** the latter occupying a more **ıtral** position. Between the gastric and renal surfaces of the spleen, usually **newhat** on the gastric surface, runs an elevated ridge, sometimes called the **ermediate** border, which may present a distinct tubercle (fig. 634). Along **margins** of this ridge is attached the visceral layer of the peritoneum. This **rounds** the entire organ and is reflected as the gastrolienal and phrenolienal **ıments.**

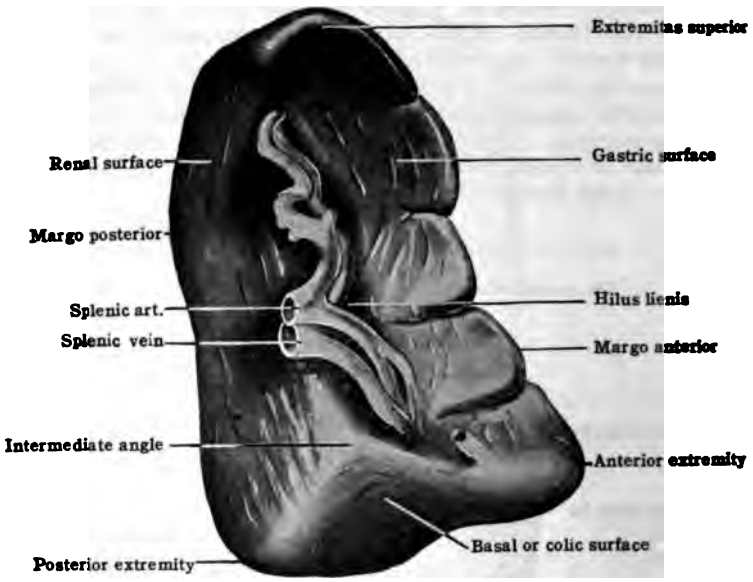
The shape of the spleen varies considerably in different individuals. Even **he same individual** it changes its shape to some extent in accommodating itself **the surfaces of the** contracted or distended viscera. When the stomach is **pty and the colon** distended, the tetrahedral form is more pronounced. In **opposite case, the** colic surface may disappear entirely.

The spleen has a rather dark, brownish red color, which after death soon changes to a **plish tint. Its consistency** is soft. It is surrounded by a tough, fibrous capsule, con-

taining many elastic elements, which allow for considerable expansion of the splenic substance, and numerous smooth muscle-fibers. The latter are present, to some extent, in the trabeculæ and assist in the rhythmical contractions of the organ. The peritoneum is closely applied to the capsule.

The size of the spleen is also subject to great individual variation. It easily enlarges under blood-pressure. A few hours afer meals its size is also increased. The length of the organ

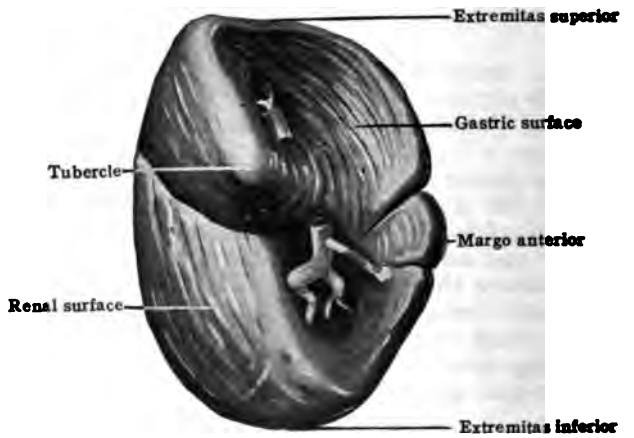
FIG. 633.—TETRAHEDRAL SPLEEN, VISCERAL SURFACE.



varies from 10 to 14 cm.; the width from 6 to 10 cm.; the thickness from 3 to 4 cm.; and the weight varies from 80 to 300 grams or more. After the age of 40 years, a slight involution of the spleen sets in.

Topography.—The spleen lies in the left hypochrondiac region (fig. 965), its cranial end sometimes reaching into the epigastric region. It is situated in a shallow excavation, formed dorsally by the kidney and suprarenal, laterally by the costal part of the diaphragm, cranially by the dome of the diaphragm, caudally

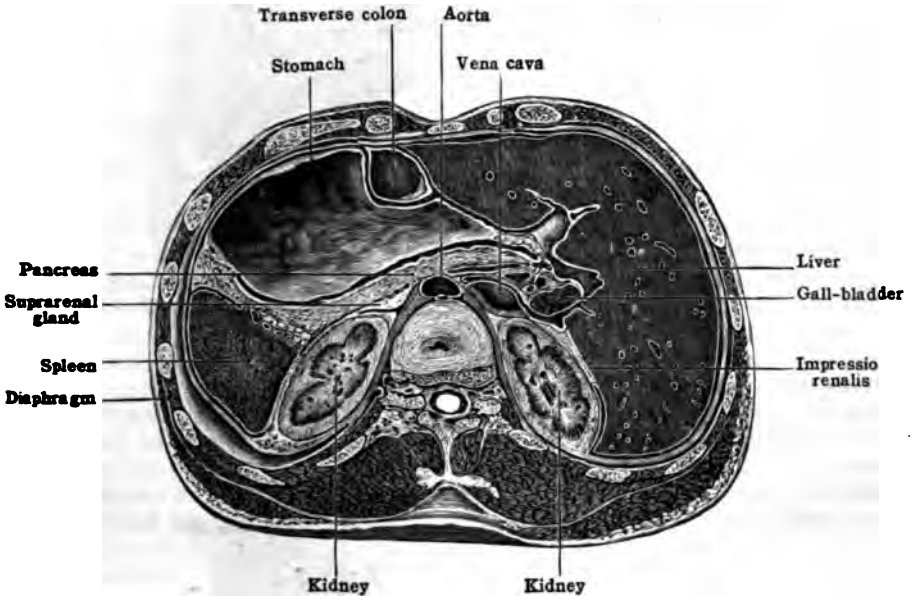
FIG. 634.—SPLEEN SHOWING TUBERCLE ON THE INTERMEDIATE BORDER.



by the left colic flexure and phrenocolic ligament, ventromedially by the stomach. The long axis of the organ runs about parallel with the tenth rib (fig. 1115), the spleen lying laterally to a line drawn from the left sternoclavicular articulation to the tip of the eleventh rib. The upper extremity lies in the region of the costal angle, the lower nearly reaches the midaxillary line. The width of the spleen extends through the 9th and 10th intercostal spaces. (See p. 1375.)

Nowhere, except near the hilus, is the spleen attached to the peritoneum. refore it easily slides in its bed and follows the movements of the diaphragm. important suspensory ligament of the spleen is the **gastrolienal ligament,** se peritoneal layers are continued from the anterior (greater sac) and pos- or (lesser sac) surfaces of the stomach to the anterior and posterior borders he hilus, respectively. The anterior layer is continued over the entire surface he spleen, and then meets the posterior layer to be reflected from the hilus of spleen to the adjacent surface (fig. 920). This double reflection forms the rt **phrenolienal** (lienorenal) ligament which carries the splenic vessels and tail of the pancreas. This ligament is variable in form and extent. The **enocolic** ligament, although not attached to the spleen, supports the lower remity ofthe organ (fig. 924).

635.—Cross-section of the Body at the Lower Part of the Epigastric Region. (Rüdinger.)



Blood-supply.—The *splenic artery* and *vein* run in the phrenolienal ligament to the hilus. artery is rather tortuous, especially in older persons, and lies above the vein. It branches ral (about six) times into the vessels of the superior and inferior group before reaching the n. The splenic vein is likewise formed outside the hilus by several tributaries.

At the hilus some *lymph-vessels* are found which send a few branches into the capsule and er trabeculæ. No lymph-vessels go through the splenic tissue proper. About 8 orr 10 ph-nodules, connected with these vessels, are found near the hilus, betweenthe layecrs of gastrolienal ligament (splenic nodes), and some along the superior border of the pancreas ncreaticosplenic nodules).

Nerve-supply.—Nerve-fibers from the median and anterior parts of the celiac plexus, in the n of a dense network, the *splenic plexus*, follow the splenic artery into the organ. Also rs from the right vagus can be traced in. The few medullated fibers are probably sensory.

Development.—The spleen develops in the mesenchyma of the dorsal mesogastrium. A use accumulation of leucoblasts is noticeable at the beginning of the second fetal month o 10 mm. embryos). This area very soon becomes considerably vascularized, especially the s forming loose capillary plexuses. Later, angioblasts are carried into this zone, and the en begins to assume its hemopoietic function. During fetal life, red as well as white blood- s are formed in the spleen. After birth the formation of erythrocytes ceases. For further ils on the development of the spleen, see p. 36.

Variations.—Sometimes *lobulated spleens* are found, in which the above-mentioned notches g the anterior border are exaggerated. Also on the diaphragmatic surface and on the pos- or border deep incisions may appear, so that the entire organ seems to be divided up into s. Such a spleen probably represents an atavistic type, the organ being lobated in the r vertebrates and even in some mammals.

Another, not uncommon, abnormality is the formation of *accessory spleens.* These are lly small nodules in the neighborhood of the main organ. Sometimes their number is quite sive. In man over 400 have been counted in a single individual, widely distributed ugh the peritoneal cavity; in dogs and cats, over 800. Sometimes a group of such small ules (isolated lobules) takes the p ace of th main organ. Whether in the above mentioned

cases all these numerous nodes actually represent *accessory spleens* or *hemal nodes* is still open question. It is difficult to make a differential diagnosis of very small nodules. There however, no doubt that the body of the spleen can break up into its units. A congenital sence of the spleen is extremely rare.

SECTION VIII

THE NERVOUS SYSTEM

REVISED FOR THE SIXTH EDITION

BY IRVING HARDESTY, A.B., PH.D., D.SC.

PROFESSOR OF ANATOMY, THE TULANE UNIVERSITY OF LOUISIANA

HE nervous system of man, both anatomically and functionally, is the most highly developed and definitely distributed of all the organ-systems of the body. It consists of an aggregation of peculiarly differentiated tissue-ents, so arranged that through them stimuli may be transmitted from and to he other tissue systems or functional apparatuses. It is a mechanism with s so adjusted that stimuli affecting one tissue may be conveyed, controlled, ified, and distributed to other tissues so that the appropriate reactions result. e protoplasm will react without nerves, while muscle will contract without nediation of nerves, yet the nervous system is of the most vital importance to igher organisms in that the stimuli required for the functioning of the organs so distributed throughout their component elements that the necessary ionious and coordinate activities are produced. For this purpose the ous system permeates every organ of the body; nerve cell-bodies, accu-ted into groups, give rise to the nerves which ramify and divide into smaller smaller branches till the division attains the individual nerve-fibers of which nerves are composed, and even the fibers bifurcate repeatedly before their termination upon their allotted elements from which they receive and to h they impart stimuli. So intimate and extensive is the distribution through-that could all the other tissues of the body be dissolved away, still there would ft in gossamer its form and proportions—a phantom of the body composed ely of nerves.

he parent portion or **axis** of the system extends along the dorsal midline of ody, surrounded by bone and, in addition, protected and supported by a s of especially constructed membranes or meninges, the outermost of which e strongest. The cephalic end of the axis, the **encephalon,** is remarkably ged in man, and is enclosed within the largest portion of the bony cavity, ranium, while the remainder of the central axis, the **spinal cord,** continues gh the foramen magnum and lies in the vertebral canal.

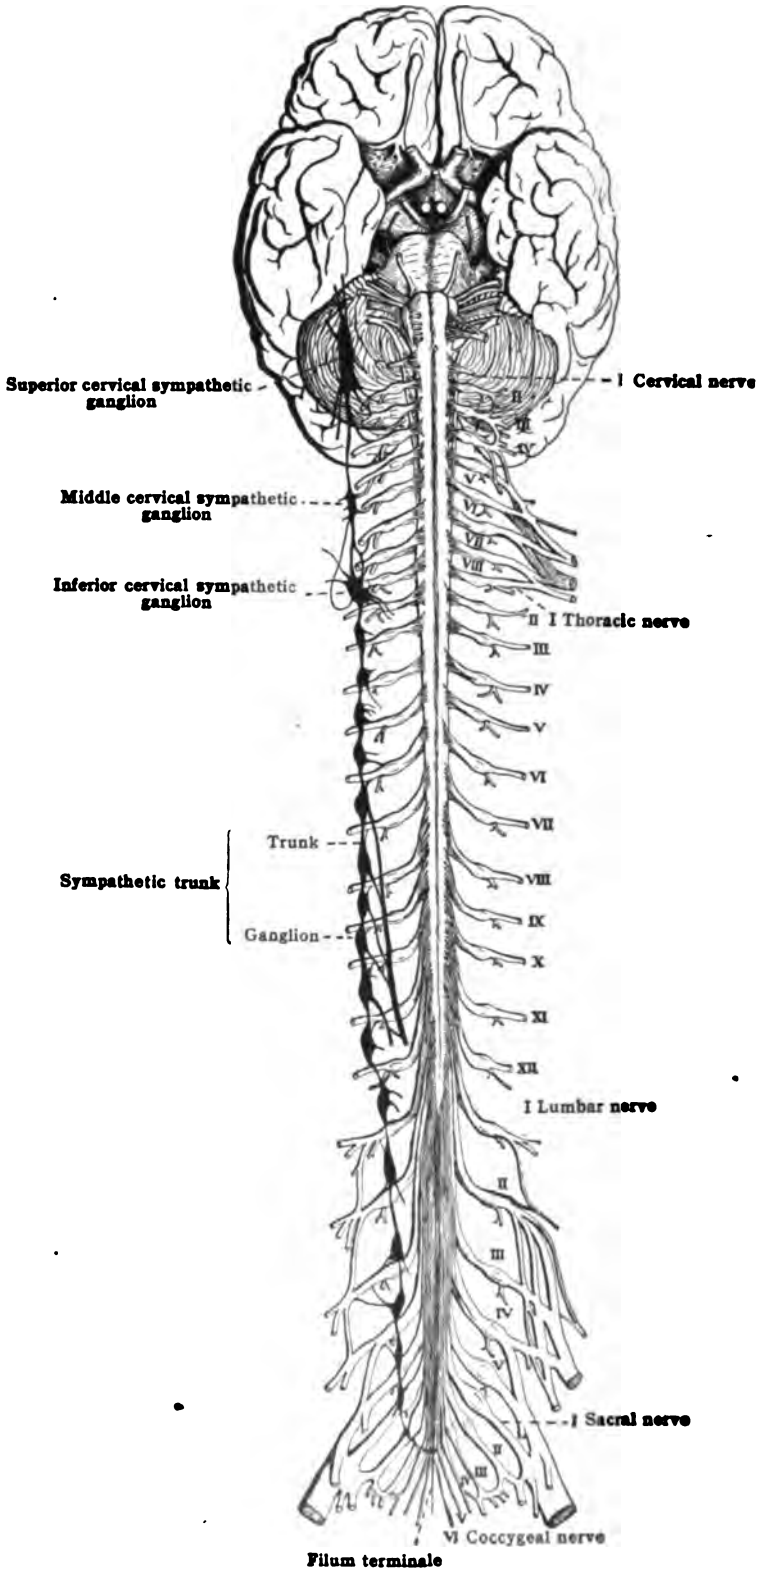
he intimate connection of the axis with all the parts of the body is attained eans of forty-six pairs of nerves, which are attached to the axis at somewhat ar intervals along its extent. They course from their segments of attach-through the meninges and through their respective foramina in the bony y to the periphery. Of these *craniospinal nerves,* fifteen pairs pass through ranium and are attached to the encephalon, and thirty-one pairs to the l cord. Some of the cranial nerves and all of the thirty-one pairs of spinal s contain both *afferent fibers,* which convey impulses from the peripheral es to the central axis, and *efferent fibers,* which convey impulses from the axis e peripheral tissues. The different pairs of nerves possess the two varieties ers in varying proportions.

pon approaching the spinal cord, each spinal nerve is separated into two roots posterior or *dorsal root* and its anterior or *ventral root.* The afferent fibers the axis by way of the dorsal roots, which are, therefore, the sensory roots, he efferent fibers leave the axis by way of the ventral or motor roots.

s usually studied, the nervous system is referred to in two main divisions:—
) The *central nervous system,* composed of—(*a*) The spinal cord, or medulla lis, and (*b*) the brain or encephalon.

FIG. 637.—SHOWING THE VENTRAL ASPECT OF THE CENTRAL NERVOUS SYSTEM, WITH THE PROXIMAL PORTIONS OF THE CRANIOSPINAL NERVES ATTACHED AND THE RELATION OF THE PROXIMAL PORTION (SYMPATHETIC TRUNK) OF THE SYMPATHETIC NERVOUS SYSTEM. THE ENCEPHALON OR BRAIN IS STRAIGHTENED DORSALWARD FROM ITS MORE HORIZONTAL POSITION WITH REFERENCE TO THE SPINAL CORD. THE SPINAL GANGLIA AND THE DORSAL AND VENTRAL ROOTS OF THE SPINAL NERVES MAY BE NOTED.

(Composite drawing in part after Allen Thompson from Rauber—modified.)



(2) The *peripheral nervous system*, composed of—(*a*) The craniospinal nerves, and (*b*) the sympathetic nervous system.

All these parts are so intimately connected with each other that the division is purely arbitrary. The craniospinal nerves are anatomically continuous with the central system; their component fibers either arise within or terminate within the confines of the central system, and thus actually contribute to its bulk. The sympathetic system, however, may be more nearly considered as having a domain of its own. By communicating rami, it is intimately associated with the craniospinal nerves and thus with the central system, both receiving impulses from the central system and transmitting impulses to portions of its structure. But, while its activities are largely under the control of the central system, it is thought possible that impulses may arise in the domain of the sympathetic system and, mediated by its nerves, produce reactions in the tissues it supplies without involving the central system at all. For this reason, as well as because of the structural peculiarities of the sympathetic system, the nervous system is sometimes divided into—(1) the craniospinal system, consisting of (*a*) the central system and (*b*) the craniospinal nerves; (2) the sympathetic nervous system, consisting of (*a*) its various peripheral ganglia and their outgrowths forming its plexuses (sympathetic system proper) and (*b*) efferent fibers arising within the central system and terminating in sympathetic ganglia (visceral efferent, "autonomic" or preganglionic fibers).

Within and closely proximal to the central system or axis are grouped the parent cell-bodies whose processes comprise the nerve-fibers of the craniospinal nerves. Other groups of nerve cell-bodies, distributed in the periphery without the bounds of the central system, give rise to the fibers, nerves and plexuses of the sympathetic proper. Any group of such cell-bodies situated in the periphery, whether belonging to the craniospinal or sympathetic system, is known as a *ganglion*.

THE DEVELOPMENT OF THE NERVOUS SYSTEM

The essential elements of the nervous system, the nerve cell-bodies and the essential portion of all nerve-fibers, central, craniospinal and sympathetic, develop from one of the embryonic germ layers, the ectoderm, and all arise from a given region of that germ layer. Further a small portion of the supporting tissue of the nervous system, the neuroglia, is considered as of the same origin.

In its development the nervous system is precocious. It is the first of the functional apparatuses to begin differentiaton and is the first to acquire its form. The first trace of the embryo appears on the developing ovum as the *embryonic area*, and the rapidly proliferating cells of this area shortly become arranged into the three germinal layers:—the outer layer or *ectoderm*, the middle layer or *mesoderm*, and the inner layer or *entoderm*. Early in the process of this arrangment there is formed along the axial line of the embryonic area a thickened plate of ectodermal cells, the *neural plate*. In the further proliferation of these cells, the margins of the neural plate, which lie parallel with the long axis of the embryonic area, rise slightly above the general surface, forming the *neural folds*, and the floor of the plate between the folds undergoes a slight invagination, the process resulting in the *neural groove* (fig. 638, A, A′ and B, B′). As development proceeds and the embryonic area assumes the form of a distinct embryo, the neural folds or lips of the groove gradually converge, and beginning at the oral end, finally unite. Thus the groove is converted into the *neural tube*, extending along the dorsal midline and enclosed within the body of the embryo by the now continuous ectoderm above (fig. 638, C′ and D, D′).

For a time the neural tube remains connected with the inner surface of the general ectoderm along the line of fusion by a residual lamina of ectodermal cells. This lamina is known as the *ganglion-crest* (neural crest). It is a product of the proliferation of the ectoderm during the process of fusion, consists of the cells which composed the transition between the closing lips of the original groove and the general ectoderm, and whose fusion aided in the closure of the tube. The ectoderm soon becomes separated from the ganglion crest and the cells of the crest become distinctly differentiated from the cells of the neural tube. The essential elements of the entire nervous system together with the neuroglia are derived from the cells of the neural tube and the cells of the ganglion-crest.

Before the caudal extremity of the tube is entirely closed, its oral end undergoes marked enlargement and becomes distended into three vesicular dilations, the anterior, middle, and posterior primary *brain-vesicles*. The anterior of these primary vesicles give off a series of secondary vesicles and by these, followed by further dilations, flexures of its axis, and by means of localized thickenings of its walls, the portion of the tube included in the three primary vesicles develops into the encephalon or brain of the adult. The remainder of the tube becomes the spinal cord. This latter portion retains the simpler form. By the proliferation and migration laterally of the cells lining this portion of the tube, there results a comparatively even bilateral thickening of its walls so that the mature spinal cord retains a cylindrical form throughout its length.

The proliferating and migrating cells of the wall of the neural tube are known as *germinal cells*. Their cell-boundaries are soon lost and the entire wall becomes a syncytium. The products of their division are apparently indifferent at first, but later they become differentiated into two varieties: (1) *spongioblasts*, or those nuclei which will control the development of neuroglia, and (2) *neuroblasts*, or those which will increase in size, give off processes and become

FIG. 639.—DIAGRAMS OF TRANSVERSE SECTIONS OF EMBRYONIC SPINAL CORDS SHOWING THE MIGRATION OF THE ELEMENTS OF THE GANGLION CREST TO FORM THE SPINAL AND SYMPATHETIC GANGLIA AND THE ORIGIN OF THE DORSAL AND VENTRAL ROOTS OF THE SPINAL NERVES.

nerve cell-bodies. As described below, the processes given off by a neuroblast are of two general characters: (1) a long process or axone which goes to form nerves, nerve-roots, and nerve-fasciculi, and (2) dendritic processes which are numerous, branch much more frequently and extend but a short distance from the cell-body. An adult cell-body with all its processes is known as a *neurone* and the neuroblasts of the developing system become transformed into the neurones of the varying sizes, shapes, and arrangements of processes characteristic of different divisions and localities of the nervous system. Usually the first process to be noted is that which will become the axone or nerve fiber.

Neurones whose cell-bodies belong to the peripheral nervous system are not developed within the walls of the neural tube or central nervous system at all. These, comprising the spinal ganglion neurones and those of the sympathetic system, are derived from the cells of the ganglion-crest. The wedge-shaped lamina of cells, comprising the ganglion-crest, through rapid cell division, gradually extends outward and ventralward over the surface of the neural tube along either side. Soon the proliferation becomes most active in regions proximate to the mesodermic somites or body segments and this activity, together with the stress of the growing length of the body, results in the ganglion-crest (originally a lamina) becoming segmented also. The segments or localized ganglion-masses thus formed are the beginning not only of the spinal ganglia, but also of the ganglia of the entire sympathetic system. The elements of the crest migrate to assume a more lateral position, and then occurs a separation of their ranks. A portion of them remain in a dorsolateral position near the wall of the neural tube and develop into the neurones of the *spinal ganglia* (the sensory neurones of the spinal nerves), but others wander further out into the periphery and become the neurones of the

hetic. Certain of those in this more nomadic group settle within the vicinity of the al column and by sending out their processes, form the *sympathetic trunk* or the proximal f sympathetic ganglia; others migrate further, but in more broken rank, and become glia of the *prevertebral plexuses* (as the cardiac, celiac and hypogastric plexuses), or the d intermediate chain of ganglia; while still others wander into the very walls of the

ral organs and occur singly or in groups in such plexuses as those of Auerbach and Meissthin the tunics of the walls of the alimentary canal. Scattered along between these al, intermediate, and distal groups there are to be found small straggling ganglia, many h contain so few cell-bodies that they are indistinguishable with the unaided eye. All ympathetic neurones, however, are probably directly anatomically associated with and he control of the neurones of the central system through *visceral efferent fibers* passing n by way of the rami communicantes or by way of the peripheral distribution of the and cranial nerves.

from the ectodermal syncytium, while the white and elastic fibrous tissues are derived
mesodermal or mesenchymal syncytium. Before any connective tissue fibrils are dev
either syncytium, before and at the time of the ingrowth of blood-vessels into the de
ganglia and the neural tube from the mesenchyme about them, there occurs an invasi
mesenchymal syncytium into the ectodermal syncytium. This invasion occurs both
pendent ingrowths and fusions at the periphery of the neural tube and by the mese
tissue being carried in by the ingrowing blood-vessels. After the mixture of the nuclei
from this fusion of the syncytia from the two sources, nuclei of mesodermal origin c
distinguished from those of ectodermal origin. Further, axones outgrowing from
bryonic ganglia and neural tube carry with them adhering portions of the ectodermal sy
into the surrounding mesenchymal (fig. 646, A).

As development proceeds further, each syncytium becomes resolved into a reti
granular endoplasmic processes, containing the nuclei, with transparent exoplasm o
its meshes. Fibers soon form in the exoplasm and from these develop the connecti
fibers, whether neuroglia within the central nervous system or mesenchymal fibrous tis
without and within it. Certain of these fibrils of course surround the axones imbedde

them and from condensations of such fibrils are derived the fibrous sheaths of the s
sheath nuclei being acquired from the adjacent nuclei of the original syncytium. The
become more dense or pronounced as the axones extend and the fibrous tissue inc
growth, but there are always present fine marginal fibrils by which the sheaths gra
looser fibrous tissue about them. It is generally believed that the tissue giving ri
axone sheaths is of mesodermal origin. However, in amphibian larvæ, Harrison has
some sheath nuclei at least are derived from the nuclei of the ectodermal syncyt
ganglion crest, and Neal has noted in elasmobranchs the fact that nuclei migrate fro
tral wall of the neural tube along with the axones growing out to form the ventral r
spinal nerves. Whether all or any of these nuclei are originally ectodermal, and, if s
such ectodermal tissue gives rise to all axone sheaths, especially in the higher a
questionable contentions.

Axones possessing only fibrous sheaths comprise the *non-medullated nerve-fi*
majority of the sympathetic fibers are of this variety, and Ranson has found num
medullated fibers present in the spinal and cranial nerves and spinal cord. The
accepted form of non-medullated sympathetic fibers may be seen in fig. 652, C.

Medullated fibers are those which possess an investing coat of fat or myelin in
the fibrous sheath. Most of the fibers in the central nervous system and most of th
ing to the craniospinal nerves proper acquire myelin sheaths. Myelin begins to a
axones shortly after the beginning development in the syncytium of the fibrils of
connective tissue, and thus after the beginnings of what will become the fibrous she
fibrous portions of the sheaths in the central nervous system develop less rapidly
more scant than those of the medullated fibers of the peripheral nerves. Probab
of this, it has been claimed that myelin begins to appear on the axones of the cen
before the appearance of the fibrous sheath. In man, the first appearance of myeli

about the fourth month, but myelinization is not completed till after birth. The craniospinal nerves contain completely medullated fibers before the central system does.

Myelin first appears as small droplets adhering to the axone at irregular intervals. These droplets increase in size and number and gradually accumulate to form a practically continuous sheath of fat immediately investing the axone. They probably result from the coalescence of finer droplets floating in the surrounding fibrillated stroma. However, collecting upon the axone, the myelin retains the form of an emulsion, and as it increases in amount it incloses the adjacent fibrils which serve as a framework supporting the droplets of the emulsion in its meshes. Thus supported, the increasing myelin does not inclose the adjacent nuclei and endoplasm of the original syncytium. Probably because of the fibrous support of the myelin thus obtained, medullating fibers may be often seen presenting the beaded appearance shown in fig. 646, C, instead of an even distribution of the emulsion after it has become continuous along the axone. The 'beads' probably represent the uneven beginning of the accumulation indicated in B

FIG. 647.—SHOWING SOME OF THE VARIETIES OF THE CELL-BODIES OF THE NEURONES OF THE HUMAN NERVOUS SYSTEM, INCLUDING THE DENDRITES AND SMALL PORTIONS OF THE AXONES. AXONE SHEATHS NOT INCLUDED.

of this figure. Increasing further, the myelin becomes a cylinder of even thickness, the adjacent nuclei being pressed away against its surface and the adjacent fibrils also condensed upon it. Thus, there is good reason to believe that the fibrous portion of the sheath, the *primitive sheath* or *neurilemma*, of the medullated axone arises as a condensation of the fibrils of the surrounding stroma during development, that the sheath cells represent certain of the nearest nuclei incorporated from the original syncytium, and that the so-called *neurokeratin* of the myelin represents the fibrous framework of the myelin inclosed by it during its accumulation upon the axone. The theory that the myelin arises as a differentiated portion of the axone and the theory that it is formed by the neurilemma have been advanced. That it is accumulated from the immediately surrounding fluid of the stroma and adheres to the axone, added droplets coalescing there, in preference to other tissue elements because of some physical or chemical peculiarity of the axone, is more probably correct.

As the medullary sheath approaches completeness, constrictions may be observed at more or less regular intervals at which the myelin emulsion is absent. These are the *nodes of Ranvier*. The process by which they arise is not clearly understood. While the fiber is growing in length, new myelin is added at the nodes. The internodal segments of the sheath increase in length with age, and each segment may possess from one to several sheath nuclei.

In adolescence, fibers whose medullary sheaths are in various stages of completeness may be found both in nerve bundles in the central system and in the craniospinal nerves, and in

both, the sheaths of some axones certainly never acquire myelin. Also, in the adult, fibers whose medullary sheaths present the beaded appearance may be observed, probably representing cases of arrested accumulation of myelin. According to Westphal there is a slight increase in the thickness of the sheath with age. Larger axones acquire thicker sheaths of myelin than smaller ones. For the craniospinal fibers, in transverse sections, the area of the section of the medullary sheath averages equal to the area of the section of the axone (Donaldson and Hoke.) Some fibers of the sympathetic system are medullated but in such the myelin sheath is relatively thinner than in the craniospinal system. Beaded sheaths are frequent in sympathetic rami, though non-medullated fibers are most abundant.

FUNDAMENTALS OF CONSTRUCTION

The functionally mature nervous system consists of peculiarly differentiated essential cell elements held in place by two forms of supporting tissue and supplied with abundant blood-vessels.

The nervous element is distinguished from all other units of the structure of organs in that its cell-body gives off outgrowths or processes of peculiarly great length and characteristic form. Knowledge of the possible lengths and complexity of these processes is comparatively recent and, to include them together with their parent cell-body, which has long been known as the *nerve-cell*, the term neurone is used. The **neurone**, therefore, may be defined as the nerve cell-body with all its processes, however numerous and far reaching they may be. As a class of tissue elements, all neurones possess characteristics distinguishing them from other tissue elements, but the varieties within this class vary greatly. They vary in form both according to function and according to their locality in the nervous system. They vary in different animals, those in the higher animals being more complex in form. Fig. 647 gives illustrations of the external form of the cell-body of a few of the types found in the human nervous system.

The cell-body of the neurone gives off two general types of processes, dendrites and axone:

(1) The dendritic processes or **dendrites.** These are the more numerous, the shorter, and the more frequently branching processes. They branch dichotomously and with rapid decrease in diameter as they branch. They serve to increase the absorbing surface of the cell-body for purposes of nutrition. Nerve impulses transmitted to the neurone are received by them and, therefore, they also serve to increase the recipient surface of the neurone. They never acquire medullary sheaths. Since they convey impulses toward the cell-body, they are known as *cellipital processes.* Their absorbing and receptive surfaces are further increased by the presence of thickly placed, very minute projections known as 'pin-head processes' or *gemmules.*

(2) The **axone** (neuraxis). Each neurone possesses properly but one of these processes. It arises from the cell-body more abruptly and quickly becomes smaller in diameter than are most dendrites before the latter decrease by branching. It is the longest process, in most cases very much longer than dendrites. Computation shows that some axones may contain nearly 200 times the volume of the parent cell-body of the neurone. Occasionally the axone gives off a few small branches near the cell-body. These are known as *collaterals* and are given off at practically right angles instead of dichotomously. Regardless of its branching, the axone maintains a practically uniform diameter throughout its long course. Its usual nervous function is to convey the impulses away from the cell-body, either to transmit them to the other neurones by contact upon their dendrites or cell-body proper, or to appropriate elements of the other tissue systems of the body. Thus the axones are the *cellifugal processes.* There is one well-known partial exception to this, namely, a part of the axone of the spinal ganglion type of neurone, the peripheral sensory neurone. The axone of this bifurcates a short distance from the cell-body into a peripheral and a central branch. See fig. 647, A, and fig. 653. The peripheral branch collects sensory impulses from the tissues of the body, the skin, etc., and, in conveying them to the central system, must necessarily convey them toward the cell-body as far as the point of bifurcation. Thence the impulse goes on in the central branch, still toward the central system but now, in conformity, away from the cell-body of the neurone. While the continued vitality of the axone is dependent upon the cell-body, in the peculiar case of the spinal ganglion neurone the impulse does not necessarily pass through the cell-body. Experiments with the lower animals have shown that the impulses pass in the fiber from the peripheral tissues to the central system when the cell-body has been cut away.

Terminations of axones.—At its final termination, well beyond its collateral branches and usually a considerable length from its cell-body, the axone practically always divides into two or more *terminal branches*, and each of these breaks up, now dichotomously, into numerous terminal twigs. These terminal twigs are known as *telodendria.* Telodendria vary in number and character of form according to the tissues in and upon which they terminate. Functionally, they are of three classes: Those terminating upon and in the other (peripheral) tissues of the body are either (1) *sensory* or (2) *motor.* In order to transmit impulses from one neurone to another, telodendria of the axone of one neurone are placed in contact with the dendrites or cell-body of another neurone forming (3) *synapses.* Upon approaching its termination, every axone loses its sheath, its telodendria being necessarily bare.

FIG. 648.—SHOWING SOME VARIETIES OF PERIPHERAL TERMINATIONS OF AXONES.

A. 'Free termination' in epithelium (after Retzius). B. Krause's corpuscle from conjunctiva (after Dogiel). C. Meissner's corpuscle from skin (after Dogiel). D. Pacinian corpuscle (after Dogiel). E. A

B

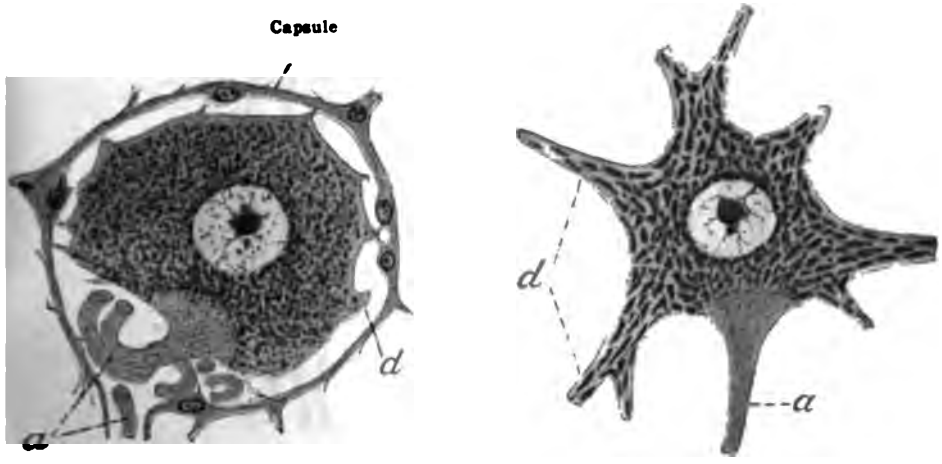
terminations are also to be found in the connective tissues of the body. A second variety of peripheral termination of afferent axones is the *encapsulated form*. These are known as 'end organs' and 'corpuscles' and are named according to their complexity and position. Three of the different forms of them are shown in fig. 648, B, C, and D. These are always situated n fibrous connective tissue from which their capsules are derived. Their most elaborate form

lamellated or Pacinian corpuscle. Besides the motor axones terminating upon the of voluntary or skeletal muscle, sensory impulses are carried from this tissue and one of forms of telodendria for this purpose terminates upon the muscle-fiber. This is known as 'neuromuscular spindle.' In it, the axone penetrates the sarcolemma and breaks into dendria which coil spirally about the muscle-fiber. The most extensive and eleborate form sensory telodendria are those which spread out in plate-form upon tendons sheaths.

Motor peripheral axones terminate upon muscle and upon the secretory cells of glands secretory axones). The motor craniospinal axones terminate upon skeletal (voluntary) muscle- ers and upon the cell-bodies of sympathetic neurones, the axones of which latter terminate son cardiac muscle, smooth muscle-fibers, and (secretory) in glands. Upon skeletal muscle, e terminal branch of the axone loses its sheath and breaks up into numerous telodendria which mselves branch and show very evident, irregular varicosities, the whole of which spread out plate-form, and lie in contact with the substance of the muscle-fiber. In man and all mam- ls, the area covered is usually somewhat oval and is marked by a granular differentiation of muscle substance. This with the telodendria is known as a *motor end-plate*. The teloden- ia of sympathetic axones ending upon cardiac and smooth muscle-fibers are fewer and simpler an those of craniospinal axones upon skeletal muscle. They consist of a few fine fibrils, with

IG. 651.—DRAWINGS ILLUSTRATING THE ABUNDANCE AND GENERAL ARRANGEMENT OF THE TIGROID MASSES IN CELL-BODIES OF NEURONES IN RESTING CONDITION.

cell-body from spinal ganglion. B, large cell-body from ventral horn of spinal cord. a, axone. d, dendrites.



A B

very small varicosities along them and at their ultimate terminations, which run longitudinally along the muscle-fiber in close relation with its substance. Those upon gland-cells are similar in character except that they often form a loose pericellular plexus about and upon the cell. The varicosities of telodendria are sometimes called *end-feet* and closer study of them has shown that they themselves consist of fine plexuses of the neurofibrils described below as contained in the cell-body of the neurone and extending throughout all its processes. Boek has found that a sympathetic axone may sometimes accompany a craniospinal axone to an end-plate on a skeletal muscle-fiber.

Synapses.—Every functionally complete nerve pathway consists of two or more neurones arranged in series, a *neurone chain*. Very often, the series consists of many more than two, the impulses being transmitted from neurone to neurone. The axone, bearing the impulse away from the cell-body of one neurone, gives off terminal branches, each of which loses its sheath and breaks up into telodendria which twine themselves upon the dendrites or cell-body of another neurone. The impulse is transferred from one neurone to another by means of contact rather than by direct anatomical continuity of the parts of the two neurones. Such terminations of axones are known as synapses.

In the terminal arrangement of the telodendria, synapses assume forms varying from compact '*pericellular baskets*' and '*climbing fibers*' to the more open arborizations composed of fewer twigs in simpler arrangements, '*end-brushes*.' In case of the spinal ganglion type of neurone, the cell-body of the majority of which has no dendritic processes, the telodendria of the visiting axone form an anastomosing pericellular plexus inclosing the entire cell-body. This and the simple end-brush form of synapses are illustrated in fig. 649. It should be mentioned that, contrary to the general belief that impulses are transmitted by simple contact of the neurones in the series, it has been claimed that the ultimate twigs of the telodendria frequently penetrate the substance of the receiving cell-body and are fused in continuity. If during the processes of growth this becomes true, instead of being an appearance produced by the technique employed, it is better considered as merely an exception to the general rule.

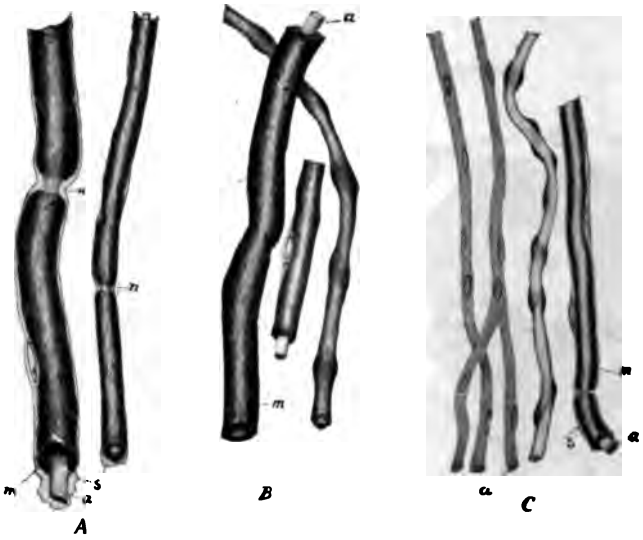
Internal structure of the neurone.—The cell-body of the neurone consists of a large, spherical, vesicular nucleus and a cytoplasm continuous into its axone and dendritic outgrowths. Its nucleus is further characterized by having most usually but one nucleolus, large, spherical and

densely staining, situated in a karyoplasm containing otherwise a remarkably small an chromatin. Of the cytoplasm, the two most interesting structures are its fibrillar and i ular components.

The **fibrillar structure**, known as the *neurofibrillæ*, represents a growth and elabor the spongioplasmic reticulum of the original embryonal cell. The filaments increase i ness during the development of the neurone, and, in the sending out of its processes, the of the original reticulum become so drawn out in the processes as to give the appear more or less parallel arrangement of threads. The reticular or net-like arrangement is more nearly retained in the cytoplasm immediately about the nucleus, since here the the outgrowing processes is less directly applied. In the cell-body of the spinal gangli of neurone, when no dendrites are given off, the net-like arrangement is apparent throug cytoplasm except in that region giving rise to the axone. On the other hand, in the ty called 'pyramidal cell' of the cerebral cortex, from which two chief processes, the axone apical dendrite, are given off from opposite poles, the more reticular arrangements at nucleus if often practically obliterated by the opposing growth stress.

FIG. 652.—SHOWING PIECES OF AXONES.

A. From a craniospinal nerve. *B*. From the spinal cord. *C*. From the sympathe axones; *m*, medullary sheath; *n*, node of Ranvier; *s*, neurilemma or sheath of Schwa occasional sheath-nuclei.



So manifest does the parallel appearance of the neurofibrillæ in the processes oft that it has been interpreted as a series of individual and independent fibrils. In the i of gold chloride and similar methods to the neurones of lower forms, the reduced reage precipitated upon the fibrils in parallel, seemingly independent lines. And, assum istence of independent fibrils, it has been contended that the neurone is not the func of the nervous system but is itself composed of numerous functional units, indivi each for the conduction of nerve impulses. More recent and trustworthy method show that the neurofibrillæ retain their original reticular form, the threads anast all planes, and that the meshes of the net may, in the processes, be so drawn in o that a parallel appearance predominates. Further, it is now held that the neuropl more fluid substance in which the fibrils lie throughout, is capable, and probably i able, of conducting impulses as the fibrils.

Of the **granules** in the cytoplasm, the most interesting are those first described Nissl. These are the most abundant of those in the cell-body and are known as tig or *Nissl bodies*. They consist of numerous basophilic granules collected into clump of varying size. They are known to disappear during fatigue of the nervous system a more abundant in animals after a period of rest. They are distributed throughou plasm of the cell-body with the interesting exception that they are not found in the i the immediate vicinity of its place of origin from the cytoplasm, leaving a free regio the *axone hillock*. As accumulated masses, they show characteristic shapes and a which are interpreted as signifying the shapes and arrangement of the spaces or n occupy in the reticulum of the neurofibrillæ. In cell-bodies of the varieties found in horns of the spinal cord or in the cerebral and cerebellar cortex, for example, the mas immediately about the nucleus are smaller, more numerous and of irregular shape. in the beginnings of the dendrites, they are larger and mostly of fusiform or diam Farther out in the dendrites, they become more and more thin and attenuated; and tant reaches of the dendrites they are invisible or absent. In the cell-body of the spir they are of irregular shape, smaller and more numerous throughout the cytoplasm, be smaller and more thickly placed in the immediate vicinity of the nucleus. In a several hours postmortem, they appear in fewer and larger masses and it was in thi

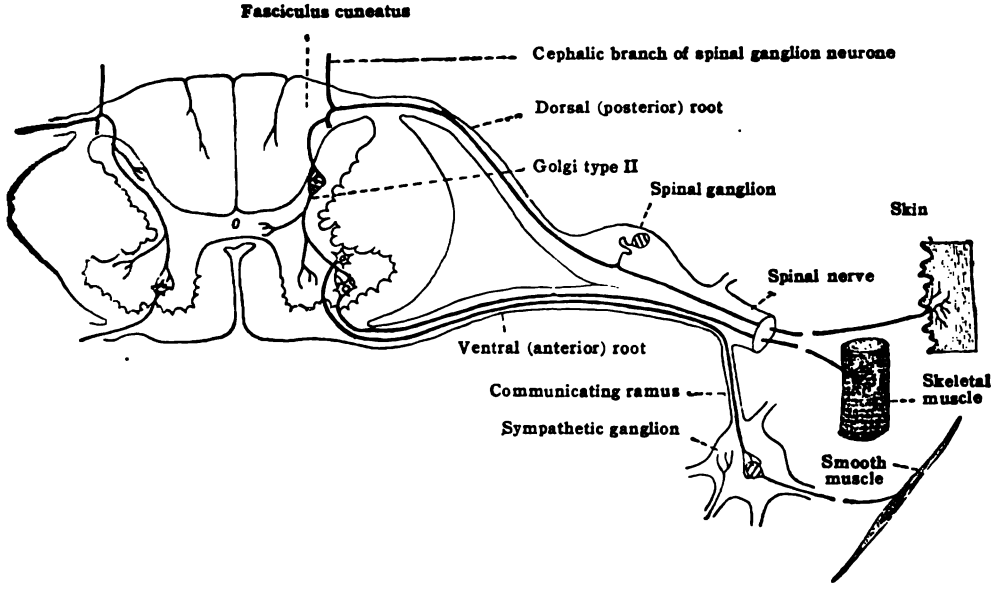
Nissl originally described them in man. Closely examined, the masses of all sizes are found to be accumulations of finer granules. Functionally they are supposed to be of nutritive significance, substances in unstable chemical equilibrium, energy stored in the cytoplasm, capable in need of being split into simpler forms usable in the activities of the neurone. The fact that tigroid masses are absent from the axone hillock, the axone, and the distant reaches of the dendrites may signify that the substance is chiefly present here only in the split and usable form. So, in the axone especially, the neurofibrillæ are so closely arranged that the meshes of their net here are too small to contain masses of appreciable size. Close examination of the axone hillock and longitudinal sections of the axone in deeply stained preparations usually shows a few very minute basophilic granules.

A second form of granules described for the neurone is that included within the name, *mitochondria*. These granules are chemically different from the tigroid masses and are thought to be present in all protoplasm, animal and plant. They are considered composed of a phosphatid, lecithin combined with a small amount of albumin, and, like tigroid masses, to represent a form of stored energy.

Pigment-granules are also found in nerve cells, probably representing an insoluble form of the waste products of the cell metabolism.

Sheaths of the Axone.—The great majority of axones acquire sheaths about them which isolate and protect them in their course through other tissues or in company with other axones.

FIG. 653.—DIAGRAM OF TRANSVERSE SECTION OF SPINAL CORD WITH ROOTS OF SPINAL NERVE AND NEIGHBORING GANGLIA ATTACHED, ILLUSTRATING SIMPLEST FORMS OF NEURONE CHAINS.



A *nerve-fiber* is an axone together with its sheaths. In transverse sections, the axone comprises the central portion of the nerve-fiber or its so-called 'axis-cylinder.' It is of course the essential portion of the fiber. As noted above in describing their development, nerve-fibers are classified according to the character of the sheaths. Those which possess sheaths of myelin, a peculiar form of fat, are known as *medullated fibers*, and those in which the sheaths are merely membranes of condensed fibrous tissue, void of myelin, are *non-medullated fibers*. A medullated fiber also possesses a fibrous membrane outside its myelin sheath, known as the *neurilemma* or sheath of Schwann. The neurilemma is of the same origin and general structure as the sheath of the non-medullated fiber, and both possess nuclei scattered along them. Medullated fibers, at more or less regular intervals, show constrictions at which the myelin sheath ceases, but over which the neurilemma continues. These constrictions are the *nodes of Ranvier*. The myelin is in the form of an emulsion, whose fat droplets are supported in a fine fibrous reticulum (neurokeratin), while the neurilemma without serves to hold it in place. The neurilemma possesses from one to three or four sheath-nuclei between adjacent nodes of Ranvier.

There is no sharp line of separation between medullated and non-medullated fibers, for in any division of the nervous system there may be found axones in all degrees of medullation. Most of the fibers belonging to the sympathetic system (processes of sympathetic neurones) are non-medullated, but both partially medullated and completely medullated sympathetic fibers may be found. (See fig. 652.) The myelin sheaths of completely medullated sympathetic fibers are always thinner and less well developed than those of medullated craniospinal fibers. Most of the fibers belonging to the craniospinal nerves and to the central nervous system are medullated, but among the fibers belonging to either there are to be found numerous non-medullated fibers. As indicated in fig. 652, nodes of Ranvier are absent in the medullated fibers of the central system.

In all the higher vertebrates, the myelin sheath always begins on the axone a short distance from its parent cell-body. The neurilemma of the medullated and the fibrous membrane of the non-medullated fiber are each faintly continuous with the fibrous connective tissue sur-

rounding it, and, in the craniospinal and sympathetic ganglia, in which each cell-body of the neurone has a fibrous capsule about it, the fibrous membrane or the neurilemma, as the case may be, is directly continuous into the capsule of the cell-body. Upon approaching its final termination, in other tissues or upon the dendrites or cell-body of other neurones, the nerve-fiber always loses its sheath, the telodendria of the axone always being bare when placed in contact with the other element. In losing the sheath, the myelin sheath, if present, always ceases and the fibrous membrane becomes continuous with the tissue investing the receiving element, whether the capsule of the ganglion cell, the sarcolemma of the skeletal muscle fiber, the corium of the skin, or the connective tissue capsule of the encapsulated terminal corpuscle.

The **connective tissue** of the nervous system is of two main varieties—*white fibrous connective tissue* and *neuroglia*. White fibrous tissue alone supports and binds together the peripheral system, and it is the chief supporting tissue of the central system. As connective tissues, these two varieties are quite similar in structure, each consisting of fine fibrillæ, either dispersed or in bundles, among which are distributed the nuclei of the parent syncytium. In both tissues nuclei are frequently found possessing varying amounts of cytoplasm which has not yet been transformed into the essential fibrils.

In addition to its enveloping membranes, the three meninges, which are of white fibrous tissue, the white fibrous tissue supporting the central system within is quite abundant. It is all sent in from without, either as ingrowths of the developing pia mater, the most proximal of the membranes, or is carried in with the blood-vessels, of the walls of which it is an abundant component. Pratically, the neuroglia as a connective tissue proper differs from white fibrous tissue only in origin and in its chemical or staining properties. Based upon the latter, there are methods of technique by which the two may be distinguished. The epithelioid lining the central canal of the spinal cord and the ventricles of the encephalon, with which the canal is continuous, is the remains of the mother tissue of the neuroglia, and in the adult is the only vestige representing its origin. The cells of this lining are known as *ependymal cells*, and they are usually classed as a variety of neuroglia.

Axones, with their medullated or non-medullated sheaths (nerve-fibers) comprise all nerves in the periphery and all nerve tracts in the central system.

White substance [substantia alba] ('white matter') consists of a portion of nervous tissue in which medullated fibers predominate. The myelin sheaths, being in the form of a fat emulsion, reflect the entire spectrum and thus appear white.

Gray substance [substantia grisea] ('gray matter') is an aggregation of nervous tissue in which medullated axones do not predominate. Thus sympathetic ganglia and sympathetic nerves may be gray, though the term is usually applied to gray portions of the central system, such as the cerebral cortex, the central gray column of the spinal cord, etc. Such gray regions contain more cell-bodies of neurones than other regions, though at least half of their volume may consist of neuroglia, white fibrous connective tissue, blood-vessels, and axones of both varieties.

Neurone chains.—As noted above, the numerous neurones comprising the nervous system are functionally and anatomically related to all the other tissues of the body and to each other. A functionally complete *nerve pathway* extends from the tissue in which the nerve impulse is aroused to the tissue in which a resultant reaction occurs. It is known that the simplest possible of such paths necessarily comprises at least two neurones. The great majority involve a greater number. The axone of one neurone bearing impulses from the peripheral tissue transfers the impulses to the dendrites or cell-body of another by synapsis, and the axone of this, in the same way, transfers them to another and so on till the final neurone receives the impulses and the telodendria of its axone transfer the impulse to the tissue element which reacts in response to the stimulus brought. Neurones are thus linked together in chains. A neurone chain may be defined, therefore, as a number of neurones associated with each other in series to form a functionally complete nerve pathway. Examples of the simplest forms of neurone chains as contained in the spinal cord are illustrated in fig. 653. An impulse aroused in the skin is borne by the spinal ganglion neurone to the spinal cord where, in the left half of the figure, telodendria of one of the terminal branches of its axone form synapses with a neurone in the ventral horn, and the axone of this bears the impulse out of the spinal cord to transmit it probably direct to skeletal muscle. This arrangement involves but two neurones and is supposed to be relatively rare. In the right half of the figure, a third neurone is seen interposed. This is a neurone, numerous in gray substance everywhere, whose axone is relatively short and branches frequently, making possible several synapses in the near neighborhood of its parent cell-body. Its type is referred to as the *Golgi neurone of type II*. This interposed, gives a chain of three neurones between the origin of the impulse in the periphery and the contraction of muscle in response. Simple chains like these can result only in reflex activities and such chains are often called *reflex arcs*. Another chain is indicated in the figure in which the reflex action involves involuntary or smooth muscle. This must involve at least one sympathetic neurone, and, should the Golgi neurone of type II form synapses with the ventral horn neurone involved, a chain composed of four neurones results. In the more extensive and complex neurone chains, such as those in which the impulse from the skin, as above, ascends to the cerebral cortex and the resultant muscular contraction is thrown under cerebral control, each of the several neurones or links in the series is not only referred to by name according to the position of its cell-body, but each is often called according to its order in the series, as 'neurone of first order,' 'second order,' 'third order,' etc.

A given axone may break into a considerable number of branches each of which forms apses with a different second neurone, or, if peripheral, the telodendria of each branch may minate upon a separate peripheral tissue element. Thus, a given impulse aroused in a pheral tissue element may be transmitted to an ever increasing number of neurones, and initial neurone may comprise the first link in a number of neurone chains. Such is quite eral in the structural plan of the nervous system throughout. It is thought possible to sider each neurone interposed in a chain as a separate source of energy, a sort of relay the nerve path; that the impulse passing through the axone is gradually weakened in overing resistance, but, when transferred to another neurone, it incites a splitting into usable n of the substance represented by the tigroid masses and mitochondria and thus a liberation nergy or a reinforcement of the impulse. Further, thus is made possible the economy of neurone serving as a link in a number of neurone chains.

The axones (nerve-fibers) taking part in the various neurone chains course in bundles of ying size, the larger of which have names. And there is a general tendency with axones of same function, the same functional direction and the same origin to course in company with

another. A fiber bearing impulses from the peripheral tissues to the central system is an *ent fiber* or sensory fiber. A fiber bearing impulses out of the central system to peripheral is an *efferent fiber* or motor fiber. Efferent fibers which bear impulses to skeletal muscle known as *somatic efferent fibers*, while those which terminate upon the cell-bodies of sympaic neurones and thus bear impulses destined for smooth muscle, cardiac muscle and glands retory) are *visceral* or *splanchnic efferent fibers*.

A nerve is a closely associated aggregation of parallel nerve-fibers coursing in the *periphery*. ay be spinal, cranial or sympathetic according to its attachment or according to the origin e majority of its fibers. It may contain several functional and structural varieties of fibers. spinal nerves contain all structural varieties. Nerve-roots are those bundles of fibers which to form a nerve. Most of the cranial nerves have but one root. Nerve-roots, in their turn, formed by the junction of smaller *root-filaments*. *Nerve-branches* result from the division he nerve, the separation of its component fibers into separate bundles. Some branches of sufficient size and significance to be called nerves and given separate names. The ller branches are called *rami*, twigs, etc.

In the *central system*, a given bundle of fibers of similar origin and functional direction is called sciculus, while two or more adjacent fasciculi coursing parallel with each other, but often of erent origin and functional directions, comprise a funiculus, a bundle of bundles. The cennervous system is bilaterally symmetrical throughout its length. A bundle of fibers arising n cell-bodies situated on one side and crossing the mid-line transversely to terminate in

the opposite side is a **commissure.** The commissures vary greatly in size and contain fibers crossing in both directions. Scattered fibers which cross the mid-line are *commissural fibers.* Fibers of varying length, arising from cell-bodies situated in one locality of the central system, which do not cross the mid-line, but terminate in other localities of the same side, above and below the level of their origin or in a different region of the same level, form **association fasciculi.** The shortest association fasciculi, not extending beyond the bounds of a given division of the central system, are known as **fasciculi proprii.** When bundles of the same origin, functional direction and significance, running one on either side of the mid-line, cross the mid-line they are said to decussate and the crossing is known as a **decussation.** In the decussations, the direction of the crossing is oblique rather than transverse.

The cell-bodies of neurones whose axones go to form certain nerve roots, fasciculi and certain commissures show a tendency to accumulation in localized masses. In the *peripheral system,* such an accumulation of cell-bodies is known as a **ganglion;** in the *central system* such is distinguished as a **nucleus.** Thus, there are the *sympathetic ganglia* which give rise to sympathetic nerves and sympathetic roots of nerves; and on the beginning of each spinal nerve there is a *spinal ganglion* which gives rise to the afferent fibers of its dorsal root and in its nerve trunk. There are *ganglia on* the *cranial nerves* which give rise to the afferent or sensory axones in them and which are of the same significance as the spinal ganglia. Every ganglion, therefore, has connected with it bundles of nerve-fibers. Some of these fibers bear impulses from neighboring ganglia or from the tissues of the neighboring organs and transmit them to the cell-bodies of the ganglion; others arise from the cell-bodies in the ganglion and bear impulses to the central system or, in case of the sympathetic, to the tissues of the peripheral organs. Necessarily, the larger the ganglion, the larger will be the bundles of fibers connected with it.

Nuclei may be considered in two general classes: (1) Recipient nuclei or nuclei of termination, and (2) Nuclei of origin. (See fig. 654.)

A nucleus of termination is an accumulation of cell-bodies in which the axones of a given fasciculus or of a nerve-root terminate, that is, cell-bodies which, by synapses, receive the impulses borne by the terminating axones. In most cases the impulses transferred to a nucleus so named are sensory in character. The nucleus may be considered as a defined region in which neurones of the next order are interpolated in a given nerve pathway or system of neurone chains. Fasciculi in the spinal cord which bear impulses to the cerebrum have their nuclei of termination in the medulla oblongata, and the sensory or afferent axones of the cranial nerves find their nuclei of termination upon entering the central system.

A nucleus of origin is an accumulation of cell-bodies of neurones which give origin to the axones going to form a given nerve-root or a fasciculus. Strictly speaking, a nucleus of termination for one nerve-tract is the nucleus of origin for another, the next link in the neurone chain. However, the term is commonly used to distinguish a group of cell-bodies giving rise to a motor nerve tract. Thus each motor cranial nerve has its nucleus of origin within the central system. The central gray substance of the spinal cord is in the form of a column continuous throughout the length of the cord and so the cell-bodies in the ventral horns of this column which give rise to the motor or efferent roots of the spinal nerves are not considered as grouped into nuclei of origin, one for each of the motor roots.

The **dorsal root** of each spinal nerve is afferent or sensory in function and its axones arise as processes of cell-bodies comprising the spinal ganglion of the nerve. The afferent or sensory fibers of the cranial nerves arise as processes of cell-bodies comprising the ganglia of the cranial nerves, which ganglia are, in development and character, with the exception of the optic, exactly homologous to the spinal ganglia.

The **ventral root** of each spinal nerve is efferent or motor in function and its fibers arise as processes of cell-bodies situated in the ventral horn of the gray substance of the spinal cord. The efferent or motor fibers of the cranial nerves arise as processes of cell-bodies accumulated as nuclei of origin in the gray substance of the encephalon, and homologous with those cell-bodies of the ventral horns of the spinal cord which give origin to the ventral-root fibers.

The general relation of the cerebrum (which includes the mesencephalon) to the remainder of the nervous system is a *crossed relation.* Neurone-chains from the general body to the cerebrum, via the spinal nerves and cord and via the cranial nerves and medulla oblongata and pons of one side, cross the mid-line to terminate in the opposite side of the cerebrum. Axones and neurone chains, arising in response in one side of the cerebrum, likewise usually decussate in descending to terminate in the respective regions of the opposite side.

Many of the names given nervous structures, prior to 1850 especially, instead of suggesting something of their functional or anatomical significance, indicate nothing more than active imaginations for accidental resemblances between the various structures of the nervous system and objects in ordinary domestic environment. Also, quite often the name given a structure is merely the name of some anatomist associated with it. The much needed elimination of these old non-descriptive names is proving a very slow process. Attempts have often increased the difficulty by making necessary the use of several names for a given structure instead of one. The most recent and concerted attempt, the nomenclature known as the BNA (anatomical names chosen by a commission appointed for the purpose which convened in Basle in 1895), has been adopted by modern text-books. It is here used in the form of the English equivalents of the Latin terms, except in cases of those Latin terms which have become so commonly used as to be considered words incorporated into the English language. The BNA has retained many of the old names and, since a name should indicate something of the locality and significance of the structure to which it is applied, it is not yet wholly satisfactory throughout. In applying the names of a few fasciculi, the BNA in the following pages is slightly modified by so compounding the name that the first word in the compound indicates the locality of origin of the faciculus and the second, the locality of its termination. Thus, '*Dorsal spinocerebellar fasciculus*' indicates the more dorsally coursing of the fasciculi which arise from cell-bodies in the spinal cord and terminate in the cerebellum. This principle applies to many of the BNA names without change, as '***lateral cerebrospinal fasciculus.***

THE CENTRAL NERVOUS SYSTEM

The central nervous system [systema nervorum centrale] or organ is an aggregation of nuclei, fasciculi and commissures—a large axis of gray and white substance—situated in the dorsal midline of the body, and the bundles of fibers connecting it with the tissues of other systems and with the peripheral ganglia are of necessity correspondingly large. So numerous are the axones connecting it and so intimately are its neurones associated that a disturbance affecting any one part of the system may extend by way of its neurone chains to influence all other parts. The enlarged cephalic extremity of this central axis, the brain or **encephalon**, is a special aggregation of nuclei and masses of gray substance, many of which are much larger than any found in the periphery.

In the study of the central nervous system its enveloping membranes or meninges are met with first, and logically should be considered first, but since a comprehensive description of these membranes involves a foreknowledge of the various structures with which they are related, it is more expedient to consider them after making a closer study of the entire system they envelop.

For convenience of study, the central nervous system is separated into the gross divisions, spinal cord and brain (encephalon) as illustrated in figure 645. Each of these divisions will be subdivided and considered with especial reference to its anatomical and functional relations to the other divisions and the interrelations of its component parts.

1. THE SPINAL CORD

The spinal cord [medulla spinalis] is the lower (caudal) and most attenuated portion of the central nervous system. It is approximately cylindrical in form and terminates conically. Its average length in the adult is 45 cm. (18 in.) in the male and 42 cm. in the female. It weighs from 26 to 28 grams or about 2 per cent. of the entire central nervous system.

After birth it grows more rapidly and for a longer period than the encephalon, increasing in weight more than sevenfold, while the brain increases less than half that amount. Its specific gravity is given as 1.038.

The line of division between the spinal cord and the medulla oblongata is arbitrary. The outer border of the foramen magnum is commonly given, or, better, a transverse line just below the decussation of the pyramids. Lying in the vertebral canal, the adult cord usually extends to the upper border of the body of the second lumbar vertebra. However, cases may be found among taller individuals in which it extends no farther than the last thoracic vertebra. With increase in stature, its actual length increases, but the extent to which it may descend the vertebral canal decreases. Up to the third month of intrauterine life it occupies the entire length of the vertebral canal, but owing to the fact that the vertebral column lengthens more rapidly and for a longer period than does the spinal cord, the latter, being attached to the brain above, soon ceases to occupy the entire canal. At birth its average extent is to the body of the third lumbar vertebra.

External Morphology of the Spinal Cord

In position in the body, the spinal cord conforms to the curvatures of the vertebral canal (fig. 645). In addition to the bony wall of the vertebral canal, it is enveloped and protected by its three membranes or meninges, which are continuous with the like membranes of the encephalon: first, the **pia mater**, which closely invests the cord and sends ingrowths into its substance, contributing to its support; second, the **arachnoid**, a loosely constructed, thin membrane, separated from the pia mater by a considerable **subarachnoid space**; third, the **dura mater**, the outermost and thickest of the membranes, separated from the arachnoid by merely a slit-like space, the **subdural space**.

The intimate association of the central system with all the peripheral organs is attained chiefly through the spinal cord, and this is accomplished by means of thirty-one pairs of spinal nerves, which are attached along its lateral aspects. The nerves of each pair are attached opposite each other at more or less equal intervals along its entire length, and in passing to the periphery they penetrate the meninges, which contribute to and are continuous with the connective tissue sheaths investing them. Each nerve is attached by two roots, an afferent or **dorsal root**, which enters the cord along its posterolateral sulcus, and an efferent or **ventral root**, which makes its exit along the ventrolateral aspect.

With its inequalities in thickness and its conical termination the spinal cord is subdivided into four parts or regions:—(1) The **cervical portion,** with eight pairs of cervical nerves; (2) the **thoracic portion,** with twelve pairs of thoracic nerves; (3) the **lumbar portion,** with five pairs of lumbar nerves; and (4) the **conus medullaris,** or sacral portion, with five pairs of sacral and one pair of coccygeal nerves. From the termination of the conus medullaris, the pia mater continues below in the subarachnoid space into the portion of the vertebral canal not occupied by the spinal cord, and forms the non-nervous, slender, thread-like terminus, the *filum terminale.* This becomes continuous with the dura mater at the lower extremity of the filum.

In the early fetus the spinal nerves pass from their attachment to the spinal cord outward through the intervertebral foramina at right angles to the long axis of the cord, but, owing to the fact that the vertebral column increases considerably in length after the spinal cord has practically ceased growing, the nerve-roots become drawn caudad from their points of attachment, and, as is necessarily the case, their respective foramina are displaced progressively downward as the termination of the cord is approached, until finally the roots of the lumbar and sacral nerves extend downward as a brush of parallel bundles considerably below the levels at which they are attached. This brush of nerve-roots is the **cauda equina.** The dura mater, being more closely related to the bony wall of the canal than to the spinal cord, extends with the vertebral column and thus envelops the cauda equina, undergoing a slightly bulbous, conical dilation which decreases rapidly and terminates in the attenuated canal of the coccyx as the coccygeal ligament [filum duræ matris spinalis].

The enlargements.—Wherever there is a greater mass of tissue to be innervated, the region of the nervous system supplying such must of necessity contain a greater number of neurones. Therefore, the regions of the spinal cord associated with the skin and musculature of the regions of the superior and inferior limbs are thicker than the regions from which the neck or trunk alone are innervated. Thus in the lower cervical region the spinal cord becomes broadened into the *cervical enlargement,* and likewise in the lumbar region occurs the *lumbar enlargement.* The spinal nerves attached to these regions are of greater size than in other regions.

The **cervical enlargement** [intumescentia cervicalis] begins with the third cervical vertebra, acquires its greatest breadth (12 to 14 mm.) opposite the lower part of the fifth cervical vertebra (attachment of the sixth cervical nerves), and extends to opposite the second thoracic vertebra. Unlike the lumbar enlargement, its lateral is noticeably greater than its dorsoventral diameter.

The **lumbar enlargement** [intumescentia lumbalis] begins gradually with the ninth or tenth thoracic vertebra, is most marked at the twelfth thoracic vertebra (attachment of the fourth lumbar nerves), and rapidly diminishes into the conus medullaris.

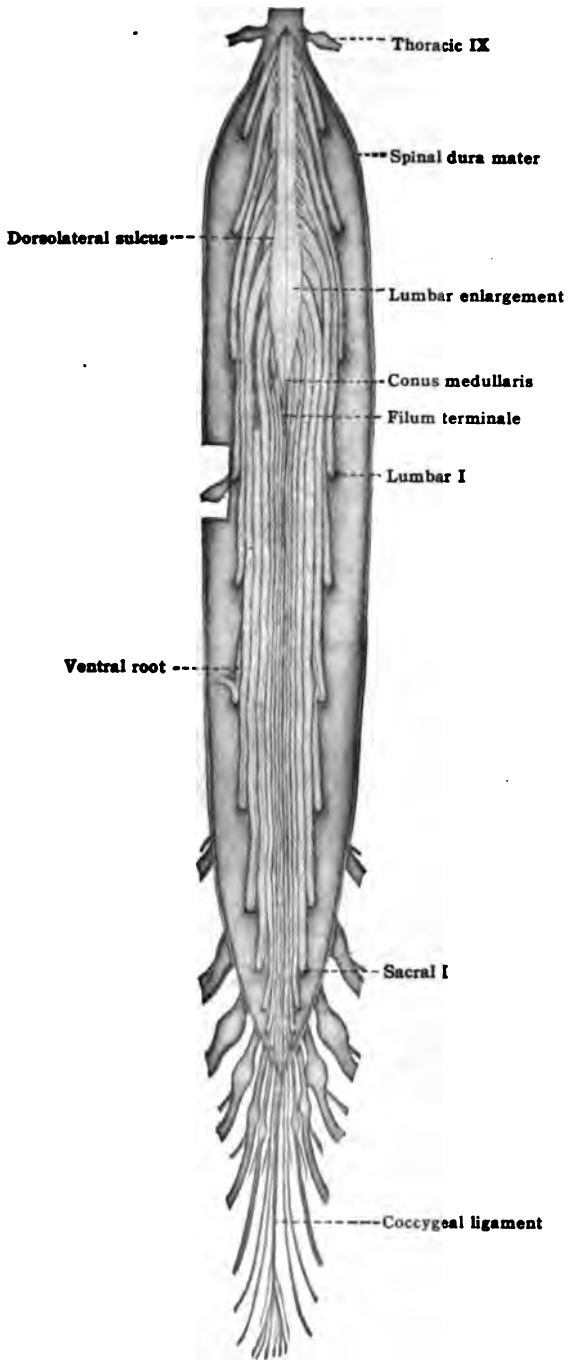
Both the lumbar and thoracic regions are practically circular in transverse section. Neither diameter of the lumbar is ever so great as the lateral diameter of the cervical enlargement. The thoracic part attains its smallest diameter opposite the fifth and sixth thoracic vertebræ (attachment of the seventh and eighth thoracic nerves).

The enlargements occur with the development of the upper and lower limbs. In the embryo they are not evident until the limbs are formed. In the orang-utan and gorilla the cervical enlargement is greatly developed; the ostrich and emu have practically none at all.

Surface of the spinal cord.—The cord is separated into nearly symmetrical right and left halves by the broad **anterior median fissure** into which the pia mater is duplicated, and opposite this, on the dorsal surface, by the **posterior median sulcus.** Along the lower two-thirds of the cord this sulcus is shallowed to little more than a line which marks the position of the posterior median septum; in the medulla oblongata it opens up and attains the character of a fissure. Each of the two lateral halves of the cord is marked off into posterior, lateral, and anterior divisions by two other longitudinal sulci. Of these, the **posterolateral sulcus** occurs as a slight groove 2 to 3½ mm. lateral from the posterior median sulcus, and is the groove in which the root filaments of the dorsal roots enter the cord in regular linear series. The ventral division is separated from the lateral by the **anterolateral sulcus.** This is an irregular, linear area rather than a sulcus. It is from 1 to 2 mm. broad, and represents the area along which the *efferent* fibers make their exit from the cord to be assembled into the respective

. This area varies in width according to the size of the nerve-roots, posterolateral sulcus, its distance from the midline varies according being greatest on the enlargements of the cord. In the cervical

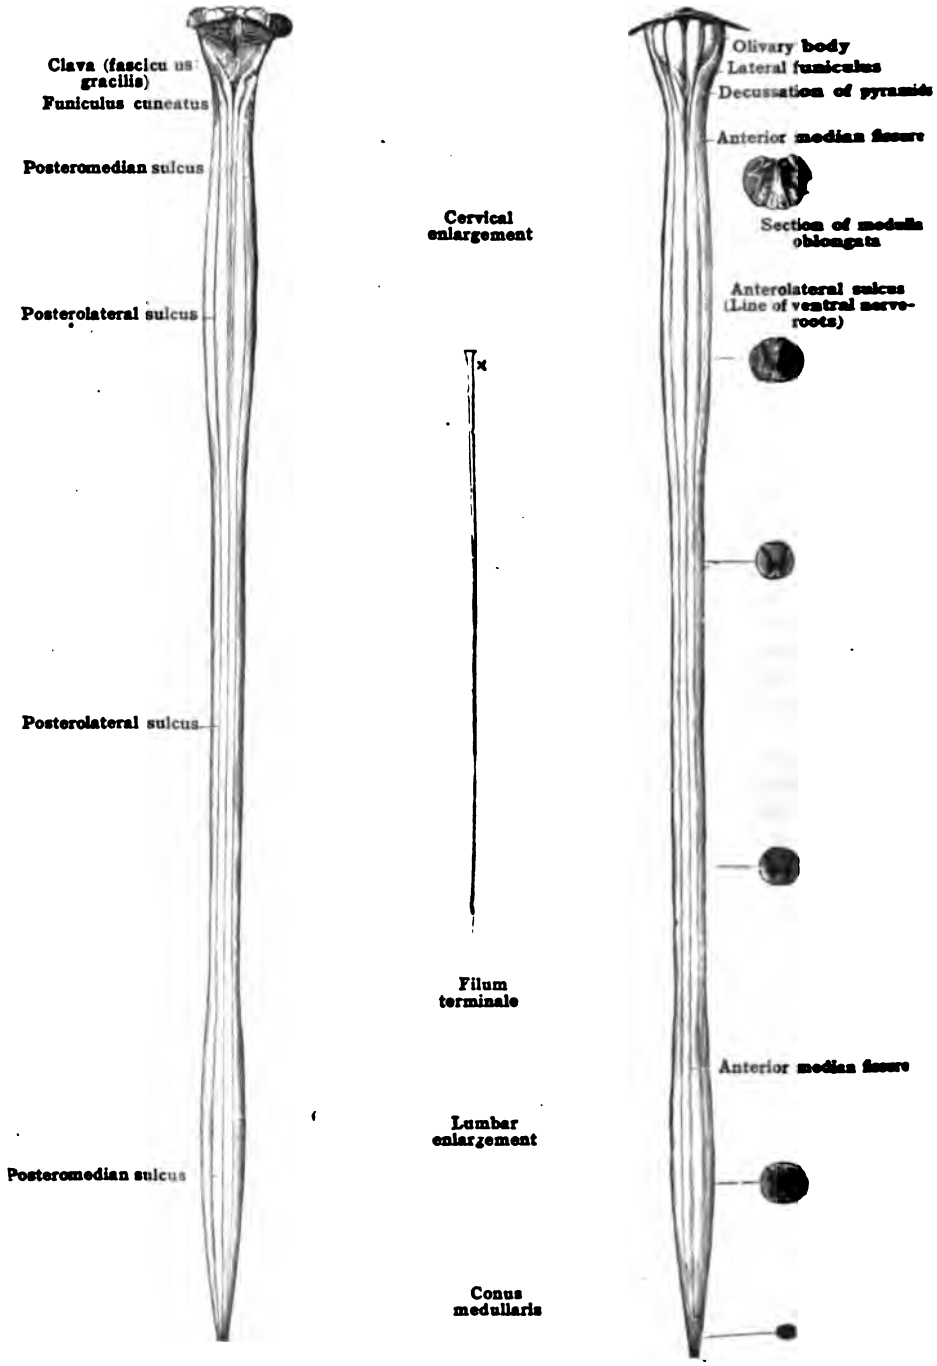
AWING FROM SPECIMEN SHOWING CAUDA EQUINA, THE ROOTS OF CERTAIN OF THE VES WHICH FORM IT, AND ITS ACCOMPANYING DURA MATER. (Dorsal aspect.)



long the cephalic part of the thoracic, the posterior division is sub-delicate longitudinal groove, the **posterointermediate sulcus,** which e evident toward the medulla oblongata and represents the line of between the fasciculus gracilis and the fasciculus cuneatus. Occa-

sionally in the upper cervical region a similar line may be seen along the ventral aspect close to the anterior median fissure. This is the **anterointermediate sulcus**, forming the lateral boundary of the ventral cerebrospinal fasciculus.

FIG. 656.—POSTERIOR AND ANTERIOR VIEWS OF THE SPINAL CORD. (Modified from Quain



Collectively, the entire space between the posterior median sulcus and the line of attachment of the dorsal roots is occupied by the **posterior funiculus**; the lateral space between the line of attachment of the dorsal and that of the ventral roots, by the **lateral funiculus**; and the space between the ventral roots and the

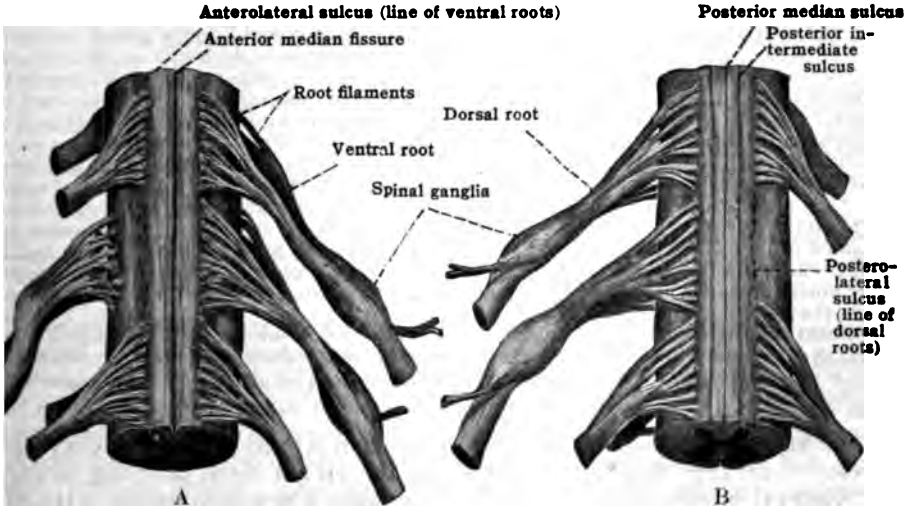
ior median fissure, by the **anterior funiculus.** Each of these funiculi is vided within into its component fasciculi.

he dorsal and ventral nerve-roots are not attached to the cord as such, but rst frayed out into numerous thread-like bundles of axones which are dis-ted along their lines of entrance and exit. These bundles are the **root-fila-s** [fila radicularia] of the respective roots. The fila of the larger spinal es are fanned out to the extent of forming almost continuous lines of attach-, while in the thoracic nerves there are small intervals between the root-ents belonging to adjacent roots. Throughout, the intervals are less be-n the fila of the ventral than between those of the dorsal roots.

Internal Structure of the Spinal Cord (Fig. 658)

y reflected light masses of medullated axones appear white when fresh, and masses are known as **white substance.** The spinal cord consists of a con-us, centrally placed column of gray substance surrounded by a variously ened tunic of white substance. The closely investing pia mater sends

657.—A, Ventral, and B, Dorsal, Views of Portion of Spinal Cord Showing Modes of Attachment of Dorsal and Ventral Roots.



erous ingrowths into the cord, bearing blood-vessels and contributing to its nal supporting tissue. The volume of white and of gray substance varies absolutely and relatively at different levels of the cord. The absolute nt of gray substance increases with the enlargements. The absolute nt of white substance also increases with the enlargements coincident with reater amount of gray substance in those regions. The relative amount of substance increases in passing from the conus medullaris to the medulla gata as explained later.

he gray substance.—All the nerve-cells of the gray substance are derived from ells forming the neural tube in the embryo, and in the adult the column of substance, though greatly modified in shape, still retains its position about entral canal. In transverse section the column appears as a gray figure of aterally developed halves, connected across the mid-line by a more attenu-portion, the whole roughly resembling the letter H. The cross-bar of the H own as the **gray commissure.** Naturally, it contains the **central canal,** is quite small and is either rounded or laterally or ventrally oval in section, ding to the level of the cord in which it is examined. The canal continues rd, and in the medulla oblongata opens out into the fourth ventricle. Down-in the extremity of the conus medullaris, it widens slightly and forms the boidal sinus or **terminal ventricle,** then is suddenly constricted into an ex-ly small canal extending a short distance into the filum terminale, and ends blindly. The gray commissure always lies somewhat nearer the ven-

tral than the dorsal surface of the cord, and itself contains a few medullate axones which vary in amount in the different regions of the cord. The medullate axones crossing the midline on the ventral side of the central canal form th ventral or **anterior white commissure**; those, usually much fewer in numb crossing on the dorsal side of the central canal, form the dorsal or **posterior wh commissure.** These two commissures comprise fibers crossing in the gray s stance as distinguished from others which cross in the white substance dor and ventral to them, namely, the dorsal cornucommissural tract and the vent commissural bundle. The axones of these four commissures serve in function associating the two lateral halves of the gray column.

Each lateral half of the gray column presents a somewhat crescentic or com shaped appearance in transverse section, which also varies at the different le of the cord. At all levels each half presents two vertical, well-defined ho themselves spoken of as columns of gray substance. **The dorsal horn** [colu posterior] extends posteriorly and somewhat laterally toward the surface of cord along the line of the posterolateral sulcus. It is composed of an **apex a neck** [cervix columnæ posterioris].

In structure the apex is peculiar. The greater portion of it consists of a mass of nerve-cells and neuroglia tissue, among which a gelatinous substance of questionable predominates, giving the horn a semi-translucent appearance. This is termed the gelat **substance of Rolando,** to distinguish it from a similar appearance immediately about the c canal, **the central gelatinous substance.** The apex of the dorsal horn is widest in the r of the enlargements, especially the lumbar, and the gelatinous substance of Rolando is marked in the cervical region. In these regions the cervix consists of a slight constrict the dorsal horn between the apex and the line of the gray commissure. In the thoracic r however, the base of the cervix is the thickest part of the dorsal horn. This thickness is the presence there of the **nucleus dorsalis,** or Clarke's column—**a column of gray sub** containing numerous nerve-cells of larger size than elsewhere in the dorsal horn, and exte between the seventh cervical and third lumbar segments of the cord. Tapering finely ends, this nucleus attains its height in the lower thoracic or first lumbar segment. Abo ventrolateral periphery of the nucleus dorsalis are scattered nerve-cells of the same t contained in it. These cells are sometimes distinguished as **Stilling's nucleus,** though C column was also described by Stilling. They are more numerous about the lower ext of the nucleus dorsalis, and they continue still more numerous in line with it below its te tion in the lumbar region.

It must be noted that the dorsal horn throughout contains numerous cell-bodies of ne mostly of small size. These are especially numerous in the margins of the horn where t referred to as the *stratum zonale*. Their significance will be given below in connectio the nerve-tracts with which they are concerned.

The **ventral horn** [columna anterior] of each lateral half of the gray fi directed ventrally toward the surface of the spinal cord, pointing towa anterolateral sulcus. It contains the cell-bodies which give origin to the e or ventral root axones, and these axones make their emergence from the cord along the anterolateral sulcus. The ventral horns vary markedly in in the different regions. In certain segments each ventral horn is thickene ally and thus presents its two component columns of gray substance: the **horn** [columna lateralis], a triangular projection of gray substance into t rounding white substance, in line with or a little ventral to the line of th commissure; and the **ventral horn proper** [columna anterior], projecting ve In the midthoracic region the lateral horn is absent except in its dorsal pa the ventral horn is quite slender; in the cervical and lumbar enlargement horns are considerably enlarged.

The gray substance is not sharply demarcated from the white. blending of the two there are often small fasciculi of white substance em in the gray, and likewise the gray substance sends fine processes among the composing the white substance. Such processes or gray trabeculæ ar marked along the lateral aspects of the gray figure and present there the ance known as the **reticular formation.** The reticular formation of the cord is most evident in the cervical region (fig. 658).

Minute structure.—The large cell-bodies of the ventral horn as a whole are divis four groups, only three of which are to be distinguished in the midthoracic region of th cord:—(1) A *ventral group* of cells, sometimes separated into a ventrolateral and a medial portion (see figs. 658, 661), occupies the ventral horn proper, is constant thr the entire length of the cord, and contributes axones to the ventral root, most of which supply the muscles adjacent to the vertebral column; (2) a ***dorsomedial group*** of cells, *in the medial* part of the ventral horn, just below the level of the central canal, gives

zones some of which go to the ventral root of the same side, some of which cross the mid- line viâ the anterior white commissure, either to pass out in the ventral root of the opposite side or (mostly) to enter the white substance of that side and course upward or downward, associating with other levels of the cord. Some if its axones terminate among the cells of the ventral horn in the same level of the opposite side; (3) a *lateral group* of cells, which is sepa- rated into a dorsolateral and a ventrolateral portion, occupies the lateral column or horn, and is best differentiated in the cervical and lumbar enlargements. Most of the axones arising from the larger cells are contributed to the ventral root of the same side, and such axones probably supply the muscles of the extremities. Some of those from its ventral portion are distributed to the muscles of the body-wall. The dorsolateral portion is that part of the lateral column which persists throughout the cord, and is considered as supplying the visceral efferent ('autonomic') fibers in the ventral roots. It is usually referred to as the dorsolateral (or intermediolateral) cell group, the only lateral group in the midthoracic region. (4) An *intermediate group*, occupying the middorsal portion of the ventral horn. Axones arising from its cells are in part contributed to the ventral root as visceral efferent fibers, but most of them course wholly within the central nervous system. Some pass to the opposite side of the cord, chiefly viâ the anterior and possibly the posterior white commissure, to terminate either in the same or different levels of the gray column. Others of longer course pass to the periphery of the cord, join one of the spinocerebel- lar fasciculi, and pass upward to the cerebellum.

Furthermore, there are scattered throughout the gray substance many small cell-bodies of neurones. These give rise to axones of shorter course, either **commissural** or **associational proper**. Of such axones many are quite short, coursing practically in the same level as that in which their cells of origin are located, and serve to associate the different parts of the gray sub- stance of that level. Others course varrying distances upward and downward for the association of different levels of the gray column.

It is evident from the above that in addition to the various nerve-cells it contains, there is also to be found a felt-work of axones in the gray substance. Many of these axones are medul- lated, though not in sufficient abundance to destroy the gray character of the substance. The felt-work is composed of four general varieties of fibers:—(1) Axones arising from the cells of the spinal ganglia which enter the cord as dorsal root-fibers and form synapses with the cell-bodies of the gray substance; (2) The terminal branches of axones entering from the fasciculi of the white substance and forming end-brushes (synapses) about the various cell-bodies in the gray substance (partly medullated); (3) axones given off from the cells of the gray substance and which pass into the surrounding white substance either to enter the ventral roots or to join the ascending and descending fasciculi within the spinal cord (partly medullated); (4) axones of Golgi neurones of type II, which do not pass outside the confines of the gray substance (non- medullated). Some axones of any of these varieties may cross the midline and thus become commissural. In general all fibers of long course acquire medullary sheaths a short distance from their cells of origin, and lose them again just before termination.

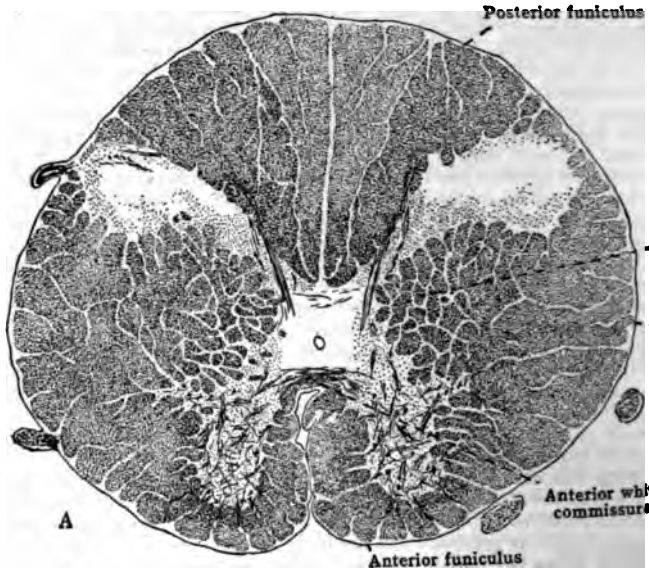
The white substance of the spinal cord.—The great mass of the axones of the spinal cord course longitudinally and form the thick mantle surrounding the column of gray substance. This mantle is divided into right and left homo- lateral halves by the anterior median fissure along its ventral aspect, and along its dorsal aspect by the posterior median septum, which is for the most part a connective tissue partition derived from the pia mater along the line of the posterior median sulcus. The mantle is supported internally by interwoven neuroglia and white fibrous connective tissue, the latter, derived from the meso- derm viâ the pia mater, closely investing it without.

The axones of the white substance belong to three general neurone systems:—(1) The *spinal association* and *commissural system* of axones which serve to cor- relate the different levels and the two sides of the spinal cord and which are proper to the spinal cord, i.e., they do not pass outside its confines. (2) The *spinocerebral and cerebrospinal system*, which consists of axones of long course, one set ascending and another descending, forming links in the neurone chains between the cerebrum and the peripheral organs. The ascending axones of this system collect the general bodily sensations which are conveyed to the cerebrum, the cells of which in response contribute axones which descend the cord, con- veying efferent or motor impulses. (3) The *spinocerebellar and cerebellospinal system* consists of conduction paths, one set ascending and another descending, which are connections between cerebellar structures and the gray substance of the spinal cord. To this might be added a fourth system of neurones (spinobul- bar) connecting and correlating the spinal cord and the medulla oblongata.

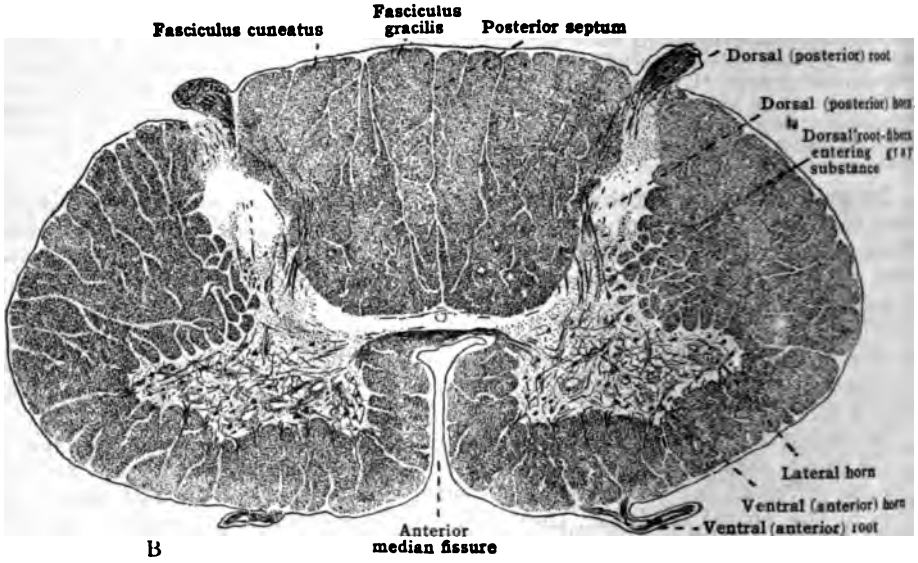
The second and third (and fourth) systems increase in bulk as the cord is ascended. The ascending axones of each system are contributed to the white substance of the cord along its length, and therefore accumulate upward; the axones descending from the encephalon are distributed to the different levels of the cord along its length, and therefore diminish downward.

The mass of the first system of axones varies according to locality (figs. 658, 664). Wherever there is a greater mass of neurones to be associated, as there is

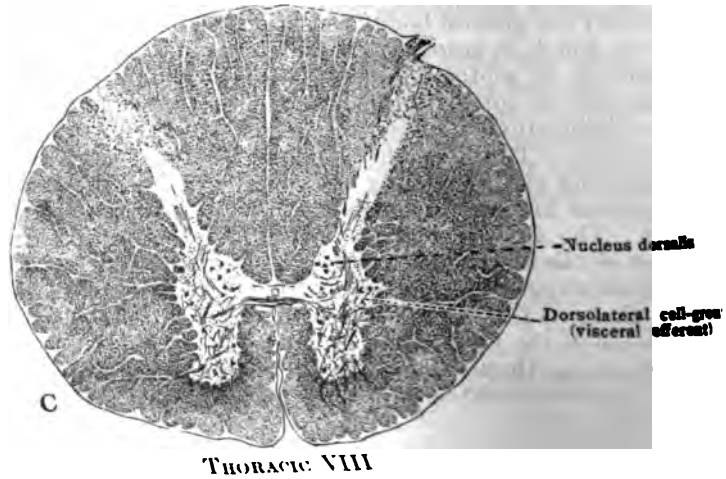
FIG. 658—TRANSVERSE SECTIONS FROM DIFFERENT SEGMENTS OF THE SPINAL CORD, SHOWING SHAPE AND RELATIVE PROPORTIONS OF GRAY AND WHITE SUBSTANCE IN THE VARIOUS REGIONS.



CERVICAL I



CERVICAL VI



THORACIC VIII

enlargements of the cord, a greater number of these axones is required. cells of origin, being in the gray substance of the cord, contribute to its nd thus both the cells and the axones of this system serve to make the ements more marked. In the lumbar and sacral regions the greater mass entire white substance consists of axones belonging to this system. It a dense felt-work about the gray column throughout the cord. Neces- this system contains axones of various lengths. Some merely associate

FIG. 658.—*Continued.*

SACRAL IV

COCCYGEAL

nt levels within a single segment of the cord; others associate the different nts with each other. Many of these axones cross the mid-line both in the nd in the white substance to associate the neurones of the two sides. For ses of distinction, such as cross the midline are called **commissural fibers,** those which course upward and downward on the same side are **association**

Coursing in longitudinal bundles about the gray substance, the latter com- he **fasciculi proprii** or 'ground bundles' of the spinal cord.

METHODS BY WHICH THE CONDUCTION PATHS HAVE BEEN DETERMINED

A purely anatomical examination of a normal adult cord, prepared by whatever means, gives no indication of the fact that the mass of longitudinally coursing fibers of the white substance is composed of more or less definite bundles or fasciculi, each having a definite origin, course and termination and, forming links (conduction paths) in a definite system of neurone chains. Present information as to the size, position, and connections of the various fasciculi is based upon evidence obtained by three different lines of investigation:—

(1) **Physiological investigation.**—(*a*) Direct stimulation of definite bundles or areas in section and carefully noting the resulting reactions which indicate the function and course of the axones stimulated. (*b*) 'Wallerian degeneration' and the application of such methods as that of Marchi. When an axone is severed, that portion of it which is separated from its parent cell-body degenerates. Likewise a bundle of axones severed from their cells of origin, whether by accident or design, will degenerate from the point of the lesion on to the locality of their termination in whichever direction this may be. This phenomenon was noted by Waller in 1852 and is known as **Wallerian degeneration.** By the application of a staining technique which is differential for these degenerating axones and a study of serial sections containing the axones in question, their course and distribution may be determined. The locality of their cells of origin, if unknown, may be determined by repeated experiment till a point of lesion is found not followed by degeneration of the axones under investigation. (*c*) The axonic reaction or 'reaction from a distance.' Cell-bodies whose axones have been severed undergo chemical change and stain differently from those whose axones are intact. Thus cell-bodies giving origin to a bundle of severed axones may be located in correctly stained sections of the region containing them.

(2) **Embryological evidence.**—In the first stages of their development axones of the cerebrospinal nervous system are non-medullated. They acquire their sheaths of myelin later. Axone pathways forming different chains become medullated at different periods. Based upon this fact a method of investigation originated by Flechsig is employed, by which the position and course of various pathways may be determined. A staining method differential for medullated axones alone is applied to the nervous systems of fetuses of different ages, and pathways medullated at given stages may be followed from the locality of their origin to their termination. In the later stages, when most of the pathways are medullated and therefore stain alike, the less precocious pathways may be followed by their absence of medullation.

(3) **Direct anatomical evidence.**—(*a*) Stains differential for axones alone are applied to a given locality to determine the fact that the axones of a given bundle actually arise from the cell-bodies there, or that axones traced to a given locality actually terminate about the cell-bodies of that locality. For example, it may be proved anatomically that the axones of a dorsal root arise from the cells of the corresponding spinal ganglion, and then these axones may be traced into the spinal cord and the terminations noted either of their collateral or terminal twigs or the fasciculus they join in their cephalic course may be determined. (*b*) The staining properties and the size and distribution of the tigroid masses in the cell-bodies of sensory neurones differ from those in the motor neurones, and recently Malone has claimed that, in the central system, the cell-bodies in the nuclei of sensory neurone-chains, those chains ascending toward the cerebral cortex, may be distinguished from the cell-bodies of the motor or descending chains by the arrangement and size of their tigroid masses. He claims further that in the same way, the cell-bodies of the somatic efferent neurones may be distinguished from those of the visceral efferent neurones. In this way the locality of origin of certain physiologically known paths may be determined.

(4) The so-called **pathologic-anatomical method** is based upon the same general principles as is the physiological (or experimental) method. A pathological lesion, a local infection or a tumor for example, may destroy a nucleus of cell-bodies or sever a bundle of axones, and the resulting degeneration, of the axones may be followed through serial sections suitably prepared. The locality of the lesion known, the path may be followed to determine the locality of its termination; its locality of termination known from the symptoms resulting, the path may be followed to its cells of origin, or to determine whatever be the locality of the lesion.

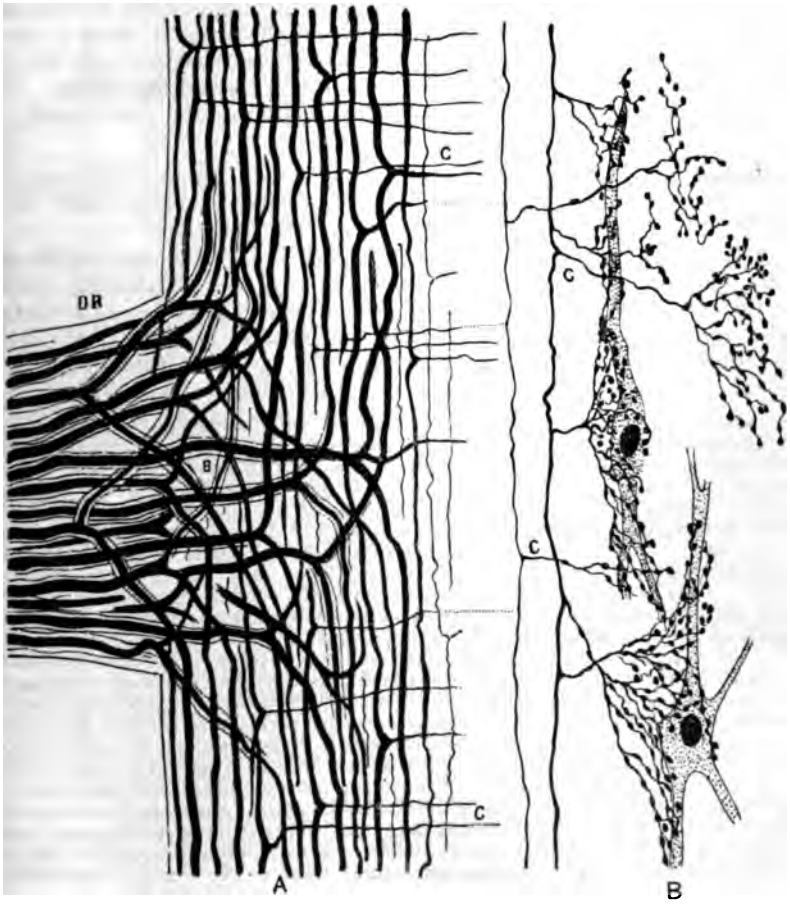
Funiculi.—In order that the various fasciculi may be referred to with greater ease, the white substance of the spinal cord in transverse section is divided into three areas known as funiculi or columns and which correspond to the funiculi already mentioned as evident upon the surface of the cord when intact. The funiculi are outlined wholly upon the basis of their position in the cord and with reference to the median line and the contour of the column of gray substance; their component fasciculi are defined upon the basis of function. (1) The *posterior funiculus* or column is bounded by the posterior median septum and the line of the dorsal horn; (2) the *lateral funiculus* or column is bounded by the lateral concavity of the gray column and the lines of entrance and exit of the dorsal and ventral roots; (3) the *ventral funiculus* or column is bounded by the line of exit of the ventral roots, and by the anterior median fissure. (See figs. 658, 661

The posterior funiculus or column [funiculus posterior].—This funiculus is composed of two general varieties of axones arranged in five fasciculi. First, an constituting the predominant type in all the higher segments of the cord, are the afferent or general sensory axones, which arise in the spinal ganglia, enter the cor

e dorsal roots, assume their distribution to the neurones of the cord, and then e of them) take their ascending course toward the encephalon. The axone e spinal ganglion neurone undergoes a T-shaped division a short distance the cell-body, one limb of this division terminating in the peripheral organs the other going to form the dorsal root. Upon entering the cord the dorsal axones undergo a Y-shaped bifurcation in the neighborhood of the dorsal , one branch ascending and the other descending (fig. 659). The longest of ascending branches form the **fasciculus gracilis** (Goll's column) and the culus cuneatus (Burdach's column). These fasciculi are the largest ascending nsory spinocerebral connections, the direct sensory path to the brain. Their ones represent the first links in the neurone chains between the periphery of ody and the cerebral or cerebellar cortex.

659.—Showing Disposition of the Dorsal Root Fibers Upon Entering the Spinal Cord. (From Edinger after Cajal.)

ws dorsal root axones DR, entering the spinal cord, bifurcating at B, and giving off ollaterals C to the neurones of the cord. B shows the telodendria of these axones or of their ollaterals forming synapses with cell-bodies of the gray substance of the cord.



threading their way toward the brain, these sensory axones of long course tend to work d the midline. Therefore those of longest course are to be found nearer the posterior n, in the upper segments of the cord, than those axones which enter the cord by the dorsal of the upper segments. Thus it is that the fasciculus gracilis, the medial of the two fas- contains the axones which arise in the spinal ganglia of the sacral, lumbar and lower ic segments (S., L. and T. 12 to 6). In other words, it is the fasciculus bearing sensory es from the lower limbs to the brain, while the fasciculus cuneatus, the lateral of the two, corresponding pathway for the higher levels (T. 6 to 1 and C.). Naturally, there is no ulus cuneatus as such in the lower segments of the spinal cord. The axones being much ed at first, it is only in the upper thoracic and cervical region that there is any anatomical reation between the two fasciculi. In this region the two become so distinct that there

is in some cases an apparent connective tissue septum between them, continuing inward to the posterointermediate sulcus—the surface indication of the line of their junction (fig. 6

Upon reaching the medulla oblongata the fibers of the fasciculus gracilis and the fasciculus cuneatus terminate about cells grouped to form the nuclei of termination of these fasciculi. The nucleus of termination of the fasciculus gracilis is situated medially and begins just below the point at which the central canal opens into the fourth ventricle; that of the fasciculus cuneatus is placed laterally and extends somewhat higher than the other nucleus. The neurones whose cell-bodies compose these nuclei constitute the second links in the neurone chains conveying sensory impulses from the periphery to the cerebral and cerebellar cortex.

The descending or *caudal branches* of the dorsal root-axones are concerned wholly with the neurones of the spinal cord. They descend varying distances, some of them as much as four segments of the cord, and give off numerous collaterals on their way to the cells of the gray column. Those terminating about cell-bodies of the ventral horn, which give rise to the ventral or motor root-fibers, are responsible for certain of the so-called *'reflex activities'* and thus contribute to the simplest of the **reflex arcs.** In descending they serve to associate different levels of the gray substance of the cord with impulses entering by way of a single dorsal root. Some of their collaterals cross the midline in the posterior white commissure, and thus transfer impulses to neurones of the opposite side. The caudal branches of longer course are scattered throughout the ventral portion of the fasciculus cuneatus (*middle root zone*), and the longest show a tendency to collect along the border-line between the fasciculus cuneatus and the fasciculus gracilis, and thus contribute largely to the **comma-shaped fasciculus.** Also a few of the longest of them in the lower levels course in the *oval bundle* or septomarginal root zone.

The ascending branches of the dorsal-root axones also give off some collaterals to the gray substance of the cord, thus extending the area of distribution of a given dorsal nerve-root to levels of the cord above the region at which the root enters.

The greater number of the terminations of dorsal root-axones within the spinal cord form synapses with neurones other than those contributing ventral root-fibers. The greater mass of the neurones concerned are those of the Golgi type II and those contributing the **fasciculi proprii** or **ground bundles** of the spinal cord, or the second variety of axones composing the posterior funiculus. The latter fasciculi arise from the smaller cells of the gray column (fig. 660).

These axones pass from the gray substance to enter the surrounding white substance, bifurcate into ascending and descending branches, which in their turn give off numerous collaterals to the cells of the gray substance of the levels through which they pass. The cell-bodies giving origin to such axones are so numerous that the entire column of gray substance is surrounded by a continuous felt-work of fasciculi proprii.

The **dorsal fasciculus proprius** (anterior root zone of posterior column) arises chiefly from cells situated in the dorsal horn (*stratum zonale*). Coincident with the ingrowth and arrangement of the fasciculi gracilis and cuneatus many of the longer fibers of the dorsal fasciculus proprius go to form both the oval bundle and the comma-shaped fasciculus. Thus these two bundles are mixed, being fasciculus proprius which contain caudal branches of dorsal root-axones. The association fibers in the oval bundle are the longest of any belonging to the dorsal fasciculus proprius. The cephalic and caudal branches combined of some are said to extend more than half the length of the cord and it has been claimed that some even associate the conus medullaris with the cervical region. Based upon this claim, Obersteiner has called the oval bundle the 'dorsomedial sacral field' and Edinger has referred to the most dorsal part of it as the *'tractus cervicolumbalis dorsalis.'* A better name for it is *lumbocervical tract*, since, to become so isolated from the gray substance, it probably arises in the lumbar region of the cord. The *'medial triangle'*, is formed by the continuation of the dorsal fasciculi proprii with the oval or septomarginal fasciculus. Some of the axones of the dorsal fasciculus proprius cross the midline to distribute impulses to the neurones of the opposite side. These commissural axones, together with certain collaterals of the dorsal root-axones, which cross the midline outside the dorsal white commissure, compose the so-called **cornucommissural tract** at the ventral edge of the posterior septum.

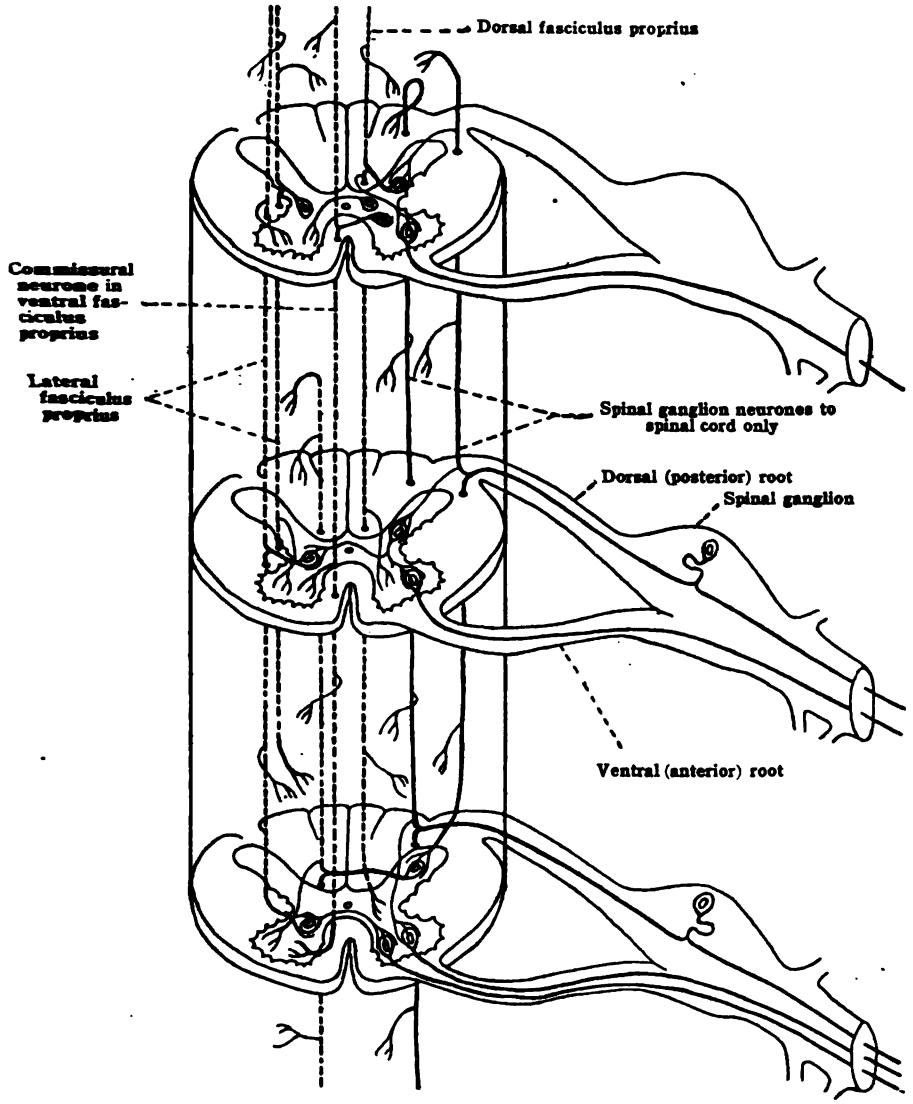
Only a minor proportion of the axones of the posterior or dorsal nerve-roots extend to the encephalon. Estimation shows that the sum of all the dorsal roots is greatly in excess of the sum contained in the fasciculi cuneatus and gracilis just before these enter their nuclei of termination. Therefore most of the ascending branches are concerned with spinal cord relations wholly.

The lateral and ventral funiculi or columns.—The region of the passage of the ventral root-fibers from the ventral horn is considered the line of demarcation between the lateral and ventral funiculi. In that it is much less definite than the demarcation between the lateral and dorsal funiculi and because it is so broad as to involve in it certain of the tracts to be considered, some extending through the line, the fasciculi comprising the two funiculi will be considered together.

The marginal zone of Lissauer, situated along the lateral margin of the posterolateral sulcus, is composed largely of dorsal root-axones which bifurcate lateral instead of medial to their line of entrance. Many of these finally work across the line of entrance into the posterior funiculus. Many of the dorsal root-fibers which do not reach the brain occur in Lissauer's zone. Lissauer's zone also contains some fibers arising from the small cells of the dorsal horn, and to this extent corresponds to a fasciculus proprius. Ranson has found that large numbers of the non-medullated dorsal root-axones which enter the cord are contributed to Lissauer's zone.

FIG. 660.—DIAGRAM ILLUSTRATING THE FORMATION OF THE FASCICULI PROPRII (ASSOCIATION FASCICULI) AND THE COMMISSURAL FIBERS OF THE SPINAL CORD, AND THE GENERAL ARCHITECTURE OF THE CORD AS A MECHANISM FOR REFLEX ACTIVITIES.

The ventral fasciculus proprius is omitted and the lateral is shown on one side only. The lower spinal ganglion neurone shown illustrates the type whose ascending branch is of much longer extent than that of the upper one. Reflex arcs involving the sympathetic are not included.



The lateral and ventral fasciculi proprii (ground or basis-bundles).—The lateral fasciculus proprius is situated in the lateral concavity of the gray column and is continuous with the other fasciculi proprii both dorsal and ventral. Beyond that it probably contains fewer commissural axones, it is of the same general significance as the others. It is the largest of the three and is frequently divided into small bundles by the reticular formation (see fig. 658).

The ventral fasciculus proprius is continuous unbrokenly around the ventral horn with the lateral, is bounded medially by the ventral median fissure and is continuous under the floor of this fissure with its fellow of the opposite side. More commissural fibers traverse it than traverse either of the other two. The neurones represented in it serve especially to associate

the different levels of the ventral horn, and it is known to contain some association-fibers extra long course—extending between the brain and cord.

The lateral cerebrospinal fasciculus (crossed pyramidal tract).—In contrast to the sensory fibers passing through the spinal cord conveying impulses destined to reach the cerebral cortex, axones are given off from the pyramidal cells of the cortex, which descend to terminate about the cells of the gray substance of the spinal cord, chiefly the cells which give origin to the ventral root-fibers.

Upon reaching the medulla oblongata in their descent, these axones are accumulated in two well-defined, ventrally placed bundles, the **pyramids**, one from each cerebral hemisphere. In passing through the brain stem the pyramids contribute many fibers which cross the midline to terminate in the motor nuclei of the cranial nerves of the opposite side, and thus decrease appreciably in bulk. According to the estimate of Thompson, only about 160,000 of the pyramidal fibers are destined to enter the spinal cord.

Upon reaching the lower part of the medulla, the greater mass of the fibers of each pyramid, which are destined to enter the cord, suddenly cross the midline in the 'decussation of the pyramids.' The remainder retain their ventral position in their descent decussating gradually in the cord itself. The pyramidal fibers which cross in the medulla course in the lateral column ventral to Lissauer's zone, and lateral to the lateral fasciculus proprius, and form the *lateral cerebrospinal fasciculus* (crossed pyramidal tract). It is a large fasciculus, oval-shaped in transection, and since its axones terminate in the gray column of the cord all along its length, it decreases in bulk as the cord is descended.

The **ventral cerebrospinal fasciculus** (anterior or direct pyramidal tract), as stated above, is the uncrossed portion of the descending cerebrospinal system of neurones. It is a small, oblong bundle, situated mesially in the anterior funiculus, parallel with the anterior median fissure. Like the lateral cerebrospinal fasciculus (crossed pyramidal tract), its axones arise from the large pyramidal cells of the motor area of the cerebral cortex, and transmit their impulses to the neurones of the ventral horns of the gray substance of the spinal cord, and almost entirely to those neurones which give origin to the ventral or motor root-fibers.

It represents merely a delayed decussation of the pyramidal fibers, for instead of crossing to the opposite side in the lower portion of the medulla oblongata, as do the fibers of the lateral fasciculus, its fibers decussate all along its course, crossing in the ventral white commissure and in the *commissural bundle* of the cord to terminate about the ventral horn cells of the opposite side. Hoche, employing Marchi's method, found that a few of its fibers terminate in the ventral horn of the same side. This conforms to the pathological and experimental evidence that there may be a few homolateral or uncrossed fibers in the crossed pyramidal tracts also. Like the crossed tract, the ventral pyramidal tract diminishes rapidly in volume as it descends the cord. Its loss is greatest in the cervical enlargement, and it is entirely exhausted in the upper half of the thoracic cord. With the exception of the anthropoid apes and certain monkeys, none of the mammalia below man, which have been investigated, possess this ventral pyramidal tract.

In addition to the dispositions of the dorsal root-axones given above, certain of them, either by collaterals or terminal twigs, form synapses with the cells of the dorsal nucleus (Clarke's column), which nucleus, tapering in its two ends, extends from about the seventh cervical to the third lumbar segment of the cord. The axones given off by these cells pass to the dorsolateral periphery of the lateral funiculus and there collect to form the **dorsal spinocerebellar fasciculus** (direct cerebellar tract of Flechsig). As such they ascend without interruption, and in the upper level of the medulla oblongata pass into the cerebellum by way of the inferior cerebellar peduncle or restiform body. Necessarily, this fasciculus is not evident in levels below the extent of the nucleus dorsalis.

Also situated superficially in the lateral funiculus is another ascending conduction path, and, like the dorsal spinocerebellar fasciculus, to which it is adjacent, it is also in great part at least a cerebellar connection. Its position suggests its name, **superficial ventrolateral spinocerebellar fasciculus (Gowers' tract)**.

This tract at present does not include as great an area in transverse section as when originally described. The more internal portion of the original Gowers' tract is now given a separate significance, and will be considered separately. While the exact location in the gray column of all the cell-bodies giving origin to the superficial ventrolateral spinocerebellar fasciculus is uncertain, it is known that certain ventral horn cells contribute their axones to it. Many of its cells of origin are scattered in the area immediately ventral to the nucleus dorsalis, others in the intermediate group and mesial portion of the lateral group of ventral horn cells. In the lumbar region these cells increase in line with the position of the nucleus dorsalis above and are quite numerous; therefore, the fasciculus arises for the most part at a lower level in the spinal cord than does the direct cerebellar tract. In degenerations it becomes visible in the upper segments of the lumbar region, and has been proved to increase notably in volume as the cord is ascended. Its

nes arise for the most part directly from cell-bodies of the same side of the cord, though it has n shown by several investigators that many of its axones come from the gray substance of the osite side by way of the ventral white commissure. Terminal twigs and collaterals of the al root-fibers, mostly of the same side, but occasionally from the opposite side, transfer sory impulses to its cells of origin. At one time Gowers' tract was considered an entity, now, even in the more limited area it occupies, it must be considered a mixture of axones of eral terminal destinations or distinct neurone systems. The destination of some of its nes has not been determined with certainty. The spinocerebellar fibers proper go to cerebellum, and there have been traced to the cortex of the superior vermis. Most of these ch the cerebellum not by way of the restiform body, as does the dorsal spinocerebellar tract, pass on in the brain-stem to the level of the inferior corpora quadrigemina, and there turn k to join the brachium conjunctivum or superior cerebellar peduncle. Only a few of its nes leave the fasciculus lower down in the medulla, to enter the cerebellum by way of the iform body, in company with the dorsal spinocerebellar tract. (Rossolimo, Tschermak.) other portion of its axones are thought to reach the cerebrum, probably the nucleus lenti-mis, though it has not been positively traced further than the superior corpora quadrigemina. ny axones in Gowers' tract of the cord correspond to those of the fasciculi proprii, and merely n varying distances in the cord, to turn again into its gray substance. Schaeffer followed some these from the lumbar region up to the level of the second cervical nerve.

In the ventromesial border of Gowers' tract and immediately upon the eriphery, near the anterolateral sulcus (exit of ventral nerve-roots), there is und in the higher segments of the cord a small oval bundle, the **spino-olivary** sciculus or **Helweg's** (Bechterew's) **bundle.** The functional direction of its bers has not been settled.

The bundle was at first thought to arise wholly within the olive in the medulla oblongata nd to terminate in the cord. More recent claims assert that it arises from cell-bodies in the ord and thus is spino-olivary. By some observers it has been traced as far down as the mid-horacic region; by others, however, only as far as the third cervical segment. Goldstein ggests that spino-olivary fibers arise from the entire length of the cord. Others hold that the sciculus contains both spino-olivary and olivospinal fibers, the latter having the shorter rtent. The olives being nuclei largely concerned with cerebellar connections, Helweg's sciculus is probably an indirect cerebellar association with the cervical spinal cord neurones. is composed of axones of relatively very small diameter, and it is one of the last fasciculi of e spinal cord to become medullated.

Considering Helweg's bundle as spinocerebellar, it may be noted that there are three spino-rebellar fasciculi, one for the cervical region, one for the thoracic and one for the lumbosacral gion of the cord, the origin of each considerably overlapping that of the succeeding.

Situated between the lateral and ventral fasciculi proprii and the super-ially placed fasciculi is an area which, in transverse sections, may be, by po-ition, referred to collectively as the **intermediate zone.** So intermingled are the ones comprising it that it has been called the **mixed zone.** It extends through oth the lateral and ventral funiculi and it contains fibers of the following func-onal varieties:

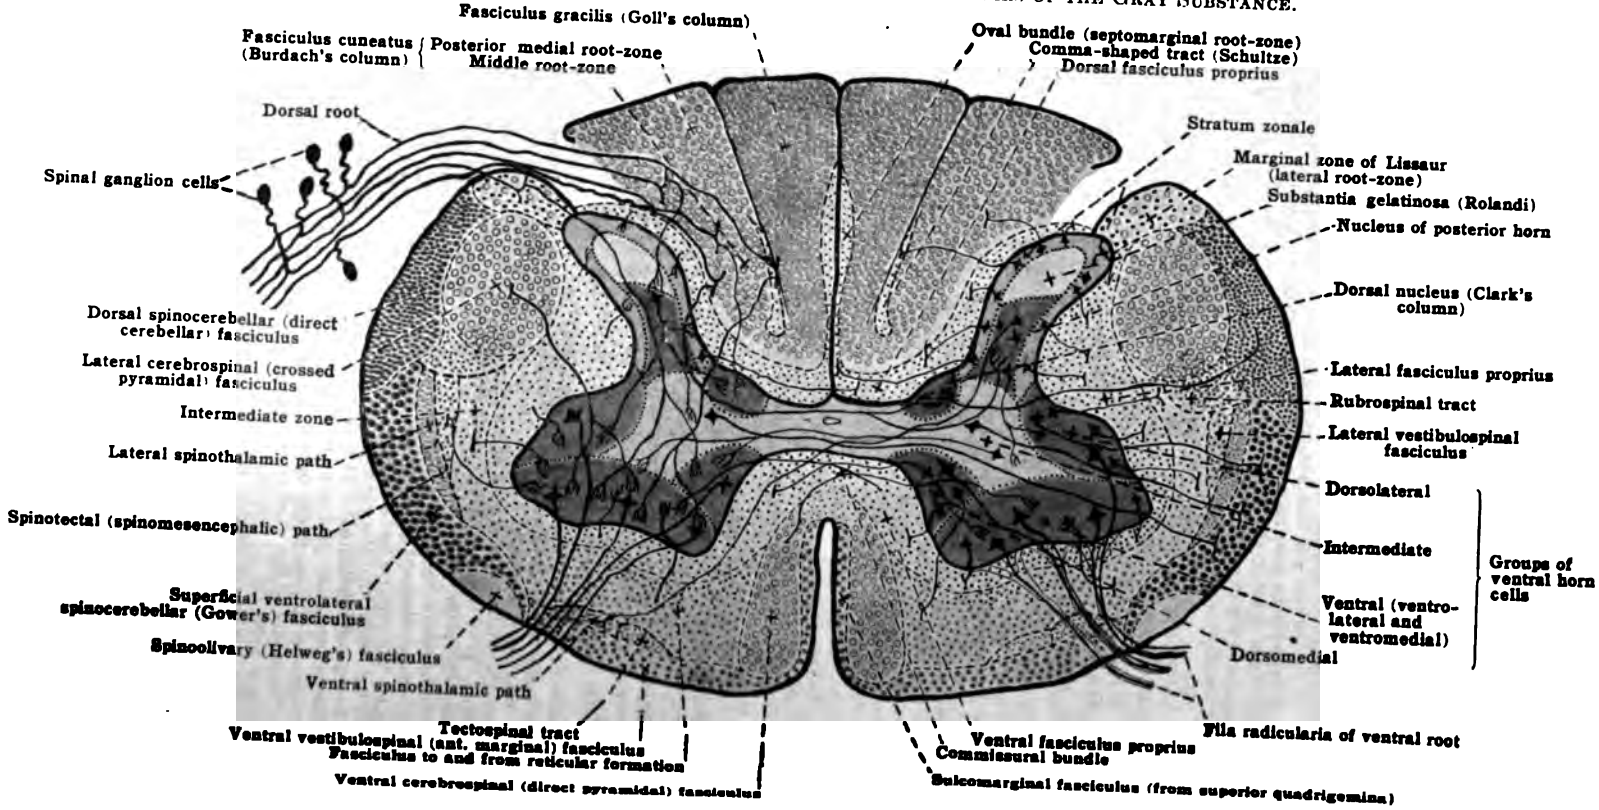
1. Fibers ascending and descending, belonging to the lateral and ventral fasciculus proprius hich are of longer extent gradually course farther away from the gray substance of the cord d such mix into the intermediate zone. It is said to contain fibers descending from the cere-llum to associate with the neurones of spinal cord, probably directly with the ventral root or otor neurones. It is doubtful that there are present in the cord any fibers arising directly om cell-bodies situated in the cerebellum. None are indicated by anatomical evidence rough degenerations. Some may occur as a downward continuation of the *tractus cere-llotegmentalis bulbi* claimed by some authors. It is thought that the cortical cerebrospinal yramidal) and rubrospinal fasciculi serve for responses to the several paths conveying sensory mpulses from the body into the cerebellum.

2. **The rubrospinal fasciculus.**—This arises from cell-bodies in the red nucleus of the tegmen-m (in the mesencephalon) and is a crossed fasciculus. Axones arising from the red nucleus one side across the midline in the mesencephalon (ventral tegmental decussation) and descend the lateral funiculus of the cord to terminate gradually about cell-bodies of the ventral horn, oth those which give rise of ventral root fibers and those which contribute to the fasciculi oprii. Its fibers are more thickly bundled in a crescentic area fitting onto the ventral side of e lateral cerebrospinal fasciculus, and some are said to mix into the area of this latter.

3. **The lateral vestibulospinal fasciculus** is a much smaller tract than one of similar signifi-nce in the ventral funiculus of the cord. It arises from some of the cell-bodies comprising eiter's nucleus, the lateral nucleus of termination of the vestibular nerve, and from some of ose of the spinal nucleus (nucleus of the descending root) of this nerve, all of which is in the edulla. It descends the cord, uncrossed, to terminate gradually about ventral horn cells, thus mprising a part of the apparatus for the equilibration of the body. Its fibers are thought be more closely collected in the area immediately ventral to the rubrospinal fasciculus, ut of course commingle with the latter.

4. *The corpora-quadrigemina-thalamus paths.* In the lateral, ventrolateral and medial por-ons of the intermediate zone are small tracts, both ascending and descending, which connect e spinal cord with the thalamus (diencephalon) and the quadrigeminate bodies of the mesence-halon. These are crossed paths. The ascending fibers arise from cell-bodies situated in the

FIG. 661.—SCHEMATIC REPRESENTATION OF THE SHAPE AND POSITION OF THE VARIOUS FASCICULI OR CONDUCTION PATHS OF THE SPINAL CORD AND THE GROUPING AND SIGNIFICANCE OF THE CELL-BODIES OF THE GRAY SUBSTANCE.



al horns and carry sensory impulses received by direct synapses made by collaterals and inal twigs of the dorsal root-fibers invading the dorsal horns. Of the descending com-nts, fibers arising in the quadrigeminate bodies are best established. For description, omponents of the paths are named as follows:

a). **The spinal lemniscus** is a name used to represent collectively the sensory or ascending ponents of the corpora-quadrigemina-thalamus paths, not because of any 'band-like' shape med by the tracts but because, like the well-known lemniscus in the rhomboencephalon, they y sensory impulses from the general body, received from spinal ganglion neurones, to the brum. They are described as ascending in three paths:

The spinotectal (spinomesencephalic) path arises from cell-bodies in the dorsal horn of one , crosses in the commissures of the cord (chiefly the ventral), turns cephalad and accumulates a bundle in the lateral part of the intermediate zone, medial to Gowers' tract. It termin-s in the gray substance of the quadrigeminate bodies or tectum of the mesencephalon. se bodies likewise receive visual and auditory impulses for transmission to the nuclei of in of the oculomotor and trochlear nerves. Therefore, by this path, general body-sensa-ns may induce eye movements.

The lateral and ventral spinothalamic paths both arise from cell-bodies in the dorsal horn of side and both cross in the ventral commissures of the cord to ascend in the intermediate e of the opposite side. The lateral ascends medial to Gowers' tract in dorsal company with spinotectal tract. The ventral one ascends in the ventral funciulus of the cord, medial to spino-olivary tract and in the dorsolateral extension of the ventral vestibulospinal fascic-s. Both terminate in the inferior and lateral nuclei of the thalamus, which nuclei in their n give fibers which terminate in the cerebral cortex.

(b). The *descending* components of the corpora-quadrigemina-thalamus paths are as follows:

The tectospinal tract (of Löwenthal) which arises from the corpora quadrigemina or tectum the mesencephalon, decussates there in the 'fountain decussation' and descends the medulla longata and the spinal cord in company with the ascending fibers of the ventral spinothalamic ct. It probably distributes its impulses to the ventral horn neurones throughout the cord. nce the superior and inferior pairs of the quadrigeminate bodies receive impulses of sight and aring respectively, it may be assumed that this tract correlates these sensations with bodily ovements.

The sulcomarginal fasciculus, as its name implies, descends in the margin of the ventral edian fissure of the cord, medial to the ventral cerebrospinal fasciculus where this is present. is continuous into the cord with the median longitudinal fasciculus, one of the long associa-on-tracts of the brain, but it contains fibers which arise from the cell-bodies of the superior uadrigeminate body and which form part of the 'optic-acoustic-reflex path' of the mesen-ephalon, cross the midline in the fountain decussation and descend to distribute impulses to the entral horn of the opposite side of the cord, supposedly along its entire length. The superior uadrigemina having to do with sight, the sulcomarginal fasciculus forms the chief path by hich general bodily movements may be induced in response to visual impulses. It is a entromedial tectospinal tract.

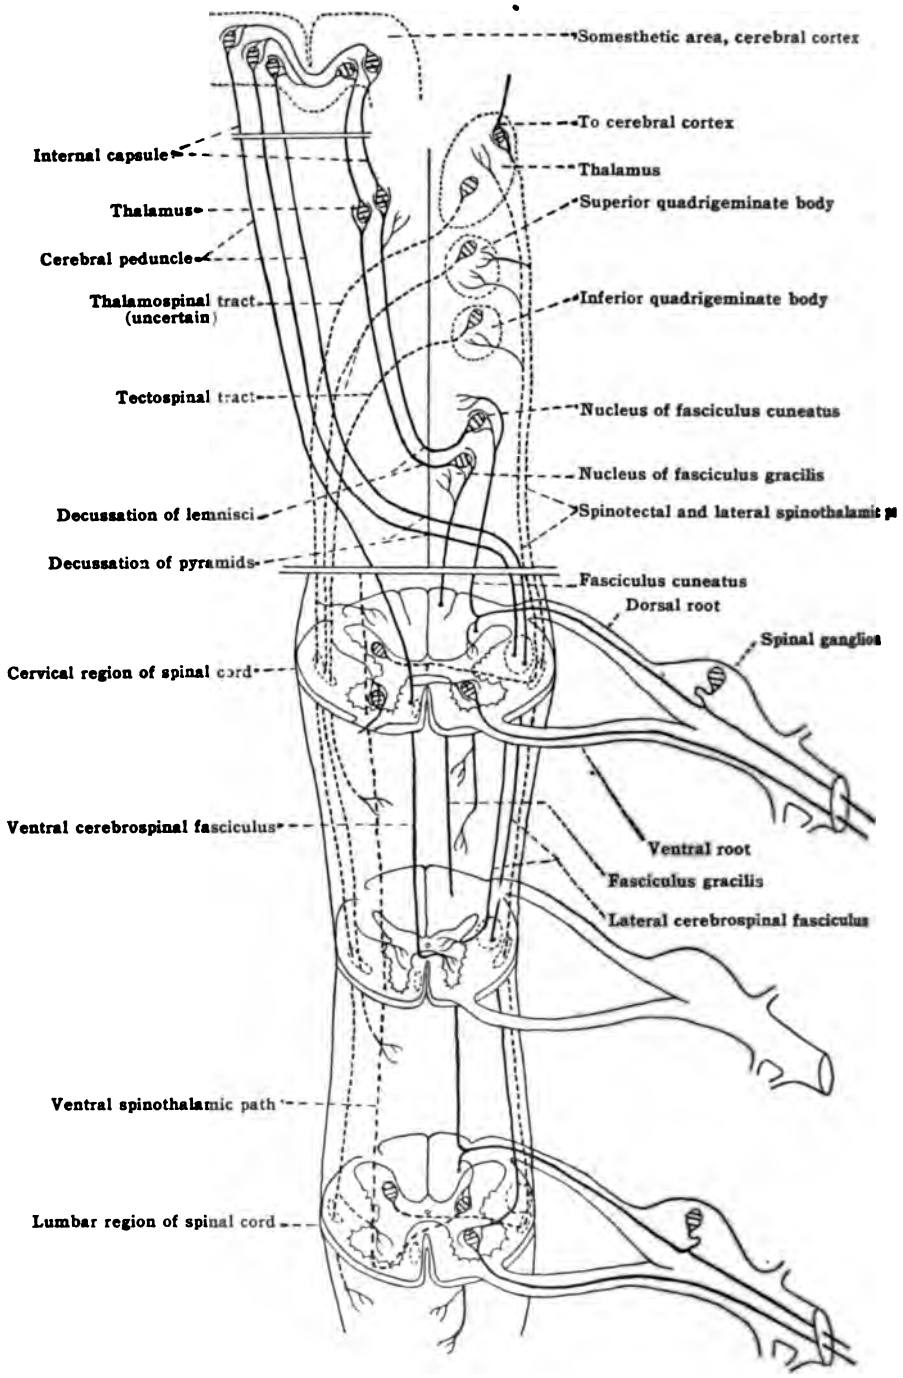
In addition to the above components of the intermediate zone, the studies of Flechsig, von echterew and others suggest that the medial portion of the zone also contains fibers both ascend-g and descending, probably uncrossed, which associate the gray substance of the spinal cord ith the reticular formation of the medulla oblongata. Among the regions to which it is claimed ey have been traced are :the nuclei of origin of the facial and eye-moving nerves and om the nuclei of termination of the vagus, glossopharyngeal, auditory and trigeminal nerves. l of the intermediate zone grades into the lateral and ventral fasciculi proprii. The fasciculi oprii proper, the axones nearest the gray substance, serve for the intersegmental association the cord itself, while the intermediate zone may be considered as carrying axones which ve to associate more distant levels of the nerve axis, i.e., the gray substance of the cord with at of its upward continuation into the medulla, pons, mesencephalon and thalami. In gen-al terms, the relation of the cord to the cerebrum is a crossed relation, while its relation to e medulla, cerebellum and pons is uncrossed.

The anterior marginal fasciculus or ventral vestibulospinal tract forms the perficial boundary of the medial portion of the intermediate zone. It is a arrow band, on the surface of the cord, and extends medially from the medial tremity of Gowers' tract (from Helweg's bundle) to the beginning of the terior median fissure.

The axones belonging to it proper are descending from the recipient nuclei of the vestib-ar nerve. Of these nuclei it has been held by some investigators that only Deiters' nucleus e lateral nucleus of termination in the upper extremity of the medulla oblongata) gives gin to the axones of the anterior marginal fasciculus. Others agree with Tschermak that superior and more laterally situated Bechterew's nucleus of the vestibular nerve also tributes axones to it, and quite probably the nucleus of the spinal root of the vestibular ds further axones. Still other investigations have suggested that a part at least of the fas-ulus comes from the nucleus fastigius (roof nucleus) of the cerebellum. Since many axones m both Deiters' and Bechterew's nucleus terminate in the nucleus fastigius, the ventral tibulospinal fasciculus is, in any case, a conduction path from the nerve for equilibration to gray substance of the spinal cord. The fasciculus is said to extend as far as the sacral re-n of the cord, its axones terminating about the cells of the ventral horns. The term 'ven-l' is added to its name to distinguish it from the vestibulospinal tract described above as rsing in the lateral funiculus. It is considered an uncrossed pathway.

The **commissural bundle** is situated about the floor of the anterior me fissure, and is the most dorsal tract of the anterior funiculus. It contains d sating or commissural axones of four varieties.

FIG. 662.—DIAGRAM OF SPINAL CORD ILLUSTRATING THE TWO CHIEF VARIETIES OF S CEREBRAL AND CEREBROSPINAL NEURONE CHAINS. The ventral tectospinal (t marginal) fasciculus, fibers descending from the superior quadrigeminate bodies, i filled in.



(1) It contains the decussating axones of the ventral **cerebrospinal fasciculus throu** the extent of that fasciculus; (2) it is chiefly composed of the **axones of the ventral fasc** proprius which arise in the gray substance (ventral horn) of **one side, cross the midline a** missural fibers, and course both upward and downward to be **distributed to the neuro**

nt levels of the gray substance of the opposite side; (3) it contains decussating axones which rom cell-bodies in the gray substance of one side and cross the midline to terminate cell-bodies in practically the same level of the opposite side. The latter are merely s belonging to the ventral white commissure which course without the confines of the grey . (4) It carries most of the decussating fibers of the spinothalamic and spinotectal tracts. ommissural bundle is present throughout the length of the spinal cord, and is largest in largements, i. e., where the association and commissural neurones occur in greater number ally.

SUMMARY OF THE SPINAL CORD

he spinal cord contains two general classes of axones arranged into three ral systems. It contains axones which—(a) enter it from cell-bodies situated ide its boundaries, i. e., in the spinal ganglia and in the encephalon, and (b) es which arise from cell-bodies situated within its own gray substance, some hich axones pass outside its boundaries both to the periphery and into the phalon; some of which remain wholly within it. Its axones comprise—(1) stem for the intersegmental association of its gray substance, both ascending descending, association proper and commissural; (2) a spinocerebral and brospinal system, ascending and descending; and (3) a spinorhombencephalic nocerebellar and spinobulbar) and a rhombencephalospinal system, ascending descending.

For these relations the gray substance of the cord contains three general classes erve-cells: those which give rise to the peripheral efferent or motor axones he ventral roots; those which give rise to central axones of long course, going he encephalon; and those which supply its central axones of short course, association and commissural systems.

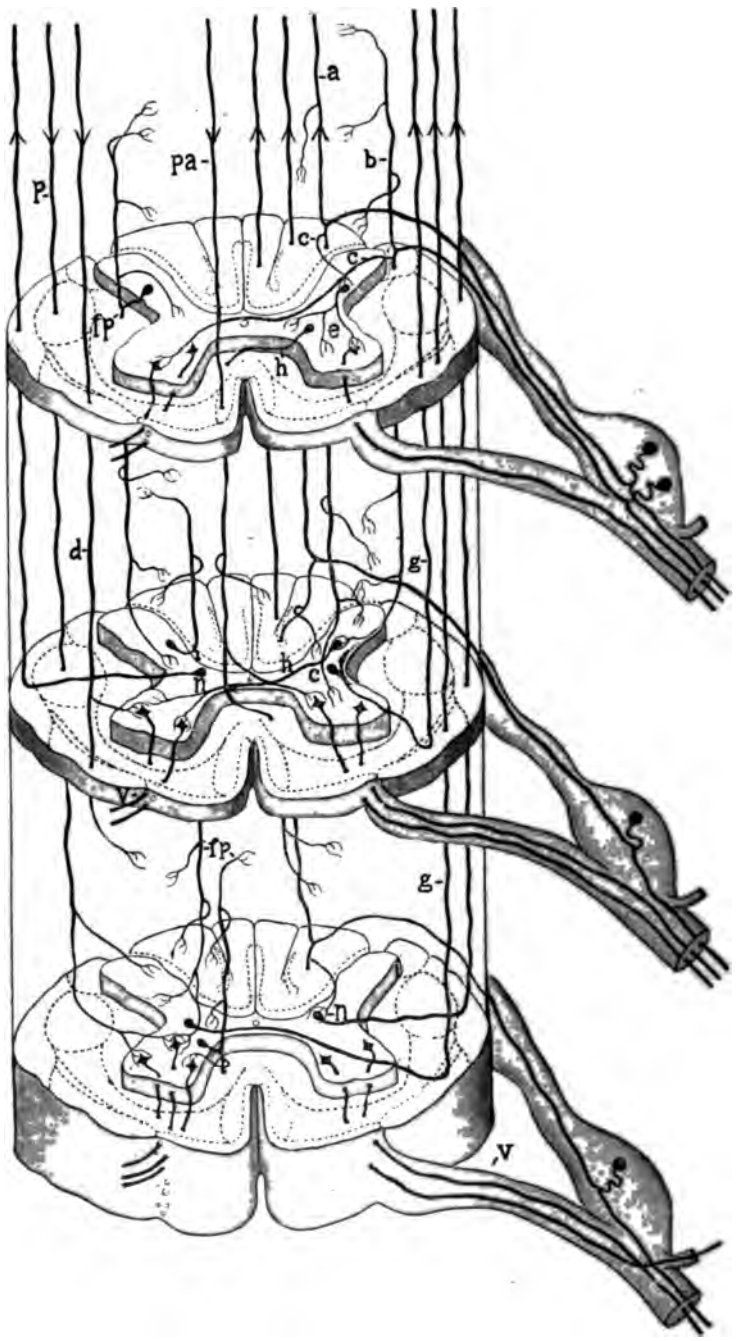
The three systems: (1) Association and commissural.—Axones of spinal ganglion (afferent) ones bifurcate within the cord into cephalic and caudal branches which extend varying nces upward and downward and terminate, (*a*) about cell-bodies whose axones are short terminate within the gray substance of the same side and in the same level as their cell-ies (*Golgi neurones of type II*); (*b*) about cell-bodies whose axones pass without the gray sub-ce, bifurcate into cephalic and caudal branches to terminate in the gray substance of the e side but in various levels above and below (association fibers in the *dorsal*, *lateral* and *ven-fasciculi proprii*); (*c*) about cell-bodies whose axones cross the midline to terminate either he same level of the gray substance of the opposite side, or bifurcate and the cephalic and al branches pass in the fasciculi proprii to terminate in various levels of the gray substance e opposite side. The longer cephalic branches of (*b*) and (*c*) may terminate in the medulla ngata. All, associated with ventral root (efferent) neurones, belong to the neurone-chains he so-called *reflex activities*.

2) **The cerebral system.**—(*a*) The cephalic branches of certain spinal ganglion neurones ed beyond the bounds of the spinal cord to terminate within the medulla. Those ascend-rom the spinal ganglia of lower thoracic and lumbosacral segments accumulate medially rm the *fasciculus gracilis* which terminates in the nucleus of this fasciculus; those arising the upper thoracic and cervical segments accumulate more laterally in the posterior fun-s to form the *fasciculus cuneatus* which terminates in the nucleus of the fasciculus cuneatus. he impulses transferred to the neurones of these nuclei are borne across the midline and ly reach the sensory-motor area of the cerebral cortex, and cell-bodies here give rise to es which *descend*, some decussating in the medulla to form the *lateral cerebrospinal fascicu-*others form the uncrossed *ventral cerebrospinal fasciculus* which crosses the midline as it de-ds the cord, practically all crossing in the cervical region. Both of these fasciculi transfer r impulses either directly to efferent ventral horn neurones, or to association neurones and e to the efferent neurones. (*c*) The cephalic and caudal branches of spinal ganglion neu-s terminate about cell-bodies in the dorsal horns of the cord whose axones cross the mid- and *ascend* laterally to terminate either in the quadrigeminate bodies (*spinotectal tract*), n the thalamus (*spinothalamic paths*). (*d*) Cell-bodies in the superior quadrigeminate es (receiving optic impulses) and in the inferior quadrigeminate bodies (probably mediating tory impulses), give axones which cross the midline in the mesencephalon and *descend*, ing the *tectospinal tracts*, to terminate in contact with the efferent neurones of the cord. es from both sources descend in the lateral funiculus, while from the superior quadrigemi-body, a separate bundle descends in the ventral funiculus as the *sulcomarginal* (*ventral pinal*) *fasciculus*. (*e*) The *rubrospinal tract* arises from cell-bodies in the red nucleus (in nesencephalon), crosses the midline in the ventral tegmental decussation and descends in ateral funiculus to transfer (probably cerebellar) impulses to the efferent neurones of the l cord.

3) **The rhombencephalic system.**—(*a*) The cephalic and caudal branches of spinal ganglion ones give telodendria about the cell-bodies forming the *dorsal nucleus* of the cord (Clarke's nn) and about cell-bodies situated in grey substances ventral to the dorsal nucleus and in with it in the lumbar and sacral regions. Axones arising from the cells of the dorsal nucleus laterally to form the *dorsal spinocerebellar fasciculus* which *ascends* into the cerebellum by of its inferior peduncle of the same side and terminates about cell-bodies of its cortex. es arising from near and in line with the dorsal nucleus, of both the *same* and opposite

FIG. 663.—SCHEMATIC REPRESENTATION OF THE MORE IMPORTANT ARCHITECTURAL REL OF NEURONES IN THE SPINAL CORD, OMITTING THOSE INVOLVING THE MESENCEPH AND THALAMUS.

a, afferent (spinal ganglion) axone of spinocerebral chain with bifurcation and caudal b, afferent axone coursing in Lissauer's zone, and distributed wholly within th c, collaterals of a and b disposed in three ways; p, pyramidal axone in lateral (c cerebrospinal fasciculus distributed to levels of grey substance; pa, axone in ventral c spinal fasciculus decussating before termination; v, ventral root or motor neuro nucleus dorsalis giving axone to dorsal spinocerebellar fasciculus; g, ascending n of Gowers' tract; d, descending axone from cerebellum (probable); fp, neurones of f proprii, association proper; h, commissural neurones; c, Golgi cell of type II.



of the cord, accumulate to form the *superficial ventrolateral spinocerebellar fasciculus*, h *ascends* to enter the cerebellum by way of its superior peduncle and terminate about the of the cerebellar cortex. (*b*) A few axones arising in the roof nucleus of the cerebellum ably *descend* in the *anterior marginal fasciculus* in company with the *ventral vestibulospinal* to terminate upon the efferent neurones of the cord. (*c*) The inferior olivary nucleus, in the lla, is a cerebellar relay and its cell-bodies are associated with the neurones of the upper ion of the same side of the spinal cord. Whether the axones arise in the olivary nucleus or e gray substance of the cord is uncertain, but the more usual supposition favors the cord thus the name *spino-olivary fasciculus* is given them. (*d*) Among its other functions, cerebellum is concerned with muscular tone and equilibration. The vestibular nerve is the rent nerve of equilibration and a large mass of the axones arising from its nuclei of termina- terminate in the cerebellum, in the roof nuclei especially. Axones arising from cell-bodies Deiters' nucleus (its lateral nucleus of termination) and in the nucleus of its descending root end the cord in the lateral funiculus to form the (lateral) *vestibulospinal tract*, and also in the rior *marginal fasciculus* to form *ventral vestibulospinal tract*. Impulses borne by these axones ch the efferent or motor root neurones. The rubrospinal fasciculus, mentioned above, also y be possibly considered as belonging to the cerebellar system. (*e*) The fasciculi proprii tain ascending and descending association-fibers between the spinal cord and the medulla ongatæ.

Sympathetic relations.—The cell-bodies of the efferent neurones in the ventral horns are two general varieties: (*a*) those whose axones terminate upon skeletal muscle (somatic erent), and (*b*) those whose axones terminate in contact with cell-bodies of sympathetic urones, *preganglionic* or *visceral efferent neurones*. The axones of the sympathetic neurones, their turn, terminate upon cardiac and smooth muscle (motor) and in glands (secretory). e the somatic, the visceral efferent neurones receive impulses within the ventral horns from the cephalic and caudal branches of spinal ganglion neurones, (*b*) the descending cere- spinal fasciculi, and (*c*) from either, by way of the fasciculi proprii and Golgi neurones of pe II. Their cell-bodies are situated for the most part in the dorsal rn (dorsolateral or intermediolateral group of cells), which is the only portion of the lateral rn present in the thoracic region of the cord. Many of the visceral efferent fibers leave the inal nerves distal to the spinal gangila and make the white communicating rami, thus going the nearest sympathetic ganglia; others pass on in the sympathetic nerves or in the trunk of e spinal nerve and its branches to terminate in more distant sympathetic ganglia. Some tones arising in symphatic ganglia enter the spinal cord by either the dorsal or ventral roots the spinal nerves or by separate roots (meningeal rami) to supply the muscle of the blood essels of the cord.

Functionally, the peripheral afferent (spinal ganglion) neurones have been referred to as *ceptors* and the efferent or peripheral motor neurones as *effectors*. According to the tissues nd organs innervated, they are grouped into (1) somatic receptors and effectors and (2) visceral ceptors and effectors. The somatic tissues are the skin, including its appendages and the pithelium of the organs of special sense, the subcutaneous fascia, membranes of joints, tendons nd skeletal muscle; the visceral tissues are all glands and glandular epithelium, cardiac uscle and all smooth muscle, including that of blood-vessels and hair-follicles. A somatic ferent neurone may give some of its branches in the cord for synapsis with visceral efferent urones.

Sherrington, Head and others who hold specific or separate afferent neurones for the differ- t sensations experienced suggest three groups of receptor neurones:

1. *An exteroceptive group*, comprising those spinal ganglion neurones whose peripheral ocesses collect impulses from the skin and its appendages especially (impulses aroused by muli outside the body), but doubtless from any or all the somatic tissues and even the visceral sues also, and which, in the cord, transfer these impulses to those cell-bodies in the dorsal rn whose axones cross the midline to form the two spinothalamic tracts of the opposite side. ie lateral of these tracts is claimed to carry sensations of pain and heat and cold, while to the ntral are given sensations of touch and pressure. These tracts terminate in the ventral and teral nuclei of the thalamus. In passing, each may give collaterals which form synapses with ie nuclei of origin of the motor cranial nerves. The inferior and lateral nuclei of the thalamus nd axones to the cerebral cortex and the corticospinal impulses aroused in response descend ie cord by way of the cerebrospinal fasciculi. The functions of the neurone chains of this oup are classed within 'conscious phenomena.' The neurones of the eye and cochlea are in- uded among the exteroceptive neurones of the cranial nerves.

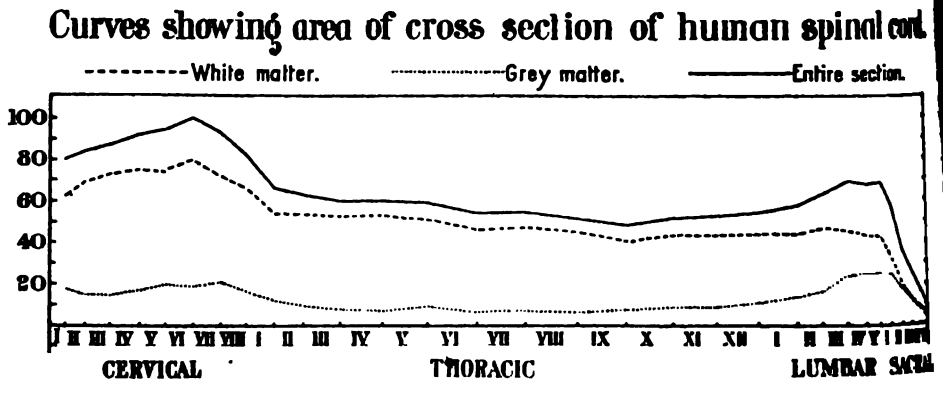
(2) *A proprioceptive group*. This group is subdivided into two classes: (*a*) spinal ganglion urones which collect impulses from the somatic tissues (skin, tendons, joints, skeletal muscle, c.) and whose cephalic branches within the cord form the fasciculus gracilis and fasciculus neatus. The nuclei of termination of these fasciculi in the medulla give rise to the medial nniscus of the opposite side and this transfers the impulses to the ventral thalamic gray sub- ance, whose cell-bodies in turn send axones to the cerebral cortex. Corticospinal impulses, scending in response, are distributed to the cord by the cerebrospinal fasciculi. The neurone ains included are claimed to mediate tactile sensations of position and spatial relations and to ake possible motor control, aiding also in regulating reactions mediated through the extero- ptive group. Most of the functions of this class are likewise within consciousness. (*b*) inal ganglion neurones which collect impulses from the somatic tissues, especially from ten- ns, joints, skeletal muscle and muscle-fasciæ, and which in the spinal cord give collaterals d terminal twigs to the cell-bodies giving origin to the dorsolateral and superficial ventro- eral spinocerebellar fasciculi. The chief functions of the cerebellum are coördination of uscular contractions and maintenance of muscular tone. Impulses from it are distributed the cord by way of the rubrospinal and cerebrospinal fasciculi. The functions of the neu- nes of this class are considered unconscious. The neurones of the vestibular nerve (auditory brinth, exclusive of cochlea) are considered *proprioceptive*.

3. *An interoceptive group* (visceral receptors), comprising those spinal ganglion neu... which collect impulses from the visceral tissues (the epithelium of the digestive canal, incl... the infoldings of the skin continuous with it, from all glands, from the epithelium lining ... cavities of the body, from blood-vessels and probably from smooth and cardiac muscle), ... which in the cord give collaterals and terminal twigs for synapses with the dorsolateral (v... efferent) cell-group of the grey column. These cell-bodies give rise to ventral root (pre... glionic) axones which form synapses in the sympathetic ganglia, the cells of which in turn gi... sympathetic or postganglionic axones for the secretory and motor innervation of glands ... smooth muscle (visceral effectors). The afferent or visceral receptors also give branches w... form synapses with the neurones of the fasciculi proprii of the cord, the longer of which ... transfer impulses to visceral efferent or preganglionic neurones in the cranial nerves. Cer... of the cranial nerves, the vagus especially, are very rich in both visceral receptors and v... effectors. The central control of the muscle of the heart and of many of the blood-vessels ... the body, of the lungs, esophagus, stomach and intestine, is largely mediated by the vagus.

It must be remembered that the above three general groups of neurones functionally ... anatomically overlap each other. An afferent neurone of either the exteroceptive or proprio... ceptive group may, in the cord, give some of its many terminals to form synapses with visce... efferent neurones, and a visceral receptor may give a branch in the cord whose synapsis w... make it a chain from the peripheral structures to the cerebral cortex, bringing sensations arou...

FIG. 664.—GRAPHIC REPRESENTATION OF THE VARYING AMOUNTS OF GRAY AND WHITE SUBSTANCE AND OF THE VARIATIONS IN AREA OF ENTIRE SECTIONS OF THE DIFFERENT SEGMENTS OF THE SPINAL CORD. (From Donaldson and Davis.)

(Based upon measurements from several adult human spinal cords.)



in the visceral organs into the domain of consciousness, as sensations of pain, pressure, temperature, etc. Also, the contention for a specific afferent neurone for conveying each of the many varieties of sensation, verbally indicated by man, is not satisfactorily supported. There are peculiar anatomical differentiations of peripheral tissue-elements (sense organs) of such character and arrangement as to be especially acted upon, specifically irritated, each by a certain form of stimuli. It is probable that, terminating in any tissue, impulses may be aroused in any spinal ganglion neurone by any form of stimulus. These impulses reaching the cerebral cortex or entering 'consciousness', are analyzed and designated there according to the character, quality and intensity of the stimulus applied and according to the locality of its application. Certain tracts in the cord carry impulses destined for certain areas of the cerebral cortex especially devoted to the analysis of certain forms of stimuli.

In transverse sections of the spinal cord (figs. 658, 664), the relative area of white substance as compared with that of gray increases as the cord is ascended. The absolute area of each varies with the locality, both being greatest in the enlargements. The gray substance predominates in the conus medullaris and lower lumbar segments. The white substance begins to predominate in the upper lumbar segments, not because of the increased presence of ascending and descending cerebral and cerebellar axones, but because of the increased volume of the fasciculi proprii coincident with the greater mass of gray substance to be intersegmentally associated in this region. In the thoracic region the greatly predominating white substance is composed mostly of the axones of long course. The greatly increased absolute amount of white substance in the cervical region is due both to the greater accumulation of cerebral and cerebellar axones in this region and to the increased volume of the fasciculi proprii necessary for the increased amount of gray substance of the cervical enlargement.

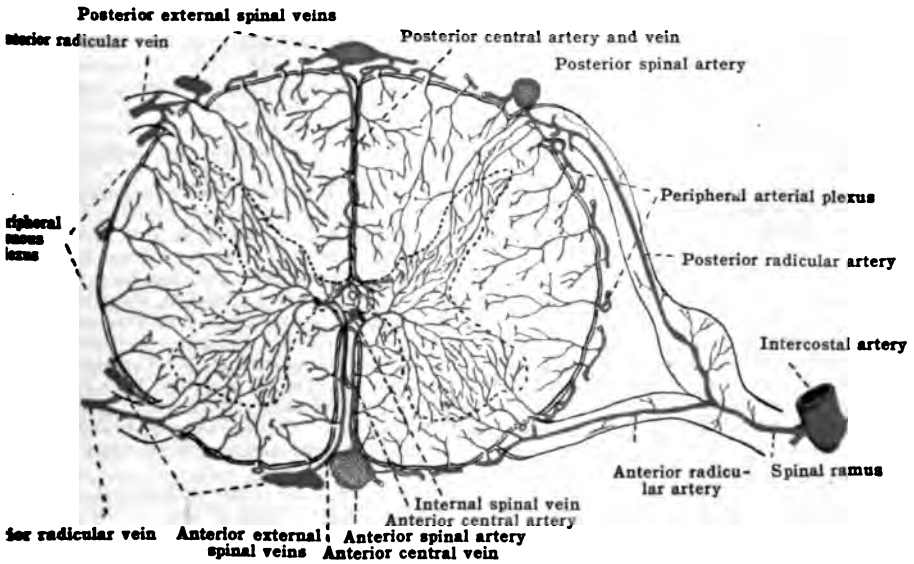
ER OF MEDULLATION OF THE FASCICULI OF THE CORD

he axones of the spinal cord begin to acquire their myelin sheaths during the fifth month of terine life and myelinization is not fully completed till between the fifteenth and twentieth . In general, axones which have the same origin and the same locality of termination—e function—acquire their sheaths at the same time. While it has been proved that the ary sheath does not necessarily precede the functioning of an axone, it may be said that sciculi which first attain complete and definite functional ability are the first to become ated. At birth all the fasciculi of the spinal cord are medullated except the spino-olivary us, and occasionally the lateral and ventral cerebrospinal tracts. The latter tracts vary erably and in general may be said to become medullated between the ninth month (before and the second year. As indicated by their medullation, those axones by which the cord bled to function as an organ *per se*, that is, the axones making possible the simpler reflex ies, complete their development before those axones which involve the brain with the ties of the cord.

ecording to Flechsig and van Gehuchten, and investigators succeeding them, the following order in which the axones of the cord become medullated:

1.) The afferent and efferent nerve-roots and commissural fibers of the gray substance.
2) The fasciculi proprii, first the ventral, then the lateral, and last the dorsal, fasciculus rius.
3) The fasciculus cuneatus (Burdach's column) and Lissauer's zone—the area of those ding spinocerebral fibers which run the shorter course and which convey impulses from pper limbs, thorax and neck.
(4) Fasciculus gracilis (Goll's column).
(5) The dorsal spinocerebellar fasciculus (direct cerebellar tract).
(6) The superficial anterolateral spinocerebellar fasciculus (Gowers' tract).
(7) The lateral cerebrospinal fasciculus (crossed pyramidal) and the ventral cerebrospina sculus (direct pyramidal tract).
(8) The spino-olivary fasciculus.
he remaining fasciciul are so mixed with other axones that it is difficult to determine the nce of their medullation. The fasciculi containing them also contain axones of the variety he fasciculi proprii and so show medullation early.

G. 665.—Semi-diagrammatic Representation of the Blood-supply of the Spinal Cord.



Blood-supply of the Spinal Cord

he spinal rami of the sacral, lumbar, intercostal, or vertebral arteries, as the case may be, npany the spinal nerves through the intervertebral foramina, traverse the dura mater rachnoid, and each divides into a dorsal and a ventral radicular artery. These accompany erve-roots to the surface of the cord, and there break up into an anastomosing plexus in ia mater. From this plexus are derived three tortuously coursing longitudinal arteries numerous independent central branches, which latter penetrate the cord direct. Of the tudinal arteries, the **anterior spinal artery** zigzags along the anterior median fissure and off the anterior central branches, which pass into the fissure and penetrate the cord. These hes give off a few twigs to the white substance in passing, but their most partial distribus to the ventral portion of the gray substance. The two **posterior spinal arteries,** one on side, course near the lines of entrance of the dorsal root-fibers. They each branch and omose, so that often two or more posterior arteries may appear in section upon either side

of the dorsal root. These give off transverse or central twigs to the white substance, but cially to the gray substance of the dorsal horns. Of the remaining central branches many the cord along the efferent fibers of the ventral roots, and are distributed chiefly to the substance; others from the peripheral plexus throughout penetrate the cord and break u capillaries within the white substance. Some of the terminal twigs of these also enter the substance. The-blood supply of the gray substance is so much more abundant than th the white substance that in injected preparations the outline of the gray figure may be distinguished by its abundance of capillaries alone. The central branches are of the ter variety. In the white substance the capillaries run for the most part longitudinally, or pa with the axones. The radicular arteries in passing give twigs supplying the spinal gangli the nerve-roots.

The *venous system* is quite similar to the arterial. The blood of the central arteries lected into corresponding central venous branches which converge into a superficial v plexus in which are six main longitudinal channels, one along the posterior median sulcu along the anterior median fissure, and one along each of the four lines of the nerve These comprise the **posterior** and **anterior external spinal veins** (fig. 665).

The **internal spinal veins** course along the ventral surface of the gray commissure, an from the convergence of certain of the twigs flowing into the *anterior central veins*. The po *central vein* courses along the posterior median septum in company with the posterior c artery, and empties into the *median dorsal vein*. The venous system communicates wi coarser extradural or internal vertebral plexus chiefly by way of the **radicular veins**.

II. THE BRAIN OR ENCEPHALON

The brain is that greatly modified and enlarged portion of the central ne system which is enclosed within the cranial cavity. It is surrounded an ported by the same three membranes (meninges) that envelop the spinal While there is a considerable subarachnoid space, the brain more nearly f cavity than does the spinal cord.

The average length of the brain is about 165 mm. and its greatest transverse d about 140 mm. It averages longer in the male than in the female. Exclusive of its dur the normal brain weighs from 1100 to 1700 gm. (40–60 oz.), varying in weight with the of the individual or with the bulk of the tissues to be innervated. Its average weight gm. (48 oz.) in males and 1250 gm. (44 oz.) in females. It averages about fifty times than the spinal cord, or about 98 per cent. of the entire central nervous system. In its pr growth it is at birth relatively much larger than at maturity. At birth it comprises a per cent. of the total body-weight, while at maturity it averages only about 2 per the weight of the body. Its specific gravity averages 1.036. In proportion to the bod the brain-weight averages somewhat higher in smaller men and women. Some ve dogs and monkeys and some mice have brains heavier in proportion to body-weig does man.

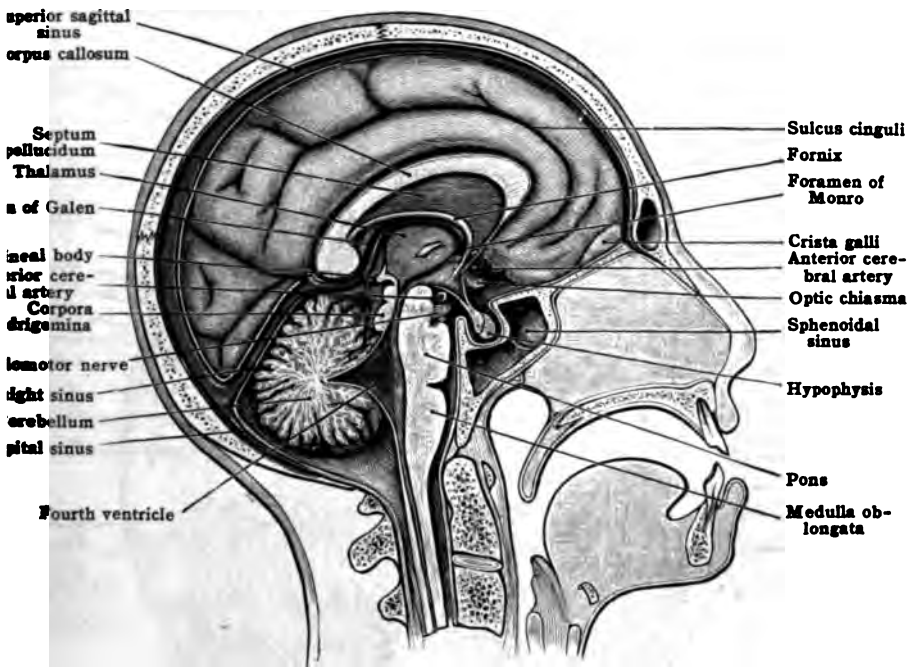
The minimal weight of the adult brain compatible with human intelligence may b at from 950 to 1000 grams. Above the minimal, there is only a general relation bet degree of intelligence and the weight of the brain, owing to the fact that several factor coincident with large brains. It may be said in general, however, that the average brai of eminent men is above the general average. Some men judged eminent have ha weighing less than the general average. Of the records generally accepted, the greate weight for eminent men is 2012 grams, recorded for the poet and novelist, Ivan Tourgeni trustworthiness of this weighing is doubted by some authorities. From the undispute the following may be taken: Cuvier, 1830 grams; John Abercrombie, 1786 grams; T 1658 grams; Kant, 1600 grams; Spurzheim, 1559 grams; Daniel Webster, 1518 gra Agassiz, 1495 grams; Dante, 1420 grams; Helmholtz, 1440 grams; Goltz, 1395 grams 1352 grams; Walt Whitman, 1282 grams; Gall, 1198 grams. In the average brain-w the races that for the Caucasian stands highest, the Chinese standing next, then th followed by the Negro, with the Australian lowest.

The differences between the meninges of the brain and those of the spinal cord occ in the dura mater. The *dura mater* is about double the thickness of that of the spi and consists of two closely adhering layers, the outermost of which is the internal pe of the cranial bones, while that of the cord is entirely separate from the periosteum vertebral canal. The inner layer is duplicated in places into strong partitions whi between the great natural divisions of the encephalon. Of these, the sickle-shaped f extends between the hemispheres of the cerebrum, the crescentic *tentorium cerebell* between the cerebellum and the overlapping posterior portion of the cerebrum, and th *falx cerebelli* occupies the notch between the hemispheres of the cerebellum. Contain these partitions of the dura mater are the great collecting venous sinuses of the brai will be considered in the more detailed description of the cranial meninges.

General topography.—In its superior aspect or **convex surface** the enc is oval in contour, with its **frontal pole** usually narrower than its occipi Viewed from above, the **cerebrum** comprises almost the entire dorsal asp occipital lobes overlapping the **cerebellum** to such an extent that only th and lower margins of the cerebellar hemispheres are visible. The great dinal fissure of the cerebrum separates the cerebral hemispheres.

aterally the **temporal lobes,** with their rounded anterior extremities, the **tem-** l **poles,** are each separated from the frontal and **parietal lobes** above by the **al cerebral fissure** (fissure of Sylvius). In the depths of this fissure and over- **ed** by the temporal lobe is situated the **insula,** or **island of Reil** (central lobe). The surface of each cerebral hemisphere is thrown into numerous folds or **ed** elevations, the **gyri cerebri** or convolutions, which are separated from each **r** by slit-like fissures, the **sulci cerebri.** The gyri (and sulci) vary greatly in **th,** in depth, and in their degrees of curvature. The larger and deeper of them similar in the two hemispheres; most of them are individually variable, but **i** gyrus of one hemisphere is homologous with that of the like region of the **r** hemisphere. By gently pressing open the great longitudinal fissure, the **us callosum,** the chief commissural pathway between the cerebral hemi-

FIG. 666.—MEDIAL SECTION OF THE HEAD OF A FEMALE THIRTY-FIVE YEARS OLD.



res, may be seen. The occipital margin of this large transverse band of white **tance** is rounded and thickened into the **splenium** of the corpus callosum, **e** its frontal margin is curved downward into its **genu** and rostrum.

The base of the encephalon (fig. 667) is more irregular than the convex surface, consists of a greater variety of structures. In the midline between the frontal **s** appears the anterior and inferior extension of the great longitudinal fissure. **en** the margins of this are separated, the outer aspect of the **rostrum** of the ***us callosum,*** the downward continuation of the curve of the genu, is exposed. The inferior surface of each frontal lobe is concave, due to its compression upon superior wall of the orbit. The *orbital gyri* with their respective *orbital sulci* **ipy** this concave area.

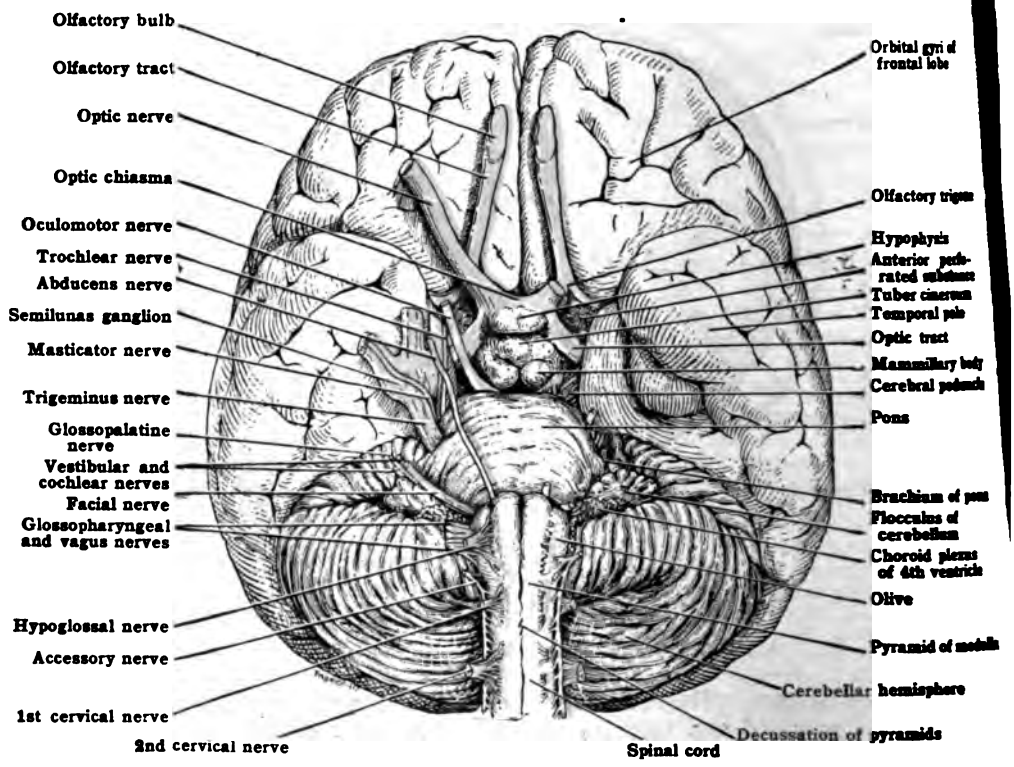
The cranial nerves [nervi cerebrales].—Along the mesial border of each orbital **l,** and parallel with the great longitudinal fissure, lie the **olfactory bulbs** con- **ed** into the **olfactory tracts.** Each olfactory bulb is the first central connec- **. or** the 'nucleus of termination' of the **olfactory nerve,** the first of the cranial **res.** A few fine filaments of this nerve may often be discerned penetrating the **tral** surface of the bulb. The olfactory bulb and tract lie in the *olfactory* ***us,*** which forms the lateral boundary of the *gyrus rectus,* the most medial **as** of the inferior surface of the frontal lobe. Upon reaching the parolfactory **a of Broca,** or the region about the posterior extremity of the gyrus rectus, each **ctory tract** undergoes a slight expansion, the **olfactory tubercle,** and then

divides into three roots or **olfactory striæ**—a medial, an intermediate, and a lateral, which comprise the **olfactory trigone.** The striæ begin their respective courses upon the **anterior perforated substance,** an area which contains numerous small foramina through which the anterolateral group of central cerebral arteries enters the brain. This region forms the anterior boundary of that area of the base of the encephalon in which the substance of the brain becomes continuous across the midline.

At the posterior boundary of the anterior perforated substance the **optic nerves** come together and fuse to form the **optic chiasma.** Thence the **optic tracts** disappear under the poles of the temporal lobes in their backward course to the *thalami,* the geniculate bodies and superior quadrigeminate bodies.

Immediately behind the optic chiasma occurs that diverticulum from the floor of the third ventricle known as the **tuber cinereum.** It is connected by its tubular

FIG. 667.—VIEW OF THE BASE OF THE BRAIN. (Spalteholz's Atlas.)



stalk, the **infundibulum,** with the **hypophysis** or pituitary body, which occupies its special depression (sella turcica) in the floor of the cranium and is usually torn from the encephalon in the process of its removal. Behind the tuber cinereum are the two **mammillary bodies** (corpora albicantia), each of which is connected with the fornix, one of the larger association fasciculi of the cerebrum. The **peduncles of the cerebrum** (crura cerebri) are the two great funiculi which associate the cerebral hemispheres with all the structures below them. They diverge from the anterior border of the **pons** (Varoli) and, one for each hemisphere, disappear under the poles of the temporal lobes. The pons (brachium pontis or middle cerebellar peduncle) is chiefly a bridge of white substance or a commissure between the cerebellar hemispheres.

The **oculomotor** or third pair of cranial nerves make their exit from the posterior perforated substance in the interpeduncular fossa just behind the corpora mammillaria.

The **trochlear nerves** emerge around the lateral aspects of the cerebral peduncles along the anterior border of the pons. The trochlear is the smallest of the cranial nerves, and the only pair arising from the dorsal aspect of the brain.

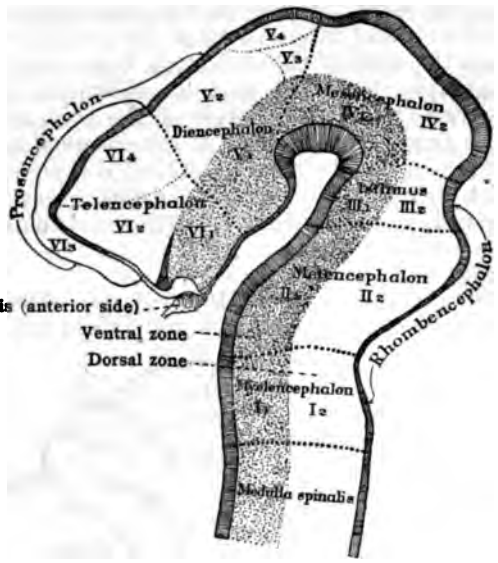
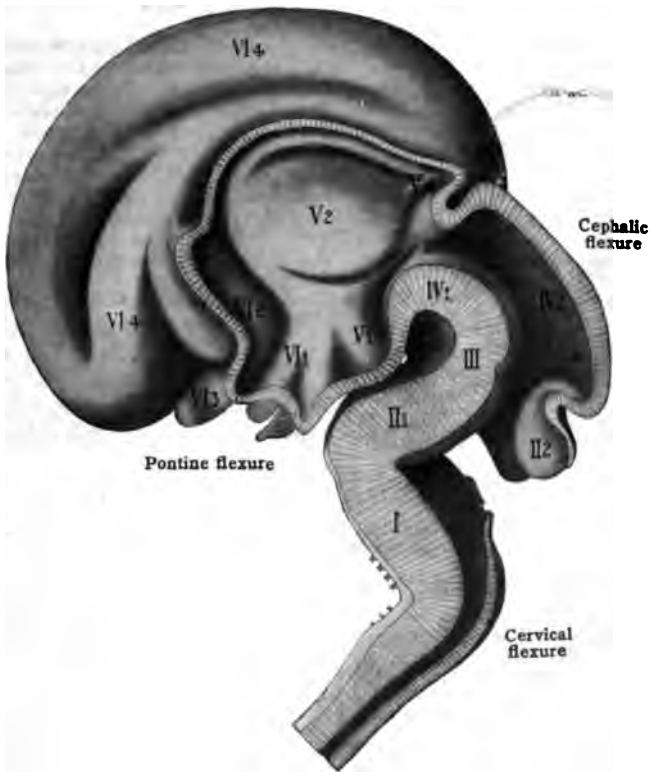
ring the localities of origin of the derivatives of the vesicles named in outline on p. 834.)



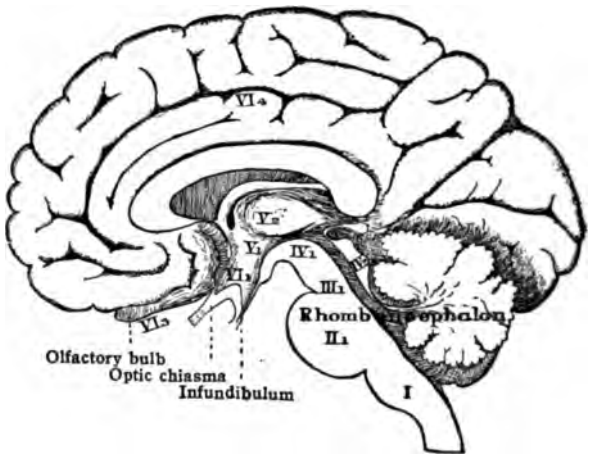
69.—SAGITTAL SECTION OF BRAIN OF HUMAN EMBRYO OF THE THIRD MONTH. (After His.)

rence numerals correspond with those of fig. 668 and those after names of parts in outline on p. 834.)



In its general conformation four natural divisions of the brain are apparent; the two most enlarged portions—(1) the cerebral hemispheres and (2) the cerebellum; (3) the midbrain (mesencephalon) between the cerebral hemispheres and the cerebellum, and (4) the medulla oblongata, the portion below the pons and above the spinal cord (fig. 645). However, the most logical and advantageous arrangement of the divisions and subdivisions of the encephalon is on the basis of their development from the walls of the embryonic brain vesicles. (See fig. 641.) On this basis, for example, both the medulla oblongata and the cerebellum with its pons are derived from the posterior of the primary vesicles, and are, therefore, included in a single gross division of the encephalon, viz., the *rhombencephalon*. In the outline on p. 834 the anatomical components of the encephalon are arranged with reference to the three primary vesicles from the walls of which they are derived, and the primary flexures and thickenings of the walls of which they are elaborations.

FIG. 670.—MEDIAN SAGITTAL SECTION OF ADULT HUMAN BRAIN. (Drawing of model by His.) (Reference numerals same as in figs. 668 and 669.)



During the early growth of the neural tube its basal or ventral portion and the lateral portions acquire a greater thickness than the roof of the tube, and thus the tube is longitudinally divided into a ventral zone and an alar or dorsal zone. This is especially marked in the brain. Thickenings arising from the dorsal zone begin as localized thickenings of the roof. For example, in the rhombencephalon the greater part of the medulla oblongata and of the pons region is derived from the ventral zone, while the cerebellum is derived from the superior part of the dorsal zone of the posterior vesicle. The first of the flexures occurs in the region of the future mesencephalon, and is known as the **cephalic flexure**; next occurs the **cervical flexure**, at the junction with the spinal cord; third, the **pontine flexure**, in the region of the future fourth ventricle. Both the cervical and pontine flexures, while having a significance in the growth processes, are almost entirely obliterated in the later growth of the encephalon.

The location of the development of the various parts of the encephalon may be determined, and their elaboration and changes in shape and position may be traced by comparing the accompanying figs. 668, 669, 670. The reference numbers in the last three figures correspond with the like numerals after the names of the parts on p. 834 in the outline of the divisions of the encephalon. The more detailed subdivisions of the parts will be met with in their individual descriptions.

THE RHOMBENCEPHALON

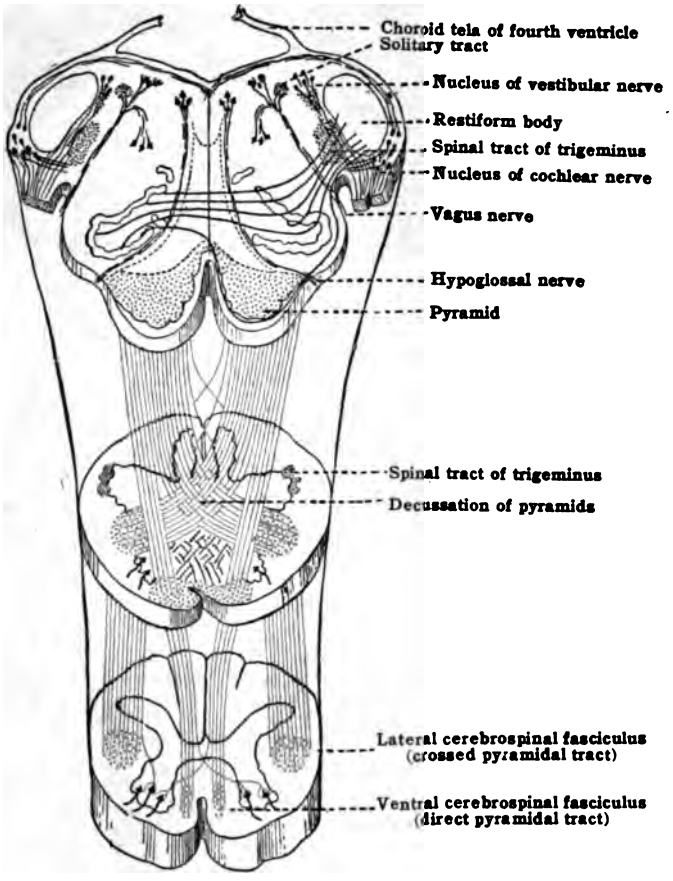
1. THE MEDULLA OBLONGATA

The **medulla oblongata** [myelencephalon] is the upward continuation of the spinal cord. It is only about 25 mm. long, extending from just above the first cervical nerve (beginning of the first cervical segment of the spinal cord) to the inferior border of the pons. It lies almost wholly within the cranial cavity, resting upon the superior surface of the basal portion of the occipital bone, with its lower extremity in the foramen magnum. Its weight is from 6 to 7 gm. or about one-half of 1 per cent. of the central nervous system. It is a continuation of the

[redacted]inal cord, and more. It contains structures continuous with and homologous [redacted]o the structures of the spinal cord, and in addition it contains structures which [redacted]ve no homologues in the spinal cord. Due in part to these additional struc[redacted]res, the medulla, as it approaches the pons, rapidly expands in its dorsoventral [redacted]nd especially in its lateral diameter. With it are associated nine of the pairs of [redacted]ranial nerves.

On its **ventral aspect** (figs. 667, 709) the anterior median fissure of the spinal [redacted]ord becomes broader and deeper because of the great height attained by the [redacted]yramids. At the level at which the pyramids emerge from the pons, the region in [redacted]which they are largest, the fissure terminates in a triangular recess so deep as to

FIG. 671.—DIAGRAM SHOWING THE DECUSSATION OF THE PYRAMIDS.
The uppermost level represented is near the inferior border of the pons.

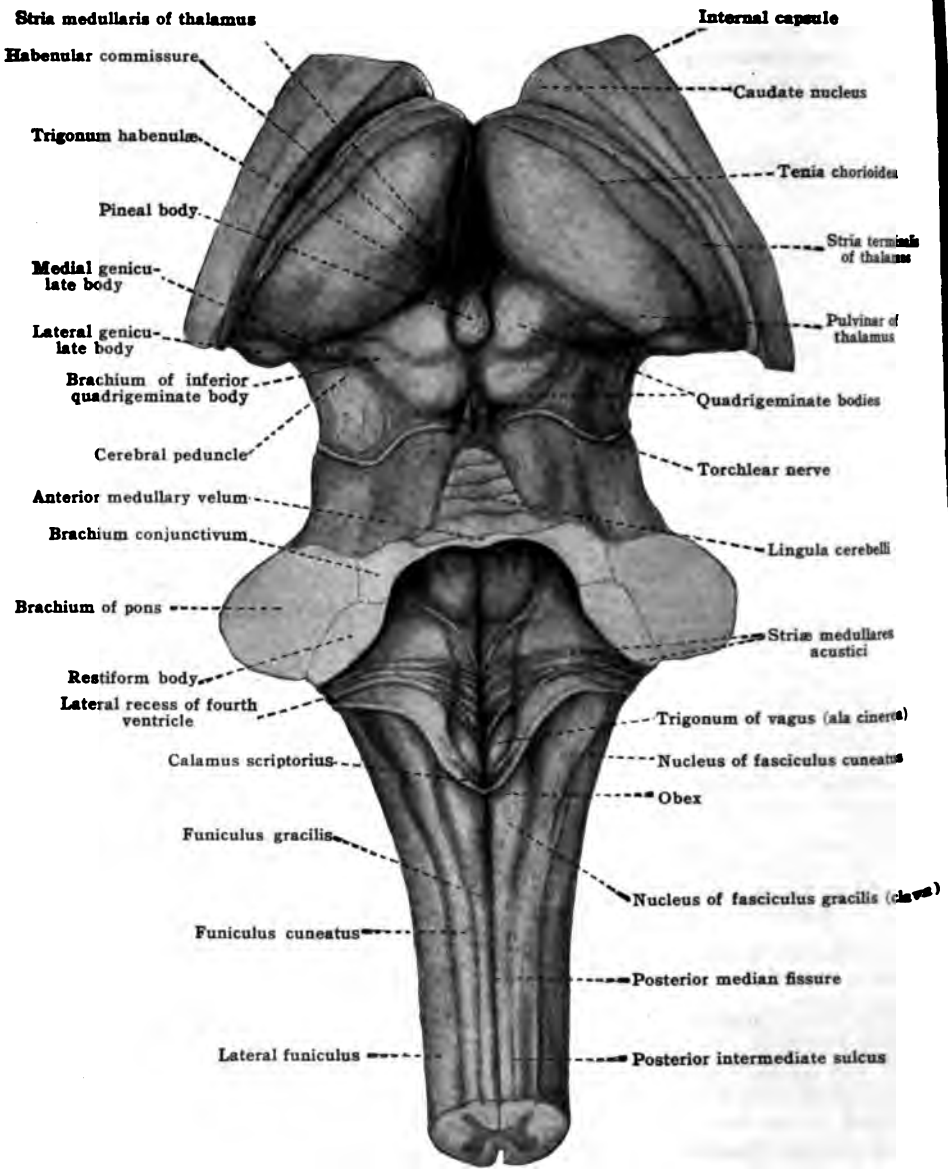


merit the name **foramen cecum.** The pyramids are the great descending cerebral or motor funiculi. In the medulla oblongata they decrease in bulk in passing toward the spinal cord, for the reason that many of the pyramidal axones are contributed to structures of the medulla, chiefly after crossing the midline. At the lower end of the medulla occurs the **decussation of the pyramids,** by which the anterior median fissure is almost obliterated for about 6 mm., and which, upon removal of the pia mater, may be easily observed as bundles of fibers interdigitating obliquely across the midline.

Not all the pyramidal fibers cross to the opposite side at this level in man, but a portion of those coursing in the lateral portion of the pyramid maintain their ventromedial position and continue directly into the spinal cord, to form there the ventral cerebrospinal fasciculus or direct pyramidal tract. However, most of such fibers finally cross the midline during their course in the cervical region of the spinal cord. The exact proportion of the direct fibers is variable, but always the greater mass of each pyramid crosses to the opposite side at the level of the decussation of the pyramids, and descends the cord as the lateral cerebrospinal fasciculus or crossed pyramidal tract. Both of these pyramidal tracts are described in the discussion of the fasciculi of the cord.

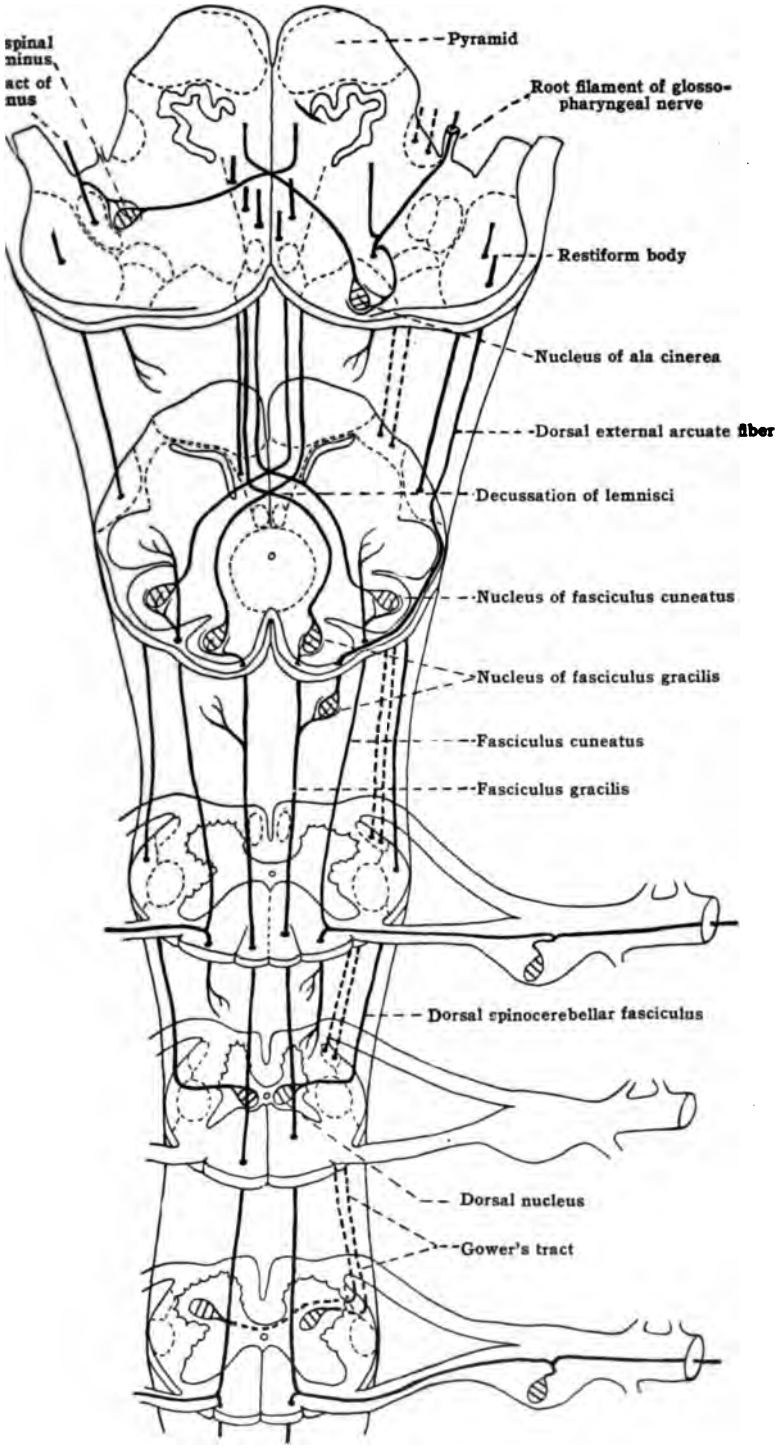
Each pyramid is bounded laterally by the **anterolateral sulcus,** also continuous with that of the same name in the spinal cord. Toward the pons this sulcus separates the pyramid from the **olive** [oliva] (inferior olivary nucleus), and in the region of the olive there emerge along this sulcus the root-filaments of the hypoglossal nerve. The olives, as their name implies, are oblong oval eminences about 1.2 cm. in length. They extend to the border of the pons, and are somewhat

FIG. 672.—DORSAL ASPECT OF MEDULLA OBLONGATA AND MESENCEPHALON, SHOWING THE FLOOR OF THE FOURTH VENTRICLE (RHOMBOID FOSSA). (Modified from Spalteholz.)



thicker at their upper ends. Their surfaces are usually smooth, **except at their** lower ends, where they frequently appear ribbed, owing to **bundles of the external arcuate fibers** passing across them to and from the *restiform* **body, which occupies** the extreme lateral portion of the medulla. Along the line **between the restiform** body and the olive are attached the root-filaments of the *vagus, glossopharyngeal,* and *spinal accessory nerves.* Both the *abducens* and the *facial* **nerve emerge along** the inferior border of the pons, the facial in line with **the glossopharyngeal, but** the abducens in line with the hypoglossus.

DIAGRAM OF THE SPINOCEREBELLAR FASCICULI AND THE ORIGIN AND DECUSSATION OF THE MEDIAL LEMNISCI.



Dorsal aspect.—The increased lateral diameter of the medulla oblongata is contributed to a great extent by the **restiform bodies.** These are the inferior cerebellar peduncles and contain the majority of the ascending fibers, which associate the cerebellum with the structures below it.

In toto, the restiform bodies are much larger than could be formed by the combined cerebellar fasciculi of the spinal cord, their great size being due to their receiving numerous axons coursing in both directions, which connect the cerebellum with structures contained in the medulla oblongata alone, so that in the medulla they increase as they approach the cerebellum. Their mesial borders form the lateral boundaries of the fourth ventricle. Their name (*restiform*, meaning rope-like) was suggested from the appearance frequently given them by the fibers of the cochlear nerve, which course around their lateral periphery to become the *striæ medullares* in the floor of the fourth ventricle.

Upon removal of the cerebellum it may be seen that below the *calamus scriptorius* (inferior terminus of the fourth ventricle) the structures manifest in the dorsal surface of the medulla are directly continuous with those of the spinal cord. The fasciculus gracilis (Goll's column) of the spinal cord acquires a greater height and volume and becomes the **funiculus gracilis** of the medulla, and because of this increased height the posterior median sulcus of the cord becomes deepened into the **posterior median fissure.** The posterior intermediate sulcus is also accentuated by the fasciculus cuneatus (Burdach's column) likewise now enlarged into the **funiculus cuneatus** of the medulla. The lateral funiculus of the medulla, of course, does not contain the lateral or crossed pyramidal tract present in the spinal cord.

At the border of the calamus scriptorius the funiculus gracilis terminates in a slight elevation, the **clava,** which is the superficial indication of the (terminal) **nucleus of the fasciculus gracilis.** Beginning somewhat more anteriorly, and having a somewhat greater length, is a similar enlargement of the funiculus cuneatus, the **tuberculum cuneatum** or **nucleus of the fasciculus cuneatus.**

These nuclei are the groups of nerve cell-bodies about which the ascending or sensory axones of the respective fasciculi terminate or where the sensory impulses are transferred to a second neurone in their course to the structures of the encephalon. These cell-bodies in their turn give off axones which immediately cross the midline and assume a more ventral position, contributing largely to the *lemniscus* or fillet of the opposite side. Thus such axones are the encephalic continuation of the central sensory ('proprioceptive')pathway conveying impulses from the periphery of one side of the body to the opposite side of the cerebrum. The crossing of these axones is known as the *decussation of the lemnisci.*

With the termination of the dorsal funiculi and the ventral course of the fibers of the lemnisci in their decussation, the central canal of the spinal cord loses its roof of nervous tissue in the medulla and comes to the surface as the fourth ventricle. The floor of the fourth ventricle, which corresponds to the floor of the central canal, is considerably widened into two **lateral recesses** opposite the junction of the inferior and middle cerebellar peduncles of either side, and, being pointed at both its superior and inferior extremities, it is rhomboidal in shape and thus is the **rhomboid fossa.** The pia mater of the spinal cord is maintained across the tip of the calamus scriptorius to form the **obex,** a small, semilunar lamina roofing over the immediate opening of the central canal. The obex carries a few medullated commissural fibers.

2. THE PONS

The **pons (Varoli)** is, for the most part, a great commissure or 'bridge' of white substance coursing across the ventral aspect of the brain-stem, and connecting the cerebellar hemisphere of one side with that of the other. In addition it contains considerable gray substance and fibers passing both to and from the structures of the brain-stem and the gray substance of the cerebellum, and fibers descending from the cerebral cortex. Each of its lateral halves forms the middle of the three cerebellar peduncles, the *brachium pontis* of either side.

In size it naturally varies directly with the development of the cerebellum, both in a given animal and relatively throughout the animal series. In man it attains its greatest relative size, and possesses a median or **basilar sulcus** in which lies the basilar artery. Its sagittal dimension varies from 25 to 30 mm., while its transverse dimension (parallel with the course of its fibers) is somewhat greater. It is a rounded white prominence interposed between the visible portion of the

cerebral peduncles (crura) above and the medulla oblongata below. Its *inferior margin* is rounded to form the **inferior pontine sulcus,** which, between the points of the emergence of the pyramids, is continuous with and transverse to the foramen cecum. Its *superior margin* is thicker and is rounded to form the **superior pontine sulcus,** which, between the cerebral peduncles, is continuous with and transverse to the interpeduncular fossa (figs. 667, 709). It is bilaterally symmetrical. The ventrolateral bulgings of its sides (and, therefore, the basilar sulcus) are produced by the passage through it of the fibers of the cerebral peduncles from above, to reappear as the pyramids below. Its ventral surface rests upon the basilar process of the occipital bone and the dorsum sellæ of the sphenoid, while its lateral surfaces are adjacent to the posterior parts of the petrous portions of the temporal bones.

The fibers of the thicker superior portion of the pons (*fasciculus superior pontis*) course obliquely downward to their entrance into the brachium of the pons and the cerebellar hemisphere; those of the lower and midportions (*fasciculus medius pontis*) course more transversely, naturally converging upon approaching the cerebellum. Certain fibers of the upper midportion course at first transversely and then turn abruptly downward across the fibers above them, to join the inferior portion of the brachium pontis. This bundle is termed the **oblique fasciculus** (fig. 709). The *trigeminus* or fifth cranial nerve penetrates the superior lateral portion of each brachium pontis near the point of the downward turn of the oblique fasciculus; its large afferent root and the masticator nerve (its small efferent root)accompany each other quite closely. On either side of the basal surface of the pons usually may be seen a small bundle of fibers which begins in the interpeduncular fossa, near or in the sulcus of the oculomotor nerve. It passes laterally along or under the superior border of the pons, loses some of its fibers in the lateral sulcus of the mesencephalon, then runs inferiorly between the superior cerebellar peduncle and the brachium of the pons to disappear in the junction of these. Being sometimes double, it is known as the **lateral filaments of the pons** (*fila lateralia pontis* or *tenia pontis*). The location of the cell-bodies giving origin to it is uncertain.

That portion of the rhombencephalon overlying the pons and forming the floor of the fourth ventricle is not really a part of the pons at all. It is merely a continuation of the brain-stem from the medulla below to the structures above. Therefore on the *dorsal surface* there is no line of demarcation between the pons and medulla below or between the pons and isthmus above. The fibers of the trigeminus and masticator nerve pass through the pontine fibers to and from their nuclei in the brain-stem.

3. THE CEREBELLUM

The **cerebellum** or *hindbrain* is the largest portion of the rhombencephalon. It lies in the posterior or cerebellar fossa of the cranium, and dorsal to the pons and medulla oblongata, overhanging the latter. It fits under the occipital lobes of the cerebral hemispheres, from which it is separated by a strong duplication of the inner layer of the dura mater, the *tentorium cerebelli.*

Its greatest diameter lies transversely, and its average weight, exclusive of the dura mater, is about 140 gm., or about 10 per cent. of the entire encephalon. It varies in development with the cerebrum, and, like it, averages larger in the male. It is relatively larger in adults than in children. Its development begins as a thickening of the anterolateral portion of the roof (dorsal zone) of the posterior of the three primary brain-vesicles. Resting upon the brain-stem, it roofs over the fourth ventricle and is connected with the structures anterior, below, and posterior to it by its three pairs of peduncles.

The surface of the cerebellum is thrown into numerous narrow folia or **gyri,** which in the given localities run more or less parallel with each other. They are separated by narrow but relatively deep **sulci.** Unlike the spinal cord and medulla, in which the gray substance is centrally placed and surrounded by a mantle of white substance, the surface of the cerebellum is itself a cortex of gray substance [substantia corticalis], enclosing a core of white substance, the *medullary body* [corpus medullare]. However, within this central core of white substance are situated definite gray masses, the *nuclei* of the cerebellum.

The **gross divisions** of the cerebellum are three: the two larger lateral portions, the **hemispheres,** and between these the smaller central portion, the **vermis.** The demarcation between these gross divisions is not very evident from the dorsal surface, because the hemispheres in their extraordinary development in man encroach upon the vermis, and, being pressed under the overlapping occipital ends of the cerebral hemispheres, they become partially fused upon the vermis along the dorsal midline.

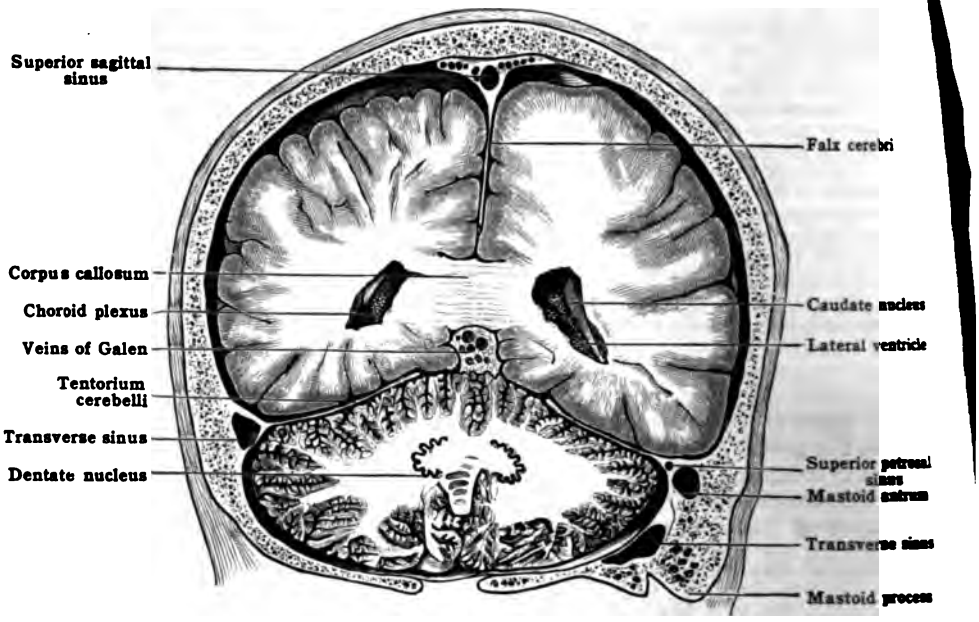
Though differentiated simultaneously with the cerebellar hemispheres in the human fetus, in most of the mammalia the vermis is the largest and most evident of the parts, and it is practically the only part which exists in the fishes, reptiles, and birds. In man, owing to the fact

that the vermis does not keep pace in development with the hemispheres, there results a very decided notch between the two hemispheres along the line of the entire ventral and inferior aspect of the cerebellum, the floor of this notch being the surface of the vermis.

The inferior portion of the notch between the hemispheres is the **posterior cerebellar notch** (incisura marsupialis); its prolongation above is wider than below, and is termed the **superior cerebellar notch.** It is occupied by a fold of the dura mater, the falx cerebelli. With the variations in contour of the cerebellum, certain of its sulci are broader and deeper, and merit the name **fissures.** These are more or less definitely placed, and subdivide the hemispheres into **lobes** and the vermis (the median lobe) into **lobules.**

Superior surface.—The superior surface is bounded from the inferior surface by the **horizontal fissure** (fig. 676) which extends anterolaterally, to the entrance of the brachium of the pons. Between this and the extreme anterior border of

FIG. 674.—SECTION OF HEAD PASSING THROUGH THE MASTOID PROCESSES AND BEHIND THE MEDULLA OBLONGATA, SHOWING THE POSITION OF THE CEREBELLUM.
(From a mounted specimen in the Anatomical Department of Trinity College, Dublin.)



the dorsal surface are two other fissures, the **posterior** and **anterior semilunar fissures.** These, like the horizontal fissure, may be traced, with slight interruptions, across the midline, and consequently mark off not only the two hemispheres but also the vermis into corresponding divisions.

The **superior semilunar lobe** [lobulus semilunaris superior] (posterosuperior lobe) of each hemisphere lies between the horizontal and the posterior semilunar fissures. It largely composes the outer border of the cerebellum, and, therefore, is the longest of the lobes.

The adjacent surface of the hemispheres anterior to the superior semilunar lobe, because of the frequently less complete development of the anterior semilunar fissure, is sometimes referred to as the **quadrangular lobe, with its** *posterior* and its *anterior portions.* On the other hand, especially when the anterior semilunar fissure is well marked, this area may be divided into—(1) the *posterior semilunar lobule*, between the posterior and anterior semilunar fissures, and (2) the *anterior semilunar lobule*, anterior to the anterior semilunar fissure (fig. 676).

Anterior to the quadrangular lobe on each hemisphere is the **ala of the central lobule** bounded by the postcentral and the precentral sulci. Anterior to this, on the anterior margin of the hemisphere, is the **vinculum lingulæ,** a slender process continuous with the lingula of the cerebellum (fig. 700).

The superior aspect of the vermis, the **superior vermis,** because of the fusion of the hemispheres, is, for the most part, a slight ridge, the **monticulus** (fig. 676).

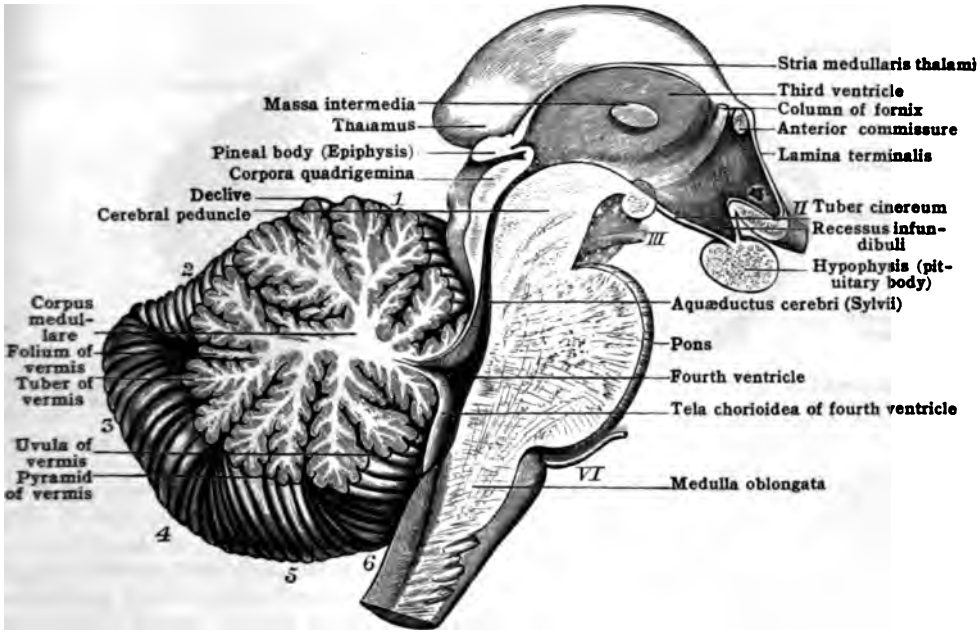
[illegible]ead of a depression. However, in the posterior portion of the superior sur[illegible]e the depression of the posterior notch begins, and here the horizontal and the [illegible]sterior semilunar fissures approach each other so closely that the correspond[illegible] subdivision of the vermis is seldom more than a single folium, the **folium ver[illegible]** (*cacuminis*).

The monticulus proper is divided into an inferior lobule, the **declive,** and a [illegible]perior lobule, the **culmen.** These appear as continuations across the midline [illegible] the posterior and anterior semilunar lobes of the hemispheres, and are sepa[illegible]ted by the corresponding fissures (fig. 676).

At the extreme anterior part of the superior surface and in the bottom of the [illegible]nterior cerebellar notch lies a more definitely defined portion of the vermis. This is the **central lobule** (fig. 676). It is broadened laterally into two pointed wings, the *alæ* of the central lobule, the folia of which, if present, are parallel with those of the anterior semilunar lobes and separated from them by the **post-central sulcus.**

FIG. 675.—MEDIAN SECTION THROUGH CEREBELLUM AND BRAIN-STEM. (Allen Thompson, after Reichert.)

1. Culmen monticuli; 2, superior semilunar lobe; 3, inferior semilunar lobe; 4, slender lobe; 5, biventral lobe; 6, tonsil.



If the anterior margin of the central lobule be lifted, the **lingula cerebell** (*lingula vermis*) will appear separated from the central lobule by the **precentra sulcus.** It is a thin, tongue-like anterior projection of the cortical substance comprising four to eight folia adhering upon the *anterior medullary velum,* the roof of the superior portion of tne fourth ventricle (figs. 675, 700).

Inferior surface.—The three cerebellar peduncles of each side join to form a single mass of white substance, and enter the ventral aspect of each hemisphere medially and ventrally in the extremity of the horizontal fissure. The inferior surface of the cerebellum is less convex than the superior surface. The hemispheres are decidedly separated by a continuation of the posterior cerebellar notch, which becomes broader, the **vallecula of the cerebellum,** which contains the inferior portion of the vermis, **vermis inferior,** and whose margins embrace the medulla oblongata. The inferior surfaces of the hemispheres are each divided by the intervening fissures into four lobes (fig. 677).

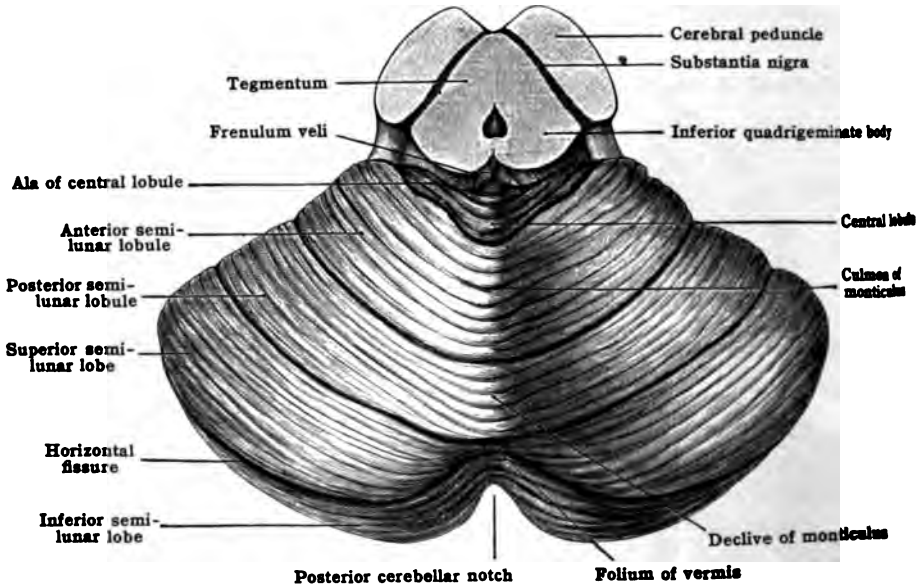
Below, the **inferior semilunar lobe** (posteroinferior lobe) is separated from the superior semilunar lobe of the superior surface by the horizontal fissure. It is the largest of the inferior lobes, and is broader at its medial extremity. Frequently

two and sometimes three of its curved sulci appear deeper than others, and separate it into two or three **slender lobules** [lobuli graciles]. More commonly there are two of these, the *lobulus gracilis posterior* and *lobulus gracilis anterior*, separated by the *posteroinferior sulcus*.

The **biventral lobe** is smaller and more curved than the inferior semilunar lobe, from the anterior margin of which it is separated by the curved **anteroinferior sulcus.** Its medial extremity is pointed and does not extend to the vermis; its lateral extremity is broader and curves anteriorly to the extremity of the horizontal fissure—the line of outer termination of the inferior semilunar lobe.

The **tonsil** [tonsilla cerebelli] (*amygdala*) is a rounded, triangular mass, placed medially within the inner curvature of the biventral lobe, and separated from it by the **retrotonsillar fissure.** Its inferior medial border slightly overlaps the vermis.

FIG. 676.—DIAGRAM OF THE SUPERIOR SURFACE OF THE CEREBELLUM. (The anterior and posterior semilunar lobes form the quadrangular lobe.)



The smallest of the lobes is the **flocculus.** It lies adjacent to the inferior and lateral surface of the mass of white substance produced by the confluence of the three cerebellar peduncles, and extends into the medial extremity of the horizontal fissure. It is so flattened that its short folia give it the appearance suggesting its name. Occasionally there is added a second, less perfectly formed portion, the *secondary flocculus*. From each floccular lobe there passes toward the midline a thin band of white substance, the **peduncle of the flocculus.** From the flocculi of the two sides the peduncles extend to meet each other at the most anterior portion of the inferior vermis, and thus form the narrow **posterior medullary velum.**

The **inferior vermis** (figs. 675, 677) is more definitely demarcated than the superior. Lying in the floor of the vallecula cerebelli, it is separated on each side from the adjacent lobes of the hemispheres by a well-marked sulcus about it, the *nidus avis*. By contour and by deeper transverse fissures (sulci) occurring at intervals across it, four divisions or lobules of the inferior vermis are recognized. These lobules, like those of the superior vermis, are each in intimate relation with the pair of lobes of the hemispheres adjacent to it on either side.

1. The **tuber vermis** is adjacent to the folium vermis of the superior aspect. It is a short, somewhat pyramidal-shaped division, whose four or five transversely arranged folia are continuous with the folia of the inferior semilunar lobes on either side.

2. The **pyramid** is separated from the tuber vermis by the *postpyramidal sulcus*. Its several folia cross the vallecula cerebelli and curve to connect with the biventral lobes on either side.

3. The **uvula** is separated from the pyramid by the *prepyramidal sulcus.* It is triangular in shape. Its base or broader superior portion appears as two laterally projecting ridges of gray substance, the **furrowed bands** or *alæ uvulæ*, which extend across the floor of the nidus avis and under the medial margins of the tonsils on either side. In these bands its folia curve and become continuous with the tonsils. The uvula and the two tonsils are sometimes referred to collectively as the *uvular lobe.*

4. The **nodule** is the smallest and most anterior division of the inferior vermis. It is separated from the uvula by the **postnodular sulcus,** and is closely associated anteriorly with the posterior medullary velum, the transverse continuation of the peduncles of the floccular lobes.

Internal structure of the cerebellum (figs. 675, 678).—The white substance of the cerebellum is continuous with its peduncles and forms a compact central mass [corpus medullare]. Over the surface of this the gray substance or cortex is spread in a thin but uniform and much folded layer. Upon section of the cerebellum certain of the sulci as well as the fissures are shown to be much deeper than is apparent from the surface. The deeper sulci separate the lobes into divisions, the **medullary laminæ,** each of which is composed of a number of folia and each of which has its own core of white substance. The folia of the laminæ line the sulci (and fissures), and also comprise their surface aspect, and are separated by the shallow, *secondary sulci.* The larger laminæ are subdivided into from two to four secondary laminæ of varying size. Such subdivision is especially marked in the vermis. Here each lamina comprises a lobule and is, therefore, separated by a fissure, and each lobule is usually subdivided with the exception of the nodule, the folium, and the lingula. In sagittal sections, or sections transverse to the general direction of the sulci, this arrangement of the laminæ gives a foliate appearance, which, especially in sagittal sections of the vermis, is termed **the arbor vitæ** (fig. 675).

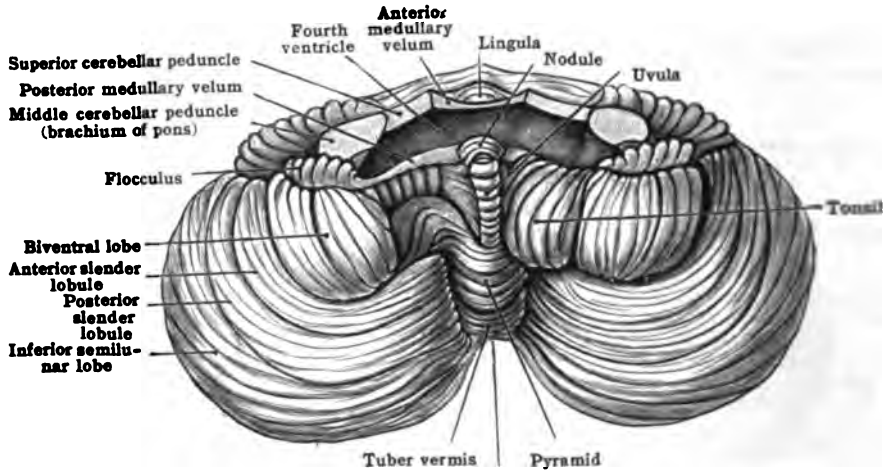
The cerebellar cortex consists of three layers and contains four general types of cell-bodies of neurones, all of which possess features peculiar to the cerebellum.

The outermost or **molecular layer** contains small **stellate cells,** 'basket cells,' with relatively long dendrites. These serve to associate the different portions of a given folium. The axones of the largest of them give off branches which form pericellular baskets about the bodies of the *cells of Purkinje,* each axone contributing to several baskets. The **layer of Purkinje cells,** or the middle layer, is quite thin. The bodies of the cells of Purkinje are arranged in a single layer, and their elaborate systems of dendrites extend throughout and largely compose the molecular layer. The dendrites of these, the most essential cells of the cortex, are displayed in the form of arborescent fans (see fig. 647), arranged parallel with each other and transverse to the long axis of the folium containing them. Their axones are given off from the base of the cell-body and acquire their medullary sheaths quite close to the cell-body, and, after giving off several collaterals in the inner layer, pass into the general white substance and thence to other

laminæ or lobes. Certain of them go to structures outside the cerebellum. The inner layer is the **granular layer.** It contains numerous small nerve-cells or 'granule-cells' which possess from two to five radiating dendrites, unbranched except at their termination, which occur suddenly in the form of three to six claw-like twigs. Their axones are given off either from the cell-body direct or more often from the base of one of the dendrites, and pass outward into the molecular layer, where they bifurcate and course in both directions parallel to the long axis of the folium, to become associated with the dendrites of the cells of Purkinje. In the layer of the cells of Purkinje there is situated at intervals a neurone of the Golgi type II (see fig. 647). The short, elaborately branched axone of this neurone is distributed among the cells of the granular layer. Axones conveying impulses to the cerebellar cortex terminate upon the granule cells in the granular layer as *'moss fibers,'* or directly upon the cells of Purkinje as *'climbing fibers,'* and probably upon the 'basket' cells and the cells of the Golgi type II.

FIG. 677.—DIAGRAM OF THE INFERIOR SURFACE OF THE CEREBELLUM AFTER THE REMOVAL OF THE MEDULLA OBLONGATA, PONS, AND MESENCEPHALON.

The tonsil of the right side is omitted in order to display the connection of the pyramid with the biventral lobe, the furrowed band of the uvula, and more fully the posterior medullary velum. The anterior notch is less evident than in the actual specimen.



Thus the neurones which receive impulses coming to the cortex are the cells of Purkinje, probably the Golgi cells of type II, the basket-cells and the granule-cells; those which distribute these impulses to other neurones of the folium are the Golgi cells of type II, the granule-cells, and the basket-cells (association neurones), and the collaterals of the cells of Purkinje. Impulses are conveyed from the cortex of a folium to that of other folia, lamina, lobules or lobes, or to the nuclei of the cerebellum, or to structures outside the cerebellum by the axones of the cells of Purkinje.

The **nuclei of the cerebellum** (figs. 678, 692) are in its central core [*corpus medullare*] of white substance. They are four in number, and all are paired, those of each pair being situated opposite each other on either side of the midline. They include (1) the dentate nucleus, (2) nucleus emboliformis, (3) nucleus globosus, and (4) roof-nucleus.

1. The largest of the cerebellar nuclei is the **dentate nucleus.** This is an isolated mass of gray substance situated in the core of white substance of each hemisphere. It is in the form of a folded or corrugated cup-shaped lamina, with the opening of the cup (*hilus*) directed anteriorly and obliquely toward the mid-line. It contains a mass of white substance and possesses a capsule. Its cell-bodies give rise to most of the fibers forming the superior cerebellar peduncles. It receives its impulses from axones of Purkinje cells and some direct from the axones of the spinocerebellar fasciculi.

2. The **nucleus emboliformis** is an oblong and much smaller mass of gray substance, which lies immediately medial to the hilus of the dentate nucleus. It is probably of the same significance as the dentate nucleus, being merely a portion separated from it.

3. The **nucleus globosus,** the smallest of the cerebellar nuclei, is an irregular horizontal mass of gray substance with its larger end placed in front. It lies close to the medial side of the nucleus emboliformis, and often appears separated into two or more rounded or globular masses.

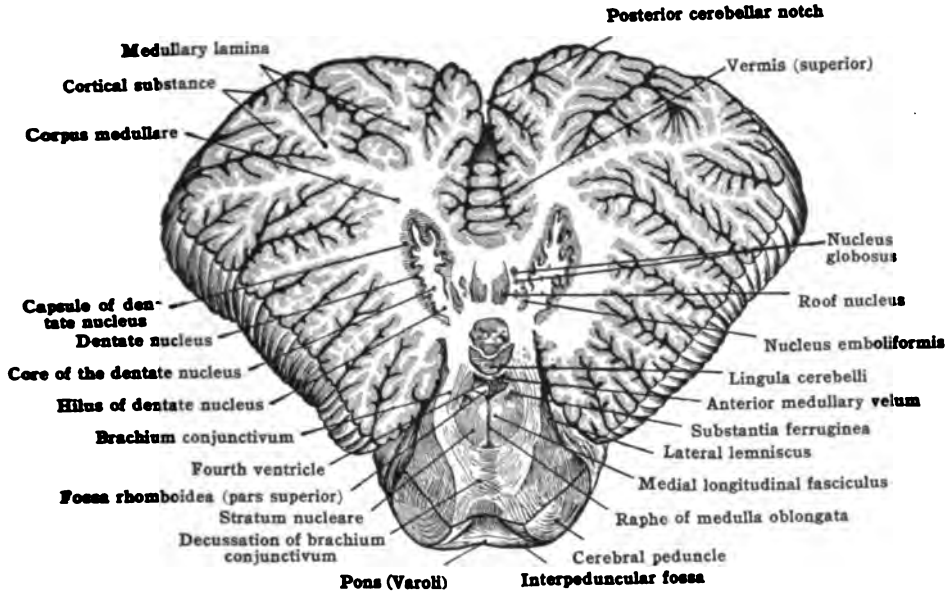
4. The **roof-nucleus** [nucleus fastigii] is the second largest of the cerebellar nuclei, and is the most mesially placed. The pair is situated in the roof of the fourth ventricle, and so near the midline that both nuclei are in the white substance of the vermis. They are ovoid in shape, and the nucleus of one side receives axones from the nucleus of the vestibular nerve chiefly of the opposite side, the decussation of these axones taking place in the vermis. Its cells are larger than those of the two first-mentioned nuclei.

The peduncles of the cerebellum.—The peduncles consist of three pairs—the **inferior**, middle, and superior. The three peduncles of each side come together at **the level** of the lower border of the pons, and the entering and emerging fibers of **which** they are composed become continuous with the central core of white substance of the cerebellar hemispheres (figs. 672, 678, 679, 680.)

The restiform body (fig. 680) of the medulla oblongata is the inferior peduncle. **It forms** the lateral boundary of the inferior portion of the fourth ventricle, and **upon reaching** the level of the pons turns sharply backward into the cerebellum. **In the** region of the turn it is encircled externally by fibers of the cochlear nerve. **It contains** fibers, both ascending and descending, between the cerebellar cortex **and the** structures below the cerebellum.

Its fibers include: (1) fibers from the spinal cord including the dorsal spinocerebellar fasciculus (direct cerebellar tract) and probably a small proportion of the ascending fibers of the superficial ventrolateral spinocerebellar fasciculus (Gowers' tract); (2) fibers from the olive of the same but chiefly from that of the opposite side of the medulla oblongata; (3) fibers

FIG. 678.—SECTION OF CEREBELLUM AND BRAIN-STEM PASSING OBLIQUELY THROUGH INFERIOR PORTION OF CEREBELLUM TO SUPERIOR MARGIN OF PONS. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York).



from the nuclei of the funiculus gracilis and cuneatus of the same and opposite sides (dorsal and ventral external arcuate fibers); (4) fibers to the olive of the opposite side; (5) fibers to the nuclei of the motor cranial nerves; (6) fibers descending to the ventral horn cells of the spinal cord. The ascending or afferent fibers of the spinocerebellar and cerebello-olivary fasciculi are the principal components of the inferior peduncle; the existence of fibers (5) and (6) is not well established. The fibers of the direct cerebellar tract terminate in the cortex of the superior vermis of both sides of the midline, but, for the most part, in that of the same side. The olivary fibers end in the cortex of both the superior vermis and the adjacent cortex of the hemispheres, and some of them terminate in the nucleus dentatus.

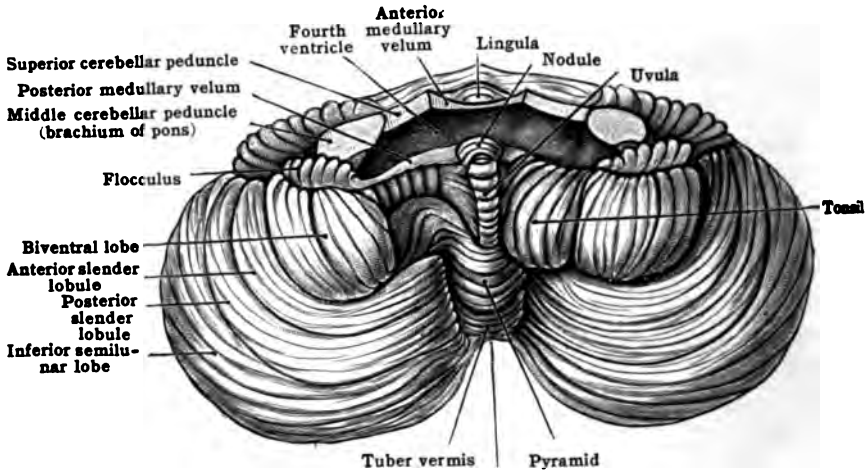
The brachium pontis or the middle peduncle (figs. 680, 698) is the largest of the three cerebellar peduncles. In it the pons fibers pass into the cerebellar hemisphere, between the lips of the anterior part of the horizontal fissure, entering lateral to the inferior peduncle.

It consists of the transverse fibers of the pons, and within the cerebellum its fibers are distributed in two main groups—the upper transverse fibers of the pons apparently pass downward to radiate in the lower portion of the hemisphere, while the lower transverse fibers pass upward and medialward to radiate in the superior part of the hemisphere and vermis. For the most part the fibers of the middle peduncle may be considered as commissural fibers, passing from one side of the cerebellum to the other. Each peduncle contains fibers coursing in opposite directions. Many of these fibers are interrupted in their course to the opposite side by cells scattered throughout the pons, *nuclei pontis*, and, therefore, in each brachium pontis some of the fibers are processes of the cells of the cerebellum and course toward the opposite side, while others are processes of the cells of the pontine nuclei, which receive impulses from cerebel-

laminæ or lobes. Certain of them go to structures outside the cerebellum. The inner la is the **granular layer.** It contains numerous small nerve-cells or 'granule-cells' which p sess from two to five radiating dendrites, unbranched except at their termination, which cou suddenly in the form of three to six claw-like twigs. Their axones are given off either from cell-body direct or more often from the base of one of the dendrites, and pass outward i the molecular layer, where they bifurcate and course in both directions parallel to the long a of the folium, to become associated with the dendrites of the cells of Purkinje. In the la of the cells of Purkinje there is situated at intervals a neurone of the Golgi type II (see 647). The short, elaborately branched axone of this neurone is distributed among the c of the granular layer. Axones conveying impulses to the cerebellar cortex terminate upon granule cells in the granular layer as *'moss fibers,'* or directly upon the cells of Purkinje *'climbing fibers,'* and probably upon the 'basket' cells and the cells of the Golgi type II.

FIG. 677.—DIAGRAM OF THE INFERIOR SURFACE OF THE CEREBELLUM AFTER THE REMO OF THE MEDULLA OBLONGATA, PONS, AND MESENCEPHALON.

The tonsil of the right side is omitted in order to display the connection of the pyra with the biventral lobe, the furrowed band of the uvula, and more fully the posterior medull velum. The anterior notch is less evident than in the actual specimen.



Thus the neurones which receive impulses coming to the cortex are the cells of Pu probably the Golgi cells of type II, the basket-cells and the granule-cells; those which dist these impulses to other neurones of the folium are the Golgi cells of type II, the granule-cel the basket-cells (association neurones), and the collaterals of the cells of Purkinje. In are conveyed from the cortex of a folium to that of other folia, lamina, lobules or lobe the nuclei of the cerebellum, or to structures outside the cerebellum by the axones of t of Purkinje.

The **nuclei of the cerebellum** (figs. 678, 692) are in its central core [c medullare] of white substance. They are four in number, and all are p those of each pair being situated opposite each other on either side of the m They include (1) the dentate nucleus, (2) nucleus emboliformis, (3) n globosus, and (4) roof-nucleus.

1. The largest of the cerebellar nuclei is the **dentate nucleus.** This is an isolate of gray substance situated in the core of white substance of each hemisphere. It is in t of a folded or corrugated cup-shaped lamina, with the opening of the cup (*hilus*) c anteriorly and obliquely toward the mid-line. It contains a mass of white substa possesses a capsule. Its cell-bodies give rise to most of the fibers forming the superior ce peduncles. It receives its impulses from axones of Purkinje cells and some direct f axones of the spinocerebellar fasciculi.

2. The **nucleus emboliformis** is an oblong and much smaller mass of gray substance lies immediately medial to the hilus of the dentate nucleus. It is probably of the sa nificance as the dentate nucleus, being merely a portion separated from it.

3. The **nucleus globosus,** the smallest of the cerebellar nuclei, is an irregular ho mass of gray substance with its larger end placed in front. It lies close to the medial sid nucleus emboliformis, and often appears separated into two or more rounded or masses.

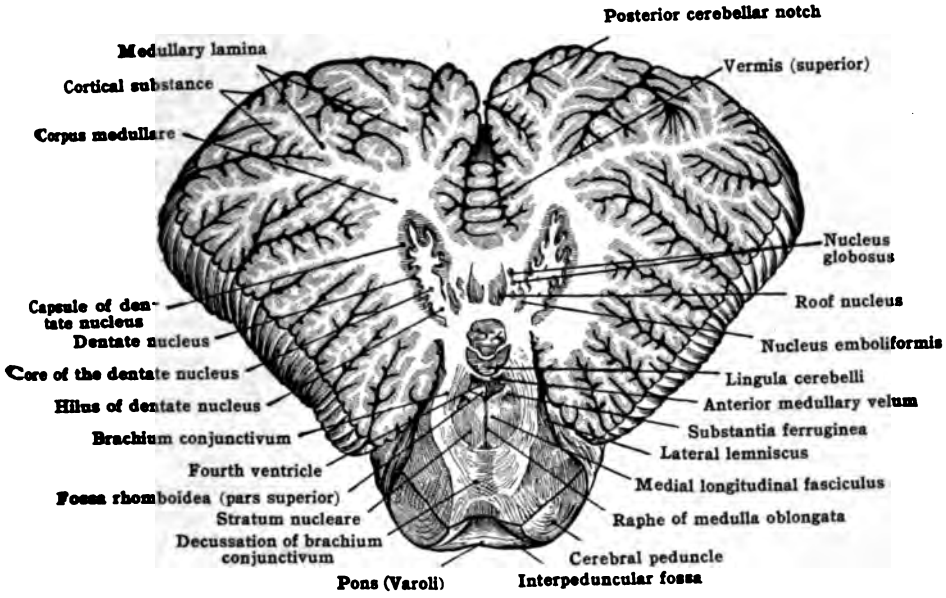
4. The **roof-nucleus** [nucleus fastigii] is the second largest of the cerebellar nuclei, an most mesially placed. The pair is situated in the roof of the fourth ventricle, and so n midline that both nuclei are in the white substance of the vermis. They are ovoid in and the nucleus of one side receives axones from the nucleus of the vestibular nerve cl the opposite side, the decussation of these axones taking place in the vermis. Its c larger than those of the two first-mentioned nuclei.

The peduncles of the cerebellum.—The peduncles consist of three pairs—the inferior, middle, and superior. The three peduncles of each side come together at the level of the lower border of the pons, and the entering and emerging fibers of which they are composed become continuous with the central core of white substance of the cerebellar hemispheres (figs. 672, 678, 679, 680.)

The restiform body (fig. 680) of the medulla oblongata is the inferior peduncle. It forms the lateral boundary of the inferior portion of the fourth ventricle, and upon reaching the level of the pons turns sharply backward into the cerebellum. In the region of the turn it is encircled externally by fibers of the cochlear nerve. It contains fibers, both ascending and descending, between the cerebellar cortex and the structures below the cerebellum.

Its fibers include: (1) fibers from the spinal cord including the dorsal spinocerebellar fasciculus (direct cerebellar tract) and probably a small proportion of the ascending fibers of the superficial ventrolateral spinocerebellar fasciculus (Gowers' tract); (2) fibers from the olive of the same but chiefly from that of the opposite side of the medulla oblongata; (3) fibers

FIG. 678.—SECTION OF CEREBELLUM AND BRAIN-STEM PASSING OBLIQUELY THROUGH INFERIOR PORTION OF CEREBELLUM TO SUPERIOR MARGIN OF PONS. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York).



from the nuclei of the funiculus gracilis and cuneatus of the same and opposite sides (dorsal and ventral external arcuate fibers); (4) fibers to the olive of the opposite side; (5) fibers to the nuclei of the motor cranial nerves; (6) fibers descending to the ventral horn cells of the spinal cord. The ascending or afferent fibers of the spinocerebellar and cerebello-olivary fasciculi are the principal components of the inferior peduncle; the existence of fibers (5) and (6) is not well established. The fibers of the direct cerebellar tract terminate in the cortex of the superior vermis of both sides of the midline, but, for the most part, in that of the same side. The olivary fibers end in the cortex of both the superior vermis and the adjacent cortex of the hemispheres, and some of them terminate in the nucleus dentatus.

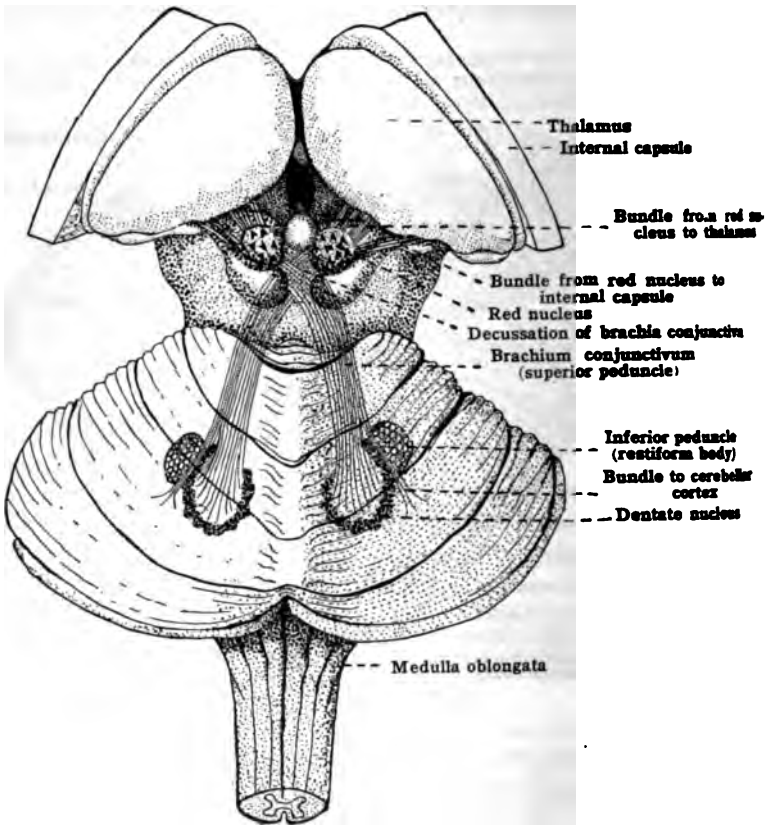
The brachium pontis or the middle peduncle (figs. 680, 698) is the largest of the three cerebellar peduncles. In it the pons fibers pass into the cerebellar hemisphere, between the lips of the anterior part of the horizontal fissure, entering lateral to the inferior peduncle.

It consists of the transverse fibers of the pons, and within the cerebellum its fibers are distributed in two main groups—the upper transverse fibers of the pons apparently pass downward to radiate in the lower portion of the hemisphere, while the lower transverse fibers pass upward and medialward to radiate in the superior part of the hemisphere and vermis. For the most part the fibers of the middle peduncle may be considered as commissural fibers, passing from one side of the cerebellum to the other. Each peduncle contains fibers coursing in opposite directions. Many of these fibers are interrupted in their course to the opposite side by cells scattered throughout the pons, *nuclei pontis*, and, therefore, in each brachium pontis some of the fibers are processes of the cells of the cerebellum and course toward the opposite side, while others are processes of the cells of the pontine nuclei, which receive impulses from cerebel-

lar axones, and course to the cerebellar hemisphere chiefly of the same side. Many cell-bo of the nuclei of the pons whose axones terminate in the cerebellum receive impulses from fib descending from the *cerebral* cortex of the opposite side—*corticopontine fibers*. Further there are evidences after degeneration that the brachium pontis also contains a few fibers to from the cerebellum and the structures of the brain-stem and spinal cord.

The **brachium conjunctivum** or superior peduncle (figs. 679, 680) emerges fr the cerebellum on the medial side of the brachium pontis and also on the superi and medial side of the course of the restiform body. It forms the lateral bounda of the superior portion of the fourth ventricle and is the cerebello-cerebral pe uncle. Its transverse section appears semilunar in shape, with the concave sid next to the cavity of the ventricle. The medial border, which inclines toward th

FIG. 679.—TRANSPARENCY DRAWING SHOWING THE ORIGIN, COURSE, AND CONNECTIONS OF TH SUPERIOR CEREBELLAR PEDUNCLES (BRACHIA CONJUNCTIVA) IN THE FORMATION OF 'STILLING'S SCISSORS.'



midline, is connected with that of the corresponding peduncle of the opposite si by the *anterior medullary velum*, which thus roofs over the superior part of t fourth ventricle. The lateral border is distinguished from the pons by an op furrow or lateral sulcus.

The superior cerebellar peduncles are almost entirely efferent pathways as to the cerebell and form the chief connections between the cerebellum and the cerebrum. They arise alm wholly from the dentate nuclei. As they course forward they slightly converge and disap under the inferior quadrigeminate bodies. Here, in the tegmentum of the mesencepha they undergo an almost total decussation, and then the majority of the fibers of each pedu having thus crossed the midline, terminate in the *red nucleus* of the opposite side. The nucleus lies in the tegmentum of the mesencephalon, below the superior quadrigeminate bo and therefore quite close to the decussation. The cells of the red nucleus, about which fibers of the peduncle terminate, in their turn send processes (axones) into (1) the rubros tract of the spinal cord and (2) into the prosencephalon, most of which latter terminate in thalamus whose cell-bodies give fibers to the cerebral cortex by way of the internal cap but some pass from the red nucleus under the thalamus to join the internal capsule.

In addition to the fibers having the origin and course described above, and which consti the greater mass of the superior cerebellar peduncle, each peduncle is said to contain fi which—(1) arise in the cerebellar cortex of the same and opposite sides of the midline, ma

om the dentate nucleus, and which join the peduncle at the side of the dentate nucleus, een it and the restiform body; (2) fibers which do not cross the midline in the decussation, erminate in the red nucleus of the same side; (3) some fibers are not interrupted in the red us, but pass directly into the thalamus; (4) a small proportion of fibers afferent as to the ellum, which arise in the structures of the cerebrum and pass into the cerebellum; and he greater part, if not all, of the ascending fibers of the superficial ventrolateral spino-ellar fasciculus (Gowers' tract) of the spinal cord. The latter, instead of entering the ellum by way of the restiform body, are deflected in the upper medulla and pass in the al tegmentum of the pons to the anterior medullary velum, where they turn backward to the cerebellum in its superior peduncle and pass to its cortex, probably from the lateral of the dentate nucleus (see fig. 697).

The anatomy of the fourth ventricle.—The fourth ventricle (figs. 672, 675, 681) is rhomboidal in shape, being considerably widened at the level of the hia pontis and pointed at each end. Its floor consists of a slight depression ne brain-stem, the *fossa rhomboidea*, and corresponds to the floor of the central al. Its pointed inferior end, the **calamus scriptorius**, is directly continuous i the central canal, and its narrowed superior end is continued into the aeductus cerebri (Sylvii) of the mesencephalon, which is nothing more than sumption of the tubular form of the canal.

The entire cavity of the ventricle is lined with an epithelium which is continuous with the nelioid ependyma of the central canal below and the aqueduct above. The entire ricle involves the *isthmus of the rhombencephalon*, the *metencephalon* and a portion of the *ulla oblongata*. It is divided for study into an inferior, an intermediate and a superior

The *roof of the superior portion* of the fourth ventricle is nervous, consisting of a lamina of white substance, the *anterior* (superior) *medullary velum*, thickened he sides by the brachia conjunctiva. At its extreme mesencephalic end (in the mus of the rhombencephalon) the anterior medullary velum is slightly thick-l by a continuation of the white substance of the inferior quadrigeminate ies, forming the **frenulum veli**. The inferior portion of the velum is continu-with the white substance of the cerebellum, and is covered by the *lingula belli*, an extension of the cortical substance of the superior vermis (figs. 672,).

The *roof of the intermediate portion* of the fourth ventricle is formed by the ebellum proper, the vermis and the medial portions of the hemispheres. The vous portion of the roof terminates with the *posterior* (inferior) *medullary m*, a thin, narrow band of white substance which is the continuation of the uncles of the floccular lobes, and which connects them at the midline with the ule of the inferior vermis.

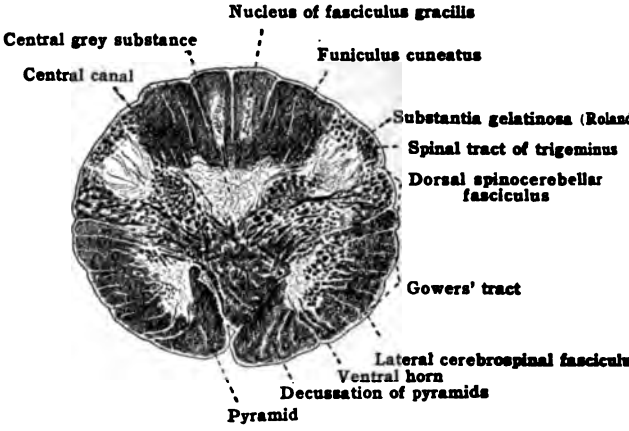
The *roof of the inferior portion* of the fourth ventricle is non-nervous. It is **choroid tela** of the fourth ventricle, a semilunar lamina consisting of the epi-al lining of the ventricle, reinforced by a continuation of the connective tissue ne pia mater and the adjacent portion of the arachnoid. Along the line of its chment to the surface of the medulla it is thickened, and in sections this por-bears the name **ligula** [*tenia ventriculi quarti*]. The thickest portion spans tip of the calamus scriptorius and is termed the **obex**. The width of the ven-ular cavity is extended laterally from its widest part into the *lateral recesses*, ow pockets on each side and around the upper parts of the restiform bodies, rior to the choroidal branches of the posterior inferior cerebellar artery ring to supply the choroid plexus of the fourth ventricle. In the midline of lower part of the choroid tela there is a more or less well-marked opening, the *men of Magendie* (medial aperture of the fourth ventricle), which is a lymph-anel connecting the cavity of the ventricle with the subarachnoid space 680). There is a similar opening from each lateral recess (*lateral apertures ey and Retzius*).

The choroid plexuses of the fourth ventricle consist of highly vascular, lobu-villus-like processes of the ventricular lining (and pia mater) of the choroid . They are reddish in the fresh specimen, and the ependymal lining of the tricle is closely adapted to the unevennesses of their surfaces. From below y run as two parallel masses on either side of the midline, which become united ve, and then are separated again into two lateral processes which bend at t angles and project into the lateral recesses. Portions frequently protrude ough the three openings of the ventricle into the subarachnoid space.

The entire brain-stem may be regarded as an upward continuation of the spinal cord, to which structures are added giving each part its peculiar character and conformation, and in which the structures characteristic of the spinal cord are modified in varying degrees.

The **pyramids,** the great descending or motor cerebrospinal fasciculi, are directly continuous into the pyramidal fasciculi of the spinal cord. They form the extreme ventromedial portion of the medulla, and from the fact that they contribute numerous fibers to the efferent nuclei (nuclei of origin) of the cranial nerves and to other portions of the gray substance of the brain-stem, they decrease appreciably in bulk in descending toward the spinal cord. Most of the fibers contributed to the medulla, as well as to other divisions of the brain-stem, decussate as they leave the pyramids, and terminate in the gray substance of the opposite side. However, the chief **decussation of the pyramids** occurs in the lower end of the medulla. Here usually about three-fourths of the fibers then comprising the pyramids cross the midline to form the lateral cerebrospinal fasciculus (crossed pyramidal tract) of the spinal cord immediately below (fig. 671). The remaining fourth, comprising the more lateral fibers, furthest away from the midline, continues uncrossed into the spinal cord as the ventral cerebrospinal fasciculus or direct pyramidal tract. The majority of the latter fibers decussate gradually in the commissural bundle and in the ventral white commissure of the cord as they approach the levels of their termination. In practically all vertebrates except man and the apes there are no ventral pyramidal fasciculi, the decussation in the medulla being a total one. In man, the proportion of fibers crossing in the chief decussation varies. Cases have been noted in which apparently the entire pyramids decussate at this level. In other cases the direct or ventral pyramidal tract

FIG. 682.—TRANSVERSE SECTION OF MEDULLA OBLONGATA AT THE LEVEL OF THE DECUSSATION OF THE PYRAMIDS.



may be much larger than usual, at the expense of the lateral. The chief decussation usually appears to be symmetrical and it occurs so suddenly that the fibers, in coursing from the ventral to the lateral positions, 'sew up' the ventral median fissure and detach the tips of the ventral horns of the spinal cord from the remainder of the gray figure, and these appear as isolated, irregularly shaped masses of gray substance in transverse sections (fig. 682). From this level upward the outline of the gray figure of the cord is lost, and the cell-columns of the ventral horns occur in more or less detached groups as the motor nuclei of the cranial nerves.

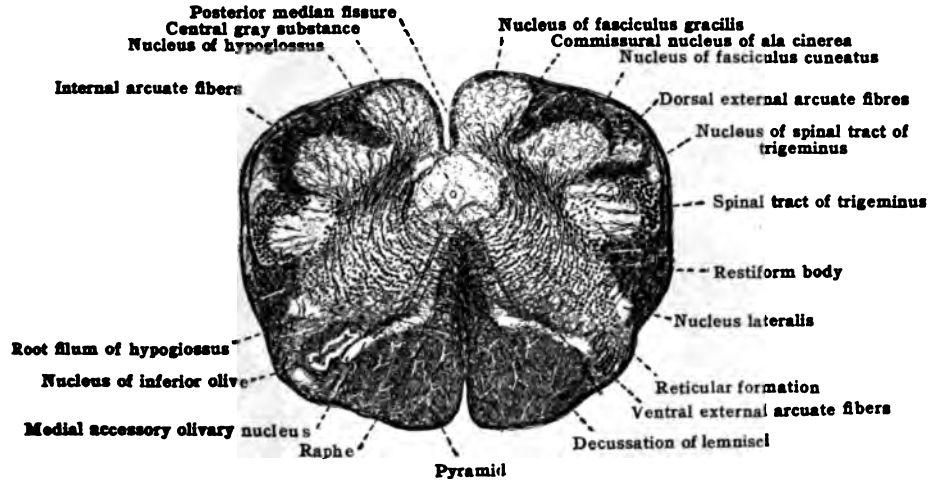
The **origin and decussation of the lemnisci** (medial lemnisci, fillet) begins immediately above the decussation of the pyramids, and here the arrangements characteristic of the spinal cord are further modified. The dorsal portion of the gray figure of the cord is manifest up to this level, but here, after a considerable increase in its thickness, the gray commissure gives rise to two thick dorsal outgrowths on each side of the midline. These dorsal projections of gray substance comprise the nuclei of termination (relays) of the chief ascending or sensory spinocerebral fasciculi of the spinal cord. The nucleus of the fasciculus gracilis (nucleus of Goll's column) arises a little before the nucleus of the fasciculus cuneatus (nucleus of Burdach's column). The former extends slightly downward from its point of origin, so that its inferior extremity is included in sections through the decussation of the pyramids (fig. 682). It produces a slight bulbous enlargement (the *clava*) of the end of the funiculus gracilis, while the nucleus of the fasciculus cuneatus corresponds to the *cuneate tubercle* of the dorsolateral contour of the medulla (figs. 673, 681). From the cells of these nuclei arise the lemniscus—the cephalic continuation of the spinocerebral pathway which conveys general bodily sensations (proprioceptive) to the cerebrum. In passing out of the nuclei the fibers of the lemniscus course in a ventromedial direction. Curving around the region of the central canal, they contribute largely to the internal arcuate fibers, then, sweeping across the midline, they convert it into the raphe, and immediately after crossing (decussating) they turn cephalad and collect to form the bundle known as the lemniscus.

In the medulla, the lemnisci are two thin bands of fibers spread vertically on each side of the raphe, with their lower or ventral edges thicker than their dorsal edges. In their course toward the cerebrum they increase in bulk, owing chiefly to fibers being added to them from the nuclei of termination of the afferent roots of the cranial nerves, which fibers likewise cross the midline as internal arcuate fibers to join the lemniscus of the opposite side. In passing through the pons, the lemnisci gradually become spread laterally (horizontally) and beyond the

their then more lateral portions are further displaced and come to course in the lateral fibers of the isthmus rhombencephali and mesencephalon, while the medial portions remain nearer the midline. This lateral spreading of each lemniscus produces the **lateral lemniscus** and the **medial lemniscus,** distinguished in sections of the superior pons and lower mesencephalic regions of the brain-stem (fig. 702). The lateral lemniscus is contributed very largely by the cell-bodies of the nuclei of termination of the cochlear nerve of the opposite side and is known as the *'auditory lemniscus.'* The **spinal lemniscus** (spinothalamic and spinotectal paths) appears in the dorsal part of the medial lemniscus during its vertical position throughout the medulla and in the lateral part of it, medial to the lateral lemniscus proper, throughout the pons and midbrain.

The reticular formation of the medulla and pons region is considerably more abundant than in the spinal cord. As in the spinal cord, it consists of gray substance through which nerve-fibers, singly and in small bundles, course in all directions, and more sparsely than in other regions. In the medulla it is traversed by the internal arcuate fibers. It may be con-

FIG. 683.—TRANSVERSE SECTION OF MEDULLA OBLONGATA AT LEVEL OF THE DECUSSATION OF THE LEMNISCI.



sidered an enlarged continuation of the middle portion of the gray column of the cord, dispersed by numerous fibers, giving it the reticulated appearance which suggests its name. Its numerous nerve-cells belong, for the most part, to the association and commissural systems of the brain stem, and, therefore, the fibers arising in it correspond largely to the fasciculi proprii of the spinal cord. As in the cord, most of the fibers are of short course, serving to associate different portions of the same level and adjacent levels with each other. Those of long course show a tendency to collect into a small, well-marked bundle which courses one on each side close to the midline, ventral to the central canal in the closed part of the medulla, and near the median sulcus of the floor of the fourth ventricle, in the open part. In the mesencephalon this bundle is continued closely ventral to the aqueductus cerebri. This bundle is known as the **medial longitudinal fasciculus** (posterior longitudinal bundle). It corresponds more nearly to the ventral fasciculus proprius of the spinal cord than to others of the fasciculi proprii. In the medulla it appears as the dorsal edge of the lemniscus, but in the shifting of the position of the lemniscus in the pons region, it retains its medial position and thus becomes isolated. By position it is especially adapted for the association of the nuclei of the cranial nerves. Evidence has been found that those fibers which arise in the superior corpora quadrigemina and descend the spinal cord in its sulcomarginal or ventral mesencephalospinal fasciculus, pass through the medulla in the medial longitudinal fasciculus. The nuclei of termination of the vestibular nerve are said also to contribute many fibers to it.

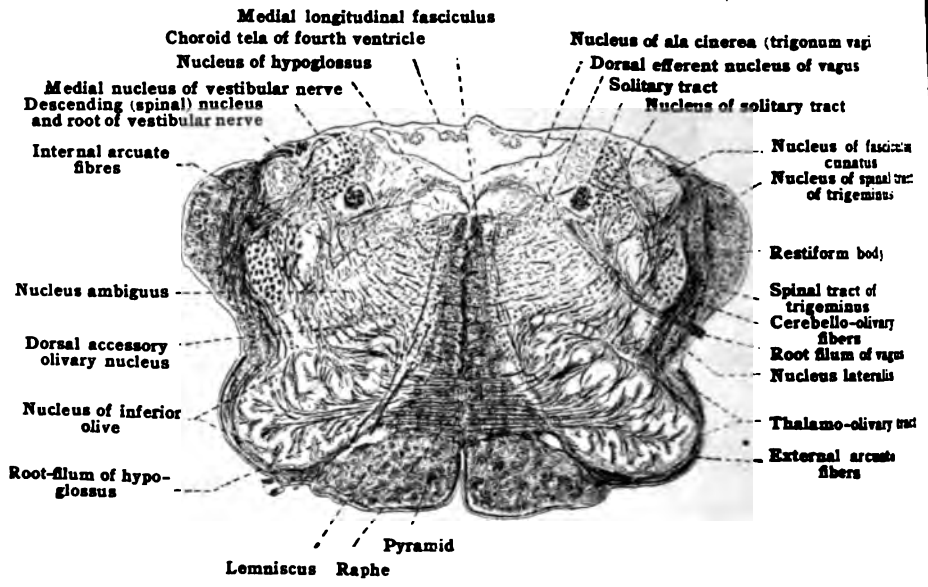
The inferior olivary nucleus is an added structure in the medulla oblongata, i. e., it has no homologue in the spinal cord. The two of them occupy the olivary prominences, *the olives* of the exterior, and constitute the most conspicuous and striking isolated masses of gray substance in sections of the medulla. They appear as crenated laminæ of gray substance folded so as to encup a dense mass of white substance, and in actual shape the entire nucleus has the form of an irregular corrugated cup with the opening or hilus on the side toward the midline (fig. 685). The mass is so crumpled that the diameter of the hilus is appreciably less than the length of the nucleus, and thus transverse sections of either extremity of it appear as closed capsules.

There are several small detached portions of the olivary nucleus known as the **accessory olivary nuclei.** These are named according to their position with reference to the chief portion or olive proper. They are plates less corrugated than the chief nucleus, and appear rod-like in sections. The largest is the *dorsal accessory olivary nucleus.* The *medial accessory olivary nucleus* is widest at its inferior end, which extends a little below the inferior extremity of the olive proper. The *lateral accessory olivary nucleus* is the smallest. In serial sections the accessory nuclei are found to be plates of gray substance usually continuous with one another.

The olivary nuclei are mainly cerebellar connections. By both ascending and descending fibers each cerebellar hemisphere is connected with the olivary nucleus of the same and opposite sides. Serial sections of a human brain with congenital absence of one cerebellar hemisphere described by Strong, show that the chief connection of a hemisphere is with the olive of the opposite side. These fibers necessarily pass between the cerebellum and the olives by way of the restiform body, and, in so doing, form an obliquely coursing bundle in the lateral border of the medulla known as the **cerebello-olivary fibers** (fig. 684). The olivary nuclei also comprise a secondary relay between the spinal cord and the cerebellum by way of the spino-olivary fasciculus of the cervical cord, and it will be noted that they receive fibers from the thalami. The latter fibers, the **thalamo-olivary tract,** approach the olive at its lateral periphery, while above through the brain-stem the tract courses in a more medial position. This tract comprises one of the cerebrocerebellar paths. Arising in the thalamus and terminating in the olive, its impulses reach the opposite cerebellar hemisphere by way of the cerebello-olivary fibers.

The **arcuate fibers** are referred to as internal and external, according as they course dorsal or ventral to the inferior olivary nucleus. The **internal arcuate fibers** comprise fibers destined for both the cerebellum and cerebrum, and also for the association of the tegmental gray substance of the two sides in which they course. Certain of the fibers pass between one restiform body (cerebellar hemisphere) and the olive of the opposite side course internal to the oliv-

FIG. 684.—TRANSVERSE SECTION OF MEDULLA OBLONGATA THROUGH NUCLEI OF VAGUS AND HYPOGLOSSUS AND THROUGH THE MIDDLE OF THE OLIVES.



of the same side, and thus form the ventral portion of the internal arcuate fibers. As noted above, the internal arcuate fibers consist in greatest part of fibers being contributed to the lemnisci, arising from the cells of the nucleus of the fasciculus gracilis and fasciculus cuneatus and sweeping downward and decussating to form the lemniscus of the opposite side. However, all the fibers arising in these nuclei do not enter the lemniscus. A few of them cross the midline with the internal arcuates, but pass on to enter the restiform body (cerebellar hemisphere) of the opposite side. Some of these course ventrally and, upon approaching the olive of the opposite side, are deflected around the ventral side of both the olive and the pyramid, and thus pass to the restiform body as external arcuate fibers also. Certain of the internal arcuate fibers arise from the cells of the nuclei of termination of the cranial nerves and from small cells situated in the gray substance of the reticular formation. These, in crossing the midline, correspond to the white commissures of the spinal cord. Some of them terminate in the medulla; others, especially those from the nuclei of termination of the sensory cranial nerves, join the lemniscus and pass toward the cerebrum; others reach the cerebellar hemisphere of the opposite side.

The **external arcuate fibers,** in addition to those mentioned above, comprise certain fibers which arise in the nuclei of the fasciculus gracilis and cuneatus and pursue a dorsolateral course to enter the restiform body (cerebellar hemisphere) of the same side. These form the dorsal segment of the external arcuates. The greater mass of the external arcuates are cerebello-olivary fibers. Certain of those passing from one olive to the restiform body of the opposite side are deflected at the raphe, and course on the ventral side of both the other olive and the pyramid in order to reach the opposite cerebello-olivary bundle. Likewise, those passing from the restiform body to the opposite olive are deflected by the olive of the same side and pursue a similar course to the raphe. While out of the hilus of each olive streams a dense mass of white substance, yet many of the fibers concerned with the olive pierce its walls from all sides. Many of the external arcuate fibers are said to be interrupted in the **nucleus arcuatus.** This is a thin sheet of gray substance, variable in amount, which lies on the ventral aspect of each pyra-

ıough it decreases inferiorly, it may be evident down to the decussation of the pyra-
nucleus receives its name from the fact that its larger portion is interpolated in the
ernal arcuate fibers. It is continuous anteriorly with the gray substance or nuclei
. The external arcuate fibers of longer course, like the olives with which they are
erned, have no homologs in the spinal cord
tral canal of the closed portion of the medulla is surrounded by a greater amount

ly *the central gelatinous substance*, and the nerve-fibers in coursing through the gray
re partially deflected by it, leaving it as a cylindrical, more evident area of gray sub-
in other regions. In the open portion of the medulla the central gray substance
rms a more transparent lamina just under the floor of the fourth ventricle. In the
lon, occurring in still greater amount, it again surrounds the reformed canal or
f the cerebrum.

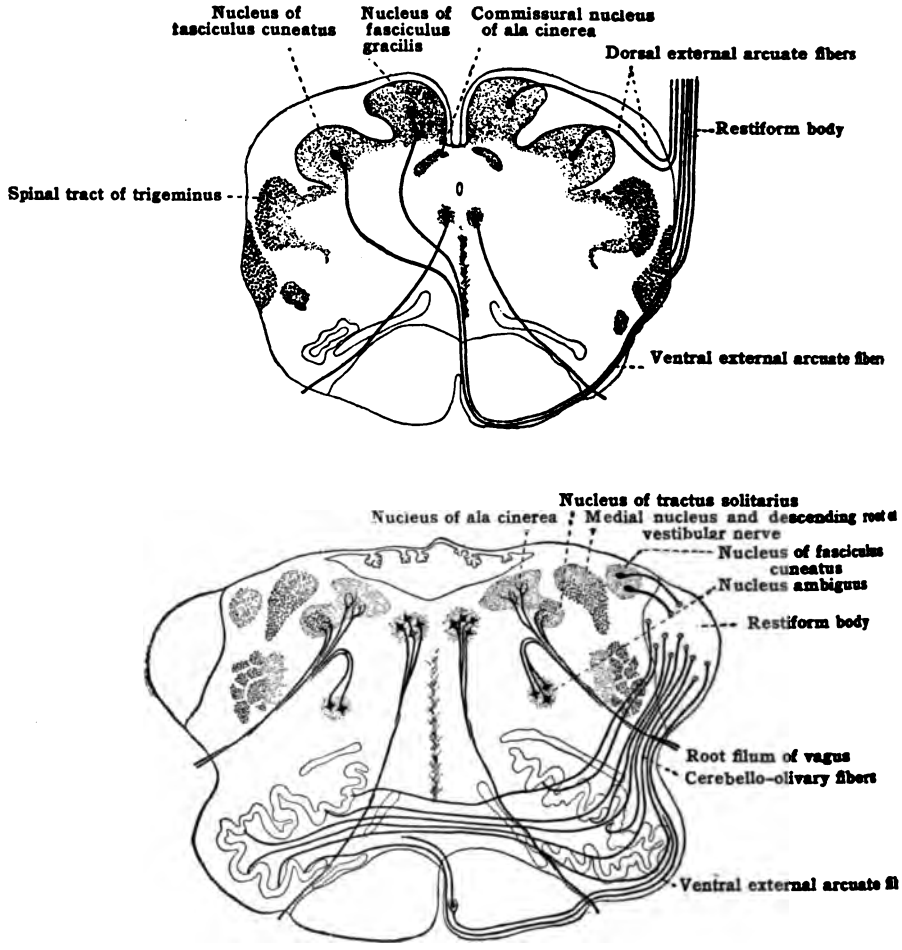
5.—Reconstruction of the Inferior Olivary Nucleus, Dorsolateral View. (After Sabin.)

entral connections of the cranial nerves are easily homologized with
d structures. Functionally the cranial nerves are of three varieties:—
notor or efferent nerves, comprising the oculomotor, the trochlear,
r, the abducens, the facial, the spinal accessory, and the hypoglossus;
nsory or afferent, comprising the olfactory, the optic, the trigeminus, the
', and the cochlear and (3) the mixed, motor and sensory nerves, com-
e glossopalatine, the glossopharyngeal, and the vagus. The **nuclei of**
the motor or efferent cranial nerves and the efferent portions of the
ves are directly continuous with the cell-columns of the ventral horns
nal cord, while the emerging root-filaments and roots of these nerves
d to the ventral roots of the spinal nerves. The **nuclei of termination**
rent or sensory cranial nerves and of the sensory portions of the mixed
rrespond directly to the nuclei of the fasciculus gracilis and fasciculus
and to the cell-bodies of association and commissural neurones of the
nd cord and, functionally, are merely anterior continuations of these.
uclei of the efferent or motor cranial nerves lie in two parallel lines, one
midline and the other more laterally placed. The nuclei giving origin
ılomotor, the trochlear, the abducens, and the hypoglossus are near the
ınd correspond to the ventromedial and dorsomedial cell-groups of the
orns of the spinal cord; the nuclei of origin of the masticator (motor
ıe trigeminus) of the facial, and the nucleus ambiguus contributing to
: portions of the glossopharyngeal and vagus nerves, together with the
f the spinal accessory, correspond to the ventrolateral and dorsolateral
ıs of the ventral horns of the spinal cord. The nerve-roots having medial
origin are those which make their exit from the brain-stem along the
lial superficial line, while those having the more lateral nuclei comprise
lateral line of roots apparent on the surface of the stem. Some of the
bers of the vagus, supposedly visceral efferent, arise from a small nucleus
lial to the nucleus ambiguus, the *dorsal efferent nucleus of the vagus.*
efferent fibers in the glossopharyngeal and glossopalatine nerves arise
nuclei corresponding to the dorsal efferent nucleus of the vagus, that for
palatine being called the *salivatory nucleus.* The first two pairs of cranial

nerves, the olfactory and optic, are attached to the prosencephalon. These a purely sensory, and make their entrance near the midline of the brain, both hav superficially placed nuclei of termination. Of the other nerves, all having sens or afferent functions enter the brain along the lateral or more dorsal line, and t ganglia giving origin to their afferent axones correspond directly to the spi ganglia of the dorsal or afferent roots of the spinal nerves.

Commissural and associational neurones are much more numerous in t brain-stem than in the spinal cord. Their axones serve to correlate the structu

FIGS. 686 AND 687.—DIAGRAMS SHOWING THE COMPOSITION OF THE CEREBELLAR PORTI OF THE INTERNAL AND EXTERNAL ARCUATE FIBERS.



on the two sides of the midline and to associate the different levels of the s side. Just as in the spinal cord, those of longer course form fasciculi pro Many of their axones descend into the spinal cord.

Of the fifteen pairs of cranial nerves, eleven pairs are attached to the med oblongata and pons, viz., the trigeminus, the masticator, abducens, fa glossopalatine, vestibular, cochlear, glossopharyngeal, vagus, spinal access and hypoglossus.

The hypoglossus, the motor nerve of the tongue, has its nucleus of origin beginni the lower portion of the floor of the fourth ventricle caudal to and at the level of the acc striæ. It is a long nucleus, lying close to the midline and just under the floor of the ven (hypoglossal eminence) and extending down to the region of the funiculus separans. H curves ventrally to a slight degree, and below the obex assumes a position ventrolateral t central canal, and thus extends a short distance below the level of the inferior tip of the The nerve arises as a series of rootlets which traverse the entire thickness of the medulla 684), to emerge in line in the furrow between the olive and the pyramid and fuse to forr

the nerve. The lowermost of the rootlets usually emerge below the olive. The nucleus impulses—(1) from the cerebrum by way of divergent fibers from the pyramid of the side (voluntary); (2) impulses brought in by the sensory fibers of the cranial nerves and (3) by axones from other levels of the medulla (associational). None of its axones osed to decussate, though numerous commissural fibers are known to pass between ei of the two sides.

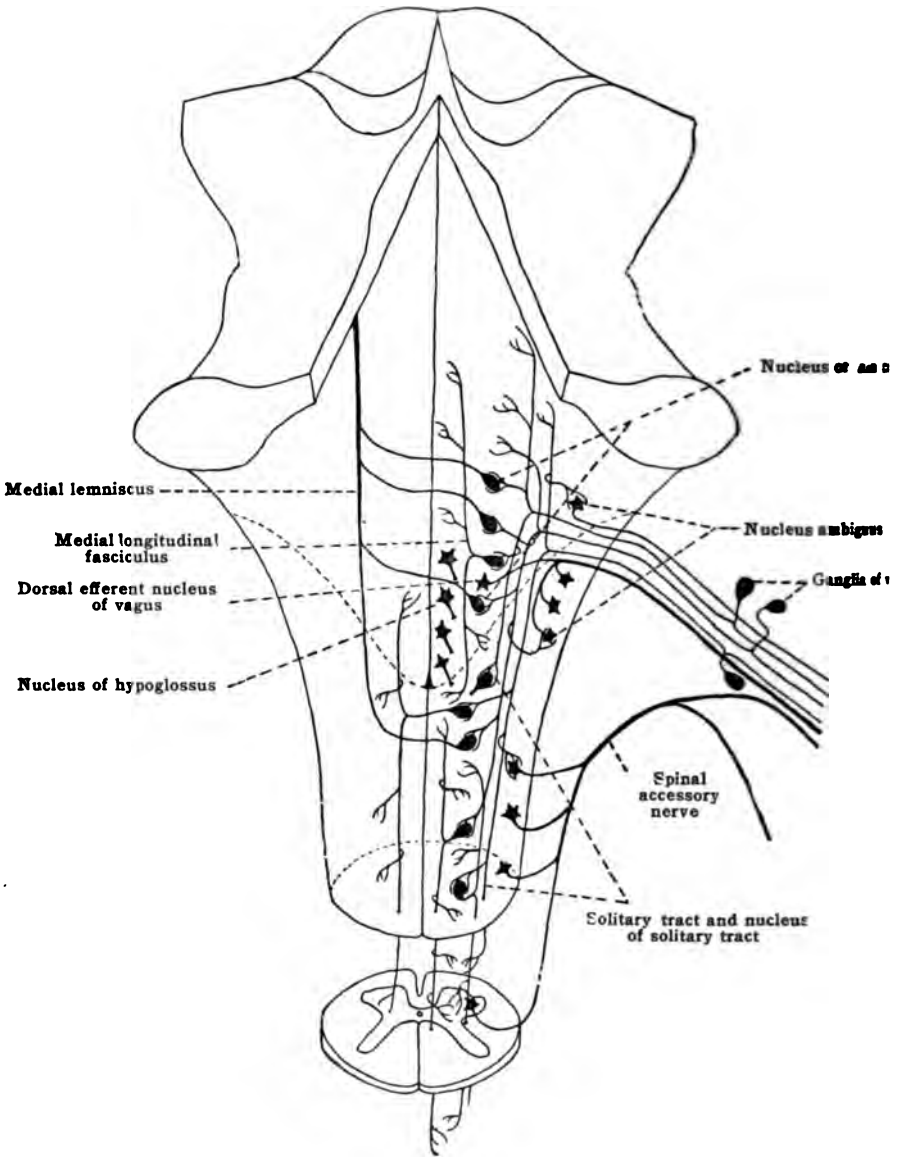
Chief motor nucleus of masticator

spinal accessory is likewise a purely motor nerve, and has a laterally placed, long, and tenuated nucleus of origin. Above, its nucleus is in line with and practically continuthe nucleus giving motor fibers to the vagus and glossopharyngeus (nucleus ambiguus). consists of the lateral and dorsolateral groups of cells of the ventral horn of the first ix segments of the spinal cord. The nerve arises as a series of rootlets which emerge and join a common trunk, which passes upward between the dorsal and ventral roots

of the upper cervical nerves and parallel with the medulla to turn lateralward in com with the vagus. (See fig. 709). The upper rootlets arise from that part of the nucleus tiguous to the inferior end of the nucleus ambiguus, and are described as comprising the ullary (bulbar) or *accessory part* of the nerve; those which arise from the ventral horn cells are described as the *spinal part.* The trunk of the spinal accessory fuses with the vagus i region between its two ganglia, and, before separation, contributes fibers (the accessory to the trunk of the vagus. Some of the accessory fibers are distributed as motor fibers t

FIG. 689.—DIAGRAM ILLUSTRATING PRINCIPAL CENTRAL RELATIONS OF THE VAGUS N EXCLUSIVE OF RELATIONS TO DESCENDING CEREBRAL OR PYRAMIDAL FIBERS.

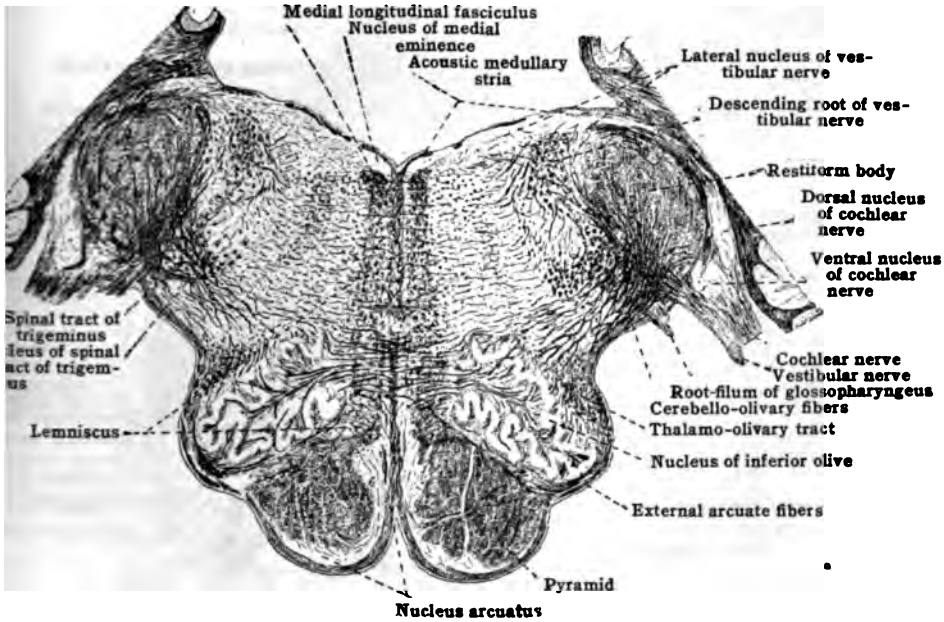


muscles of the larynx and some of them are visceral efferent fibers (visceral effectors). latter probably terminate chiefly in sympathetic ganglia which send axones to the heart. spinal part is distributed to the sternomastoid and trapezius muscles. The nucleus of the accessory receives terminal twigs of pyramidal fibers from the opposite side and is oth subjected to sensory impulses similar to those affecting the cells giving origin to the cranial nerves and motor roots of the spinal nerves.

The vagus or pneumogastric and the glossopharyngeal, though they have widely di peripheral distributions, are so similar in origin and central connections that they m described together. Both contain efferent fibers, though both are in greater part sensory. are similar as to the origin of both their efferent and afferent components. The afferent fi the vagus arise in its jugular ganglion and its nodosal ganglion (ganglion of the trunk); the a

of the glossopharyngeal arise in its superior ganglion and its petrosal ganglion. In both these fibers enter the lateral aspect of the medulla and bifurcate into ascending and descending branches, similar to those of the dorsal root-fibers in the spinal cord. Some of these fibers terminate in practically the same level of the medulla about cell-bodies situated on the same and the opposite sides. Such branches end chiefly in the nuclei of the hypoglossal and spinal accessory, and about the cells giving origin to the efferent components of the vagus and glossopharyngeal themselves—short reflex arcs. However, most of the afferent fibers terminate in the nucleus of termination of the vagus and glossopharyngeal:—(1) the **nucleus of the ala cinerea**, the middle portion of which is indicated in the floor of the fourth ventricle by the ala cinerea; (2) in the closed portion of the medulla, the lower end of the nucleus of the ala cinerea is seen to lie in the dorsolateral proximity of the central canal, and this portion is known as the *commissural nucleus of the ala cinera* (figs. 683 and 686) from the fact that fibers may be seen to pass directly from it across the mid-line; (3) the longer of the descending branches of the terminated fibers collect to form the **solitary tract**, a compact bundle situated dorsally just ventrolateral to the nucleus of the ala cinerea and quite conspicuous in sections of the medulla. The fibers of this bundle terminate in the *nucleus of the solitary tract*, which is but a ventrolateral downward continuation of the nucleus of the ala cinerea enclosing the bundles forming the

FIG. 690.—TRANSVERSE SECTION OF MEDULLA AT INFERIOR BORDER OF PONS.



t. It is most probable that the fibers of the solitary tract are chiefly from the vagus (pneumogastric), though Bruce has found evidence that the glossopharyngeal contributes to it appreciably. It decreases rapidly in descending the medulla, owing to the rapid termination of its fibers about the cells of its nucleus. It, with the axones given by the cells of its nucleus, is believed to extend as far downward as the level of the fourth cervical segment of the spinal cord. This being in the level of origin of the phrenic nerve, the tract forms a link in the respiratory apparatus which aids in the coordinated respiratory movements. The axones given off by the cells of the nucleus of the ala cinerea (terminal nuclei of the vagus and glossopharyngeal—) arise on both sides of the midline, associating nuclei of other cranial nerves with vagus and glossopharyngeal impulses, many decussating to be distributed to the structures of the opposite side. Many join the lemniscus of the opposite side and pass into the cerebrum; others are distributed to the motor neurones of the cervical cord of the same and opposite sides (reflex arcs), and no doubt others form central connections with the cells of the reticular formation of the medulla, though their precise relations have not been determined.

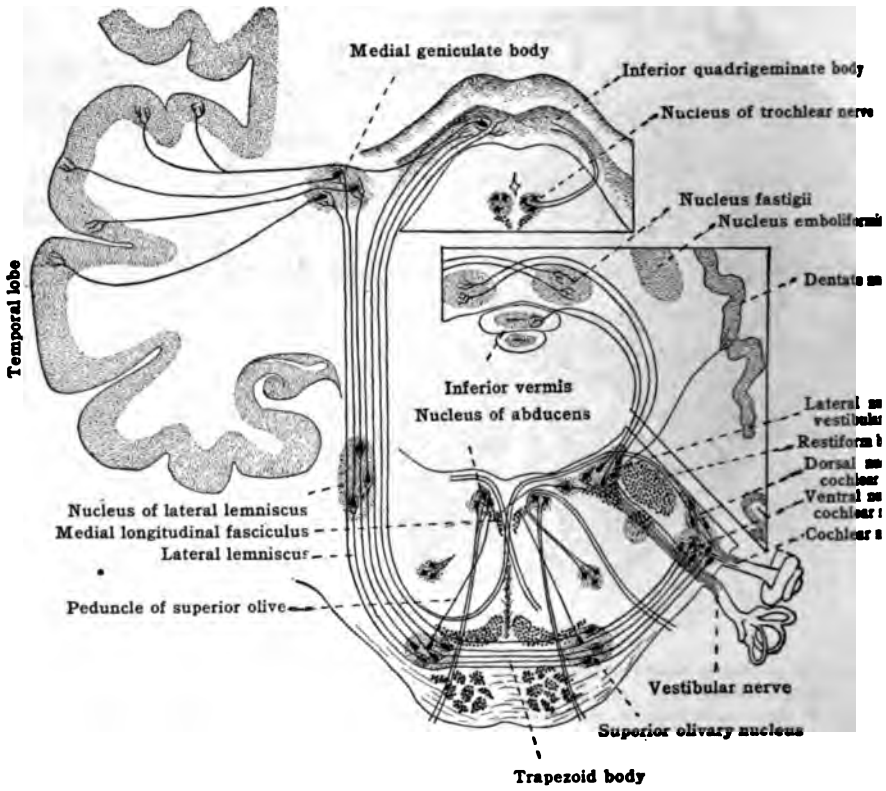
Cell-bodies in the nucleus of the ala cinerea, the nucleus of the solitary tract and in the commissural nucleus of the ala cinerea comprise the so-called **respiratory and vasomotor nuclei (centers')** of the medulla. Some of the caudal branches of the axones given off by the cells of these nuclei descend the spinal cord, not only to the segments giving origin to the phrenic nerve, but also to those supplying the intercostal and levatores costarum muscles. Some of these augment the solitary tract; most of them descend in the reticular formation of the medulla and cord. Further, axones given off by these cells convey vasomotor impulses which are distributed to visceral efferent neurones throughout the cord.

The nuclei of origin of the motor fibers of the vagus and glossopharyngeal are the **dorsal efferent nucleus of the vagus** and the **nucleus ambiguus.** The cells of the dorsal nucleus of the vagus lie somewhat clustered in the ventromedial side of the nucleus of the ala cinerea and lateral to the nucleus of the hypoglossus. Their axones pass outward among the entering or efferent vagus fibers, and it is suggested that most of them are visceral efferent fibers of the

vagus, i.e., they form synapses with sympathetic neurones. The *nucleus ambiguus* or v efferent nucleus of both nerves lies in the lateral half of the reticular formation, about m between the olive and the line traversed by the rootlets of the two nerves. Its upper larger. Its cells are considerably dispersed by the fibers of the reticular formation. axones arising from its cells course at first dorsalward and then turn abruptly outward the rootlets of the vagus or glossopharyngeal, as the case may be. The vagus is thou receive more efferent fibers from the nucleus ambiguus than does the glossopharyngea Cunningham notes that it may be questioned whether the latter nerve contains any fibers at all, there being paths by which the fibers of its motor branch (to the stylophar muscle) might enter it other than direct from motor nuclei.

The *vestibular* and *cochlear* nerves have been considered as one nerve and together desi as the acoustic or eighth cranial nerve. While both are purely sensory, are similar in de ment and their roots course together, they are distinct as to function and origin and their of termination differ. They are here described as separate cranial nerves. The two approach the brain stem together and enter it at the lateral aspect of the junction of m oblongata and pons.

FIG. 691.—SCHEME SHOWING SOME OF THE CENTRAL CONNECTIONS OF THE ACOUSTIC N (In part after Edinger.)



The **vestibular nerve** (nerve of equilibration) arises as the central processes of the bipo of the *vestibular ganglion*, and passes into the brain-stem on the ventromedial side of t form body to find its nucleus of termination (nucleus vestibularis) in the floor of th ventricle. This nucleus occupies a triangular area of considerable extent (area acus 681), and is usually subdivided into a *lateral nucleus* (Deiters'), a *medial nucleus* (Schwa *superior nucleus* (Bechterew's), and an *inferior nucleus* (nucleus spinalis). The lat downward prolongation of the general nucleus vestibularis which accompanies the *de or spinal root* of the nerve.

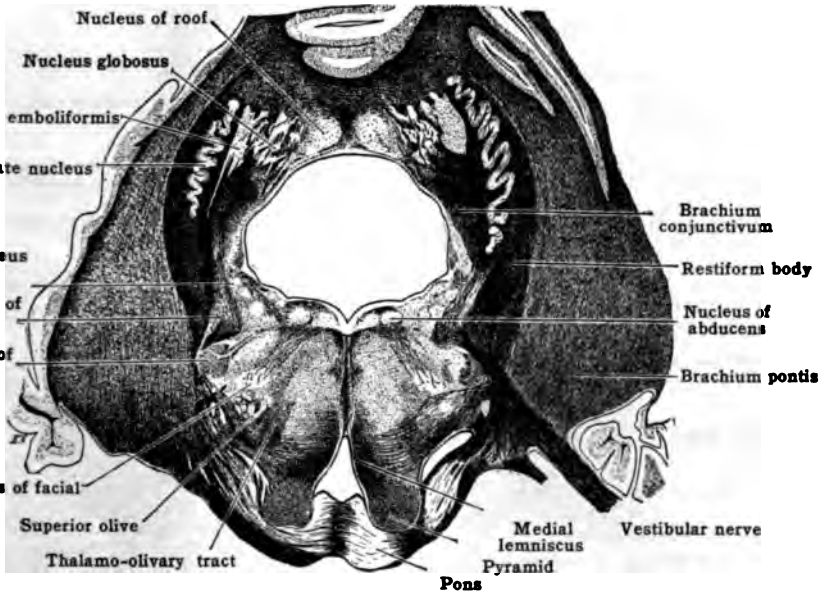
From the cells of the lateral and inferior nuclei axones are given off which form the lateral funiculus of the spinal cord (lateral vestibulospinal fasciculus, fig. 661) a anterior marginal fasciculus (ventral vestibulospinal tract). From both the lateral nuc the superior nucleus a special path is given off which passes upward and terminates in nucleus of the cerebellum (nucleus fastigii) of the opposite side and in the nucleus dent the cortex of the vermis. Also, fibers arising in the nuclei fastigii are said to termina lateral (Deiters') nucleus and other gray substance of the medulla (forming the *fastig tract*). Some fibers from the roof nucleus possibly descend into the anterior marginal fa of the spinal cord. From the medial and also from the superior nucleus fibers pas medial longitudinal fasciculus of both sides, and are distributed to the nucleus of the a of the same side and to the nuclei of the trochlear and oculomotor nerves of the opposite of the masticator nerve of the same and opposite sides. From the lateral and medi

probably from all, a few fibers arise which cross the midline to enter the lemniscus and end to the cerebrum (lateral portion of the thalamus) on the opposite side. The lateral (Deiters') nucleus is said to contribute more fibers to the medial longitudinal fasciculus than any nucleus of any other sensory cranial nerve and fewer fibers to the lemniscus. If any of these fibers descend the cord, they must do so in its anterior marginal fasciculus.

The *inferior nucleus* is accompanied by the *descending* or *spinal root* of the vestibular nerve, which begins to assemble in the nuclei above. This root is composed of both caudal branches of the entering fibers of the nerve and chiefly of fibers arising from the cells of its nuclei. Thus the vestibular nerve it corresponds in every way to the solitary tract for the vagus, and to the spinal tract of the trigeminus. Such of its fibers as descend into the spinal cord most probably do so in the lateral vestibulospinal fasciculus.

Many of the anatomical details of the central connections of the vestibular nerve have not yet been determined with exactness. In addition to whatever other functions it may have, it is considered to be the nerve of equilibration, and the connections noted above may be considered the pathways by which it exercises this function. The fibers of the apparatus which are represented in the spinal cord are supposed to convey impulses to the ventral horn (motor) cells of the cord as far down as the lumbar region.

Fig. 692.—Transverse Section through Inferior Border of Pons and Portion of Overlying Cerebellum. (From Villiger.)



The **cochlear nerve**, the auditory nerve proper, arises as the central processes of the bipolar cells of the *spiral ganglion* of the cochlea. In the lateral periphery of the restiform body, just before the latter enters the cerebellum, the nerve finds its two nuclei of termination, the *ventral nucleus* and the *dorsal nucleus* (tuberculum acusticum, fig. 681, 690).

From the **dorsal nucleus** arise the *acoustic medullary striæ*. These bundles pass around the dorsal aspect of the restiform body and course just under the ependyma of the floor of the fourth ventricle to the midline, where they suddenly turn downward into the substance of the medulla and in doing so, cross to the opposite side and join the lemniscus. As the lemniscus becomes separated higher up into a medial and lateral portion, these fibers course in the lateral lemniscus and are distributed chiefly to the grey substance of the inferior quadrigeminate body and medial geniculate body of that side. At the midline some of their fibers join the medial longitudinal fasciculus and by way of it are distributed to the nuclei of origin of the efferent fibers of other cranial nerves. In frequent cases, the acoustic striæ course so deeply beneath the ependyma as not to be superficially visible in the floor of the fourth ventricle.

From the **ventral nucleus**, fibers arise which terminate about (or give collaterals to) the cells of the **superior olivary nucleus** of the same and opposite sides. The superior olive is a small accumulation of gray substance which lies in the level of the inferior portion of the pons, and in line with the much larger inferior olivary nucleus of the medulla. However, it is not analogous to the latter in any sense. The two superior olives form links in the central acoustic chain. From cells of the superior olivary nucleus of the same and opposite sides, fibers arise which join the lateral lemniscus and terminate in the gray substance of the inferior quadrigeminate body and in the medial geniculate body, thus associating these bodies with the ventral nucleus of cochlear termination of the opposite side. From the medial geniculate body fibers arise which pass to the cortex of the superior temporal gyrus. Only a few of the fibers arising in the inferior quadrigeminate body terminate in the cortical area of hearing. In the lateral lemniscus some of the acoustic fibers are interrupted by cells of the *nucleus of the lateral lemniscus*. In crossing the midline, between the superior olives, the ventral fibers from the

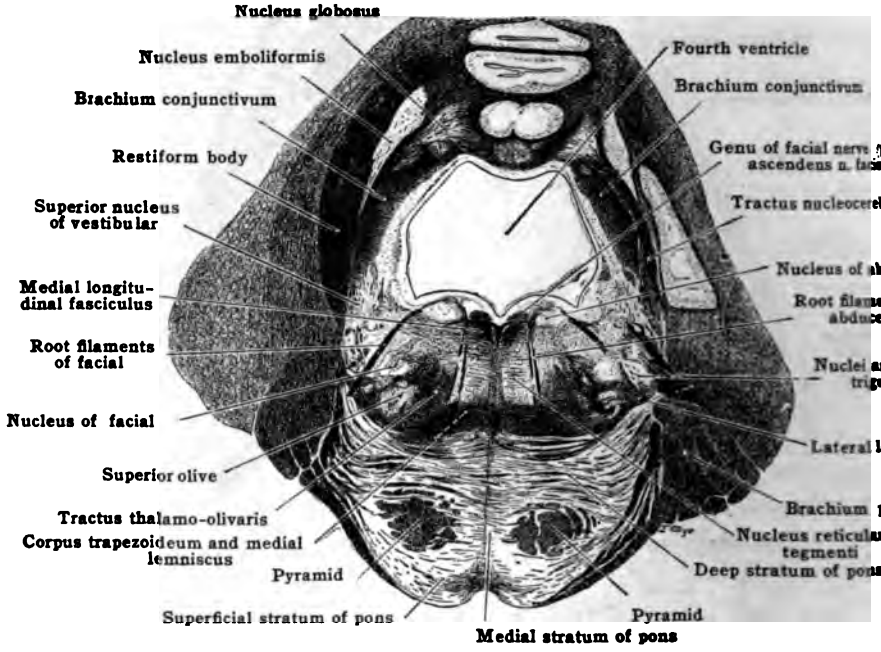
two sources form a more or less compact bundle, the **corpus trapezoideum** (trapezium). To this are added fibers crossing between the **nuclei trapezoidei, smaller masses** of gray substance just ventral to the superior olive and probably of the same significance.

Also, some fibers arising in the nuclei of termination of the cochlear nerve pass to the inferior quadrigeminate body of the same side. On the other hand, the relation with the medial geniculate body is thought to be wholly a crossed one. Further, some fibers are described as terminating in the *superior quadrigeminate body* of both the same and the opposite side. These, forming the *stratum lemnisci* of this body, are especially suggestive of associating auditory impulses with eye-movements.

All the fibers arising in the superior olivary nucleus do not enter the corpus trapezoideum and the lateral lemniscus. A small bundle, the **peduncle of the superior olive**, arises in the nucleus and courses dorsally to the region of the nucleus of the abducens. Here certain of its fibers terminate about the cells of the nucleus of the abducens, while others enter the medial longitudinal fasciculus and pass to the nuclei of the trochlear and oculomotor nerves, thus further establishing connections between auditory impulses and eye-movements.

The **facial nerve** is commonly described as consisting of the 'facial proper' and its so-called sensory root or *pars intermedia*, the two together being designated as the seventh cranial nerve. However, the pars intermedia neither serves as a sensory root for the facial nor is it part

FIG. 693.—TRANSVERSE SECTION THROUGH PONS AND PORTION OF CEREBELLUM AT LEVEL OF NUCLEI AND ROOT FILAMENTS OF ABDUCENS AND FACIAL NERVES. (From Villiger.)

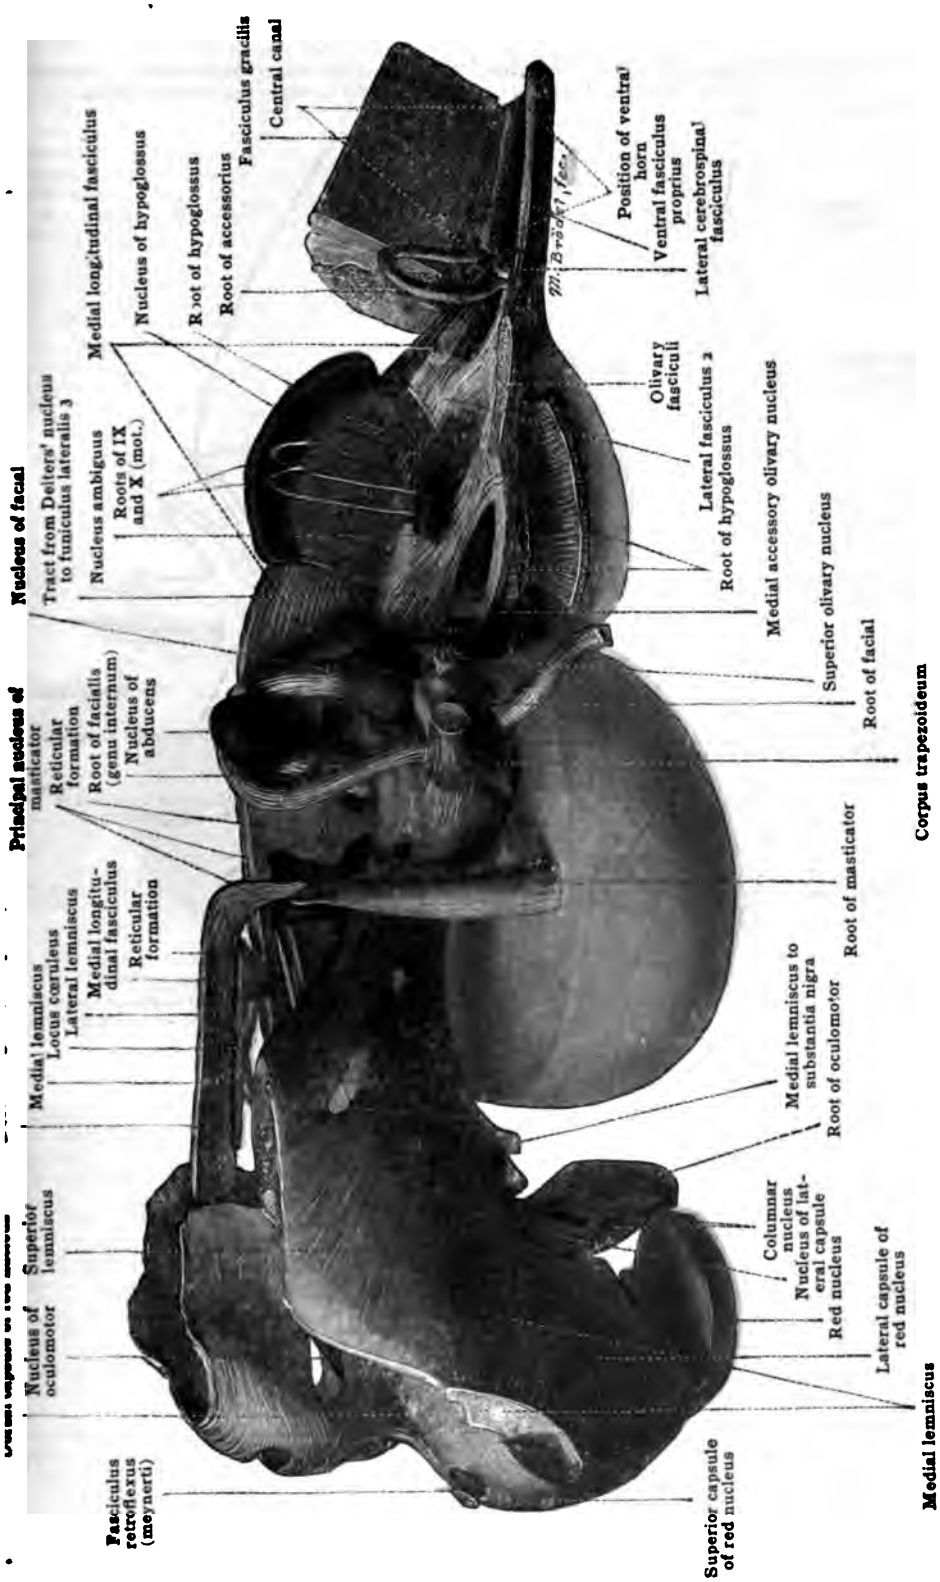


sensory. Many years ago Sapolini considered it a separate nerve and later it was called the *intermediate nerve of Wrisberg*. More recent investigations of its development and distribution, especially those of Streeter and Sheldon, further indicate that it merits a separate description and a separate name, and, indicative of its distribution, it is here described as the *glossopalatine nerve*. The facial, the glossopalatine and the abducens all have their nuclei within the level of the pons, though the roots of all appear from under its inferior border and are considered as attached to the medulla.

The **facial** [nervus facialis] has its nucleus (of origin) in the ventrolateral region of the reticular formation, superior to and in line with the nucleus ambiguus (figs. 688, 692). The axones given off by the cell-bodies of the nucleus collect into a bundle which, instead of passing ventrally and directly to the exterior of the pons, courses at first dorsomedially to the mesial side of the nucleus of the abducens (ascending root of the facial); then it turns and courses superiorly for a few millimeters, parallel with the nucleus of the abducens immediately beneath the floor of the fourth ventricle (*genu internum*, figs. 693 and 694); then it turns abruptly in a ventrolateral and inferior direction to its point of exit at the inferior border of the pons, just lateral to the olive and medial to the entrance of the vestibular nerve. Its exit usually involves a few pons fiber. In transverse sections through the middle of the nucleus of the abducens the genu of the facial appears as a compact transversely cut bundle at the dorsomedial side of this nucleus.

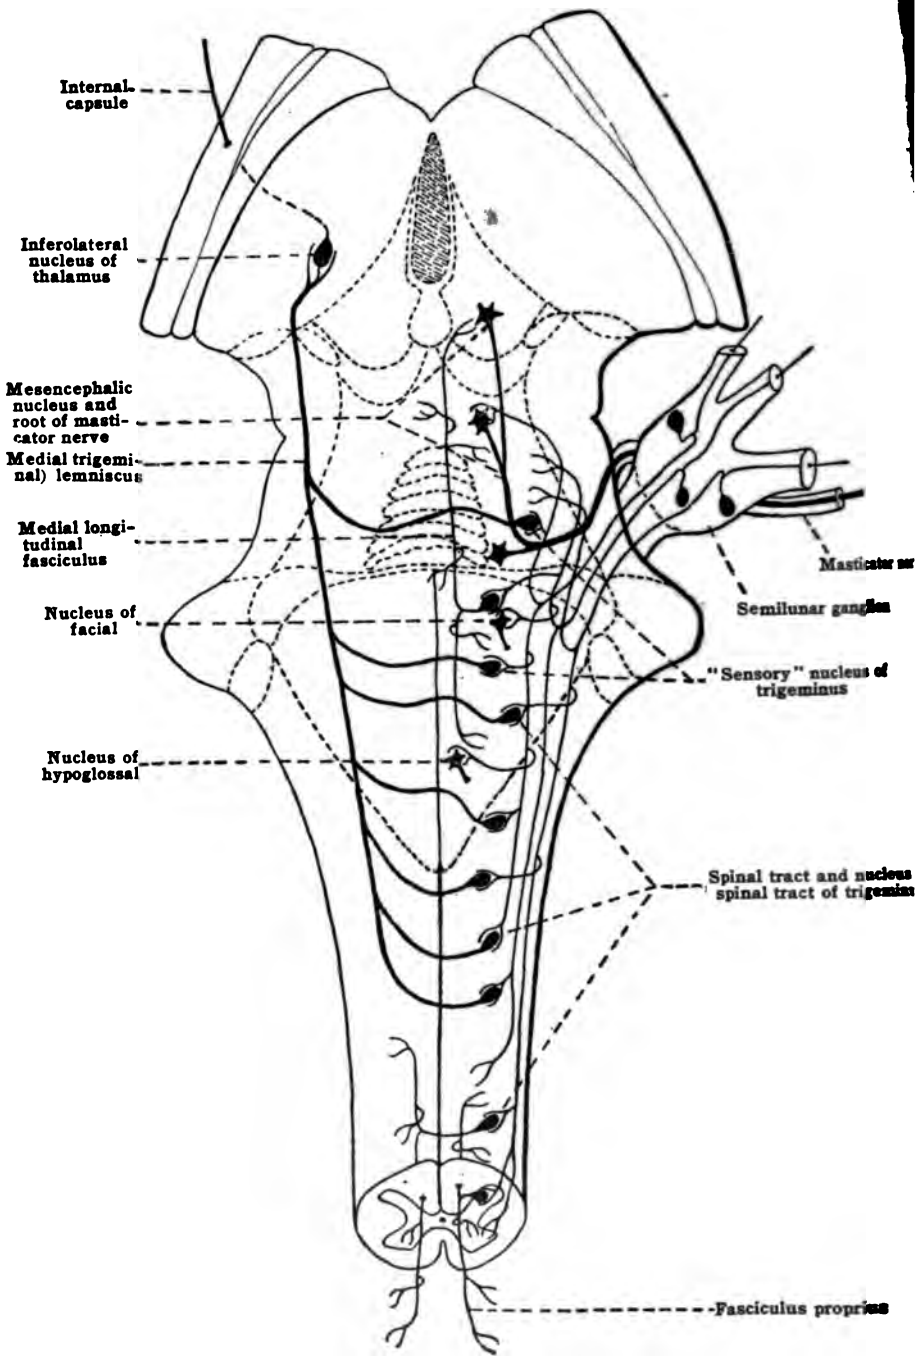
The nucleus of the facial is described as consisting of two chief groups of cells, an anterior and a posterior group which give rise respectively to the axones of the superior and inferior branches of the facial nerve. It receives cortical impulses from the lower portion of the anterior central gyrus of the cerebral cortex, from the root fibers of the trigeminus of the same side, which serves as its sensory root, and (chiefly) fibers arising from the nuclei of termination of the

Fig. 694.—Drawing of Model of Brain-stem of an Infant, showing the Nuclei of Origin of the Motor Cranial Nerves. (After Sabin.)



trigeminus. The nuclei of termination of the optic and the cochlear nerves of the same opposite sides give rise to fibers which terminate about its cells. The fibers from the cortex descend in the pyramidal fasciculi and cross by way of the raphe and arcuate fibers terminate in the nucleus of the opposite side. The anterior group of the cells of the

FIG. 695.—DIAGRAM ILLUSTRATING THE PRINCIPAL CENTRAL CONNECTIONS OF THE TRIGEMINUS AND MASTICATOR NERVES, EXCLUSIVE OF THEIR RELATIONS TO DESCENDING CEREBRAL OR PYRAMIDAL FIBERS.

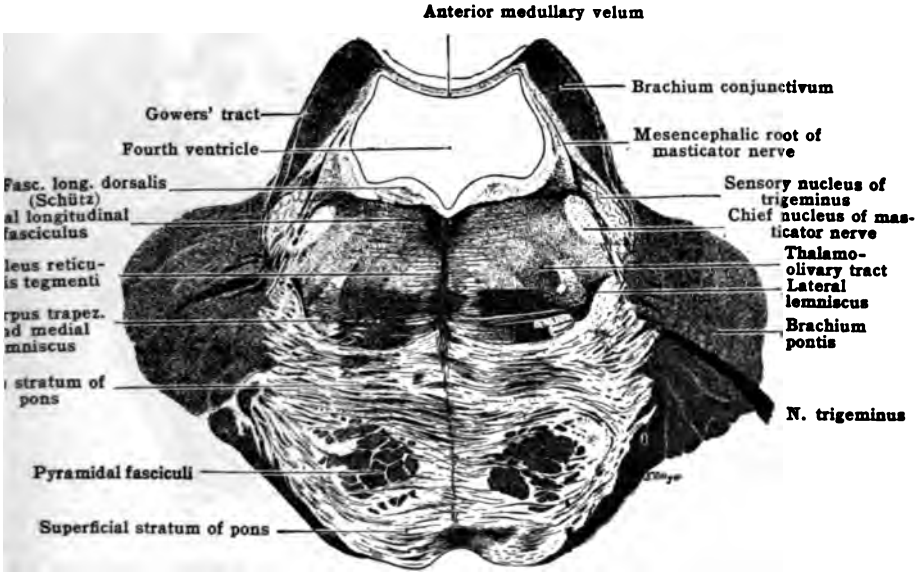


nucleus must receive cortical fibers not only from the cerebral hemisphere of the opposite also from that of the same side, evidenced by the fact that the superior branch of the nerve but little affected in facial paralysis resulting from a lesion in the cerebral cortex of one A lesion destroying the root of the nerve or its nucleus of origin will of course give total paralysis of the side of the lesion.

The glossopalatine nerve (*nervus intermedius*, sensory root of facial, etc.) is a mixed nerve largely sensory. It accompanies the facial nerve trunk from a short distance beyond the ganglion (genu externum) of the facial to its attachment to the brain stem. Its *sensory fibers* are T-fibers of the cells of the *geniculate ganglion* (at the geniculum of the facial). The peripheral processes go as the *chorda tympani* to supply the epithelium of the anterior part of the tongue and that of the palate, especially of the palatine arches, and some of its fibers share with the glossopharyngeal nerve the innervation of the taste-buds. The central processes enter the brain stem, bifurcate into caudal and cephalic branches, and find their nucleus of termination in a superior extension of the nucleus of the solitary tract (the ventral portion of the nucleus of the ala cinerea). The geniculate ganglion contains some cell-bodies of sympathetic neurones, left over in it during the period of migration form its homologue of the ganglion crest. The *efferent fibers* of the glossopalatine arise from cell-bodies lying dorsomedial to the nucleus of the facial and in the level between this and the nucleus of the masticator nerve anterior to it. Its cells are usually scattered in the reticular formation in line with the dorsal efferent nucleus of the vagus. Since most of its fibers, at least, are visceral efferent and connected with sympathetic neurones (terminate in sympathetic ganglia) and convey secretory impulses destined for the salivary glands, chiefly the submaxillary and sublingual, it has been called **the nucleus salivatorius.**

The abducens is a small, purely motor nerve, which supplies the lateral rectus muscle of the eye. Its *nucleus of origin* lies close to the midline in the medial eminence of the floor of the fourth ventricle, superior to and in line with that of the hypoglossus. Its root fibers, unite, pursue a ventral course, inclining a little laterally and curving inferiorly to emerge from

696.—Transverse Section Through Upper Part of Pons at the Level of the Entrance of the Trigeminus. (From Villiger.)



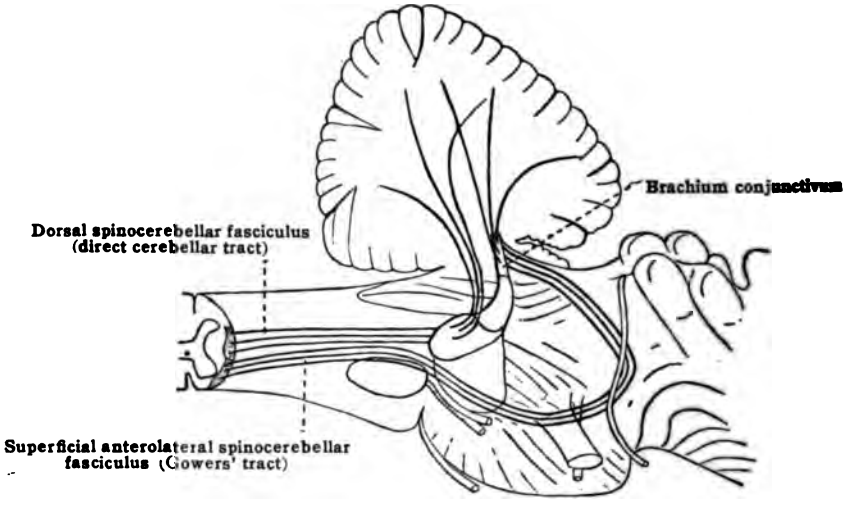
the inferior border of the pons. They pass lateral to the pyramid, and often between of its fasciculi. The nucleus receives cortical or voluntary impulses by way of the pyramidal fasciculi chiefly of the opposite side. Its connection with the auditory apparatus and the medial longitudinal fasciculus has already been noted. It probably receives afferent impulses through the fibers of the trigeminus as well as by fibers descending from the nuclei of termination of the optic nerve. It is also associated, by way of the medial longitudinal fasciculus, with the nucleus of the oculomotor nerve of the same and opposite side.

The trigeminus is considerably larger than any of the nerves inferior to it, and has the most extensive central connections of any of the cranial nerves. It is a purely sensory nerve which leaves through the brachium pontis in line with the facial nerve. It serves as the nerve of general sensibility for the face from the vertex of the scalp downward, and thus it corresponds to the afferent fibers (dorsal root) for all the nerves giving motor supply to structures underlying this domain, including the eye-muscles. Its fibers arise from its large, trilobed, **semilunar** (Gasserian) **ganglion**, situated outside the brain. This corresponds to the dorsal root-ganglion of a spinal nerve, and its cells give off the characteristic T-fibers with peripheral and central branches. The central or afferent branches upon entering the brain-steam bifurcate into ascending and descending divisions, just as the entering dorsal root-fibers of the spinal nerves, and find their *nucleus of termination* in a dorsolateral column of gray substance, lying deeply and extending longitudinally through the brain stem, and consisting of the upward continuation of the gelatinous substance of Rolando of the spinal cord. Opposite the entrance of the nerve is a considerably thickened portion of this column of gray substance, known as the *sensory nucleus* of the trigeminus, and the remainder below is called the *nucleus of the spinal tract* (figs. 688, 695). These parts are equally 'sensory.' After bifurcation the branches of the entering fibers of the trigeminus terminate about the cells of these nuclei. The descending branches are much longer

than the ascending, and in passing downward from the spinal tract of the trigeminus, which is marked in all transverse sections of the medulla oblongata (figs. 682–684, 690). The spinal tract decreases rapidly in descending the medulla, owing to the rapid termination of the fibers in the nucleus of the tract. It has been traced as far down as the second cervical segment of the spinal cord. The ascending branches terminate in the 'sensory nucleus,' and in it extension upward into the mesencephalon. This mesencephalic nucleus of termination of the trigeminus is both shorter and more scant than the spinal extension. It may extend to the superior quadrigeminate body.

Axones from the nucleus of termination of the trigeminus are distributed—(1) to the nuclei of the masticator nerve of the same and opposite sides (short or simple reflex fibers); (2) to the motor nuclei of the other motor cranial nerves, especially of the facial; (3) to the thalamus of the same and chiefly the opposite side, and thus, through interpolation of thalamic neurones, their impulses reach the somesthetic area of the cerebral cortex. These fibers form a '*trigeminal lemniscus*.' They ascend in the recticular formation of the opposite side, most of them finally coursing within the medial lemniscus. In crossing the midline they contribute to the internal arcuates. (4) Some fibers of both the trigeminus direct and from its nucleus pass laterally into the cerebellum. (5) Fibers to the quadrigeminate bodies. The longer of the reflex or association axones arising in the nucleus of termination may contribute to the medial longitudinal fasciculus; many of them descend to terminate in the gray substance of the spinal cord below the levels in which the fibers of the spinal tract proper terminate. The nucleus of termination is directly homologous to the nuclei of the fasciculus gracilis and fasciculus cuneatus, and, like the nuclei of termination of all sensory cranial nerves, it contains cell-bodies homologous to those which give rise to the fasciculi proprii and commissural fibers of the spinal cord.

FIG. 697.—DIAGRAM SHOWING THE RHOMBENCEPHALIC COURSE OF GOWERS' TRACT AND THE DIRECT CEREBELLAR TRACT.



Brachium conjunctivum
Dorsal spinocerebellar fasciculus (direct cerebellar tract)
Superficial anterolateral spinocerebellar fasciculus (Gowers' tract)

The **masticator nerve** [*portio minor n. trigemini*] is a purely motor nerve, usually called the motor root of the trigeminus from the fact only that it makes its exit from the pons by the side of the entering fibers of the trigeminus, passes outward over the ventromedial side of the semilunar ganglion and accompanies the inferior maxillary division (mandibular nerve) of the trigeminus till it divides totally into its branches for the motor supply of the muscles of mastication. It serves, therefore, as but a relatively small part of the 'motor root' of the trigeminus.

The nucleus of origin of the masticator nerve is attenuated into two parts: (1) The *chief nucleus* (*nucleus princeps*) lies on the dorsomedial side of the larger portion (sensory nucleus) of the nucleus of termination of the trigeminus. It is the larger of the two parts and gives origin to much the greater part of the masticator. (2) Scattered anteriorly and continuous with the mesencephalic extension of the chief nucleus, in line with the *locus ceruleus*, are the cell-bodies usually described as the *nucleus of the mesencephalic* (descending) *root*. These cells lie in decreasing linear distribution, through the mesencephalon, as far anterior as the posterior commissure of the cerebrum, and the *mesencephalic root* of the nerve accumulates as it descends to join the exit of the fibers arising from the chief nucleus. The average diameter of its cells is somewhat less than for the chief nucleus.

It is not clearly settled that the fibers arising from the mesencephalic nucleus of the masticator nerve go to the muscles of mastication. As suggested by Kölliker, some of these may supply the tensor veli palatini and tensor tympani muscles. Investigations of lower animals by Johnston and Willems indicate that the mesencephalic root may contain but few motor fibers, representing instead a portion of the sensory trigeminus fibers, whose cell-bodies of origin are retained during development within the central system, their peripheral processes passing out in the root of the trigeminus. It is claimed that some fibers, probably sensory, in descending give off collaterals which terminate about cells in the chief nucleus, to form simple reflex arcs.

It is claimed that each masticator nerve receives a few fibers arising from the cells of the nucleus of that of the opposite side.

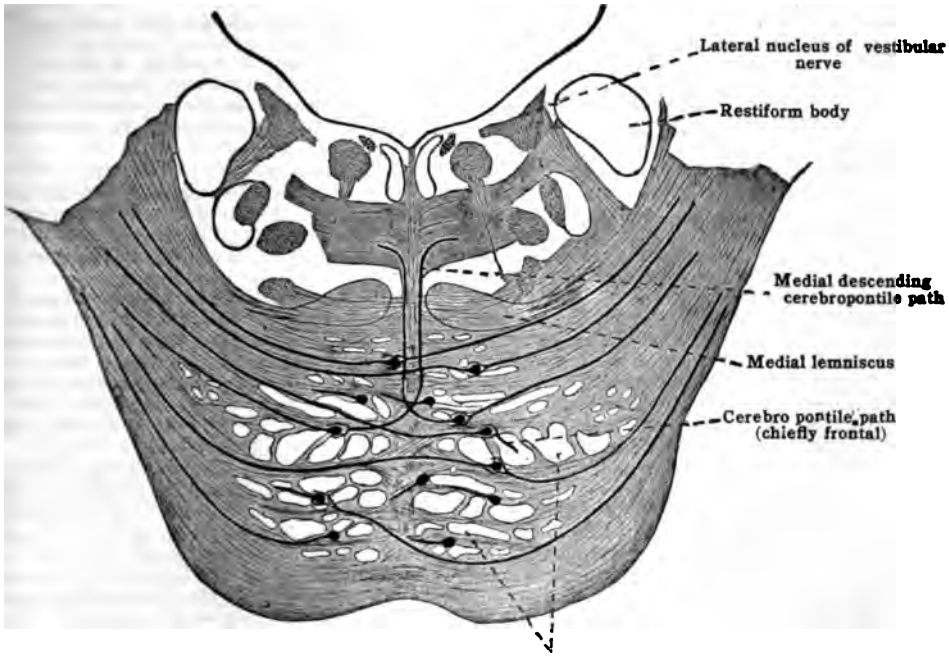
Both parts of the nucleus of the masticator receive afferent impulses brought in by the [illegible]minus of the same (chiefly) and of the opposite side, and both receive cortical impulses [illegible]bers from the inferior portion of the precentral gyrus which descend in the cerebral ped[illegible]s and cross to terminate in the nucleus of the opposite side.

The internal structure of the pons.—The nuclei and roots of the trigeminus, masticator, [illegible]ucens, facial, glossopalatine, cochlear and vestibular nerves are extended within the level [illegible]he pons, and their position and course have been described above. The pons proper [illegible] bridge) consists of a mass of transversely running fibers continuous on either side into [illegible]brachia pontis or middle cerebellar peduncles. In the animal series the relative amount [illegible]these fibers varies with the size of the cerebellum upon which they are dependent. They [illegible]relatively more abundant in man than in other animals.

In transverse sections the pons fibers are seen to course ventrally about the main axis of [illegible]brain-stem, making it possible to divide the section into a *basilar* or *ventral part* (pons proper) [illegible]a *dorsal part* (*tegmentum*). The fibers in their transverse and ventral course around the [illegible]ulla oblongata involve the pyramids. At the inferior border of the pons the fibers little [illegible]re than separate the pyramids as such from the main axis of the brain-stem, but more su[illegible]iorly the pons fibers pass through the pyramids, splitting them into the **pyramidal fasciculi.**

FIG. 698.—DIAGRAM SHOWING CONNECTIONS OF THE NUCLEI OF THE PONS

The plane of the section is obliquely transverse or parallel with the direction of the brachia pontis.



These pyramidal or chief *longitudinal fibers* of the pons are the continuation of the basal portion of the cerebral peduncles through the pons, to emerge as the pyramids proper at its inferior border. They occupy an intermediate or central area among the pons fibers of either side, leaving the periphery of the pons uninvaded. The *superficial pons-fibers* form the solid bundle of its ventral and lateral periphery and the *deep pons-fibers* form similar bundles dorsally enclosing the area of pyramidal fasciculi (figs. 693, 696, 698).

In the transverse sections through the *inferior portion* of the pons, the *dorsal or tegmental part* consists of structures continuous with and analogous to the structures of the medulla oblongata immediately below, exclusive of the pyramids. In addition, this region contains the superior olivary nucleus and the corpus trapezoideum. The significance of these structures and their relation to the nucleus of termination of the cochlear nerve is shown in figs. 691–693. In this region the *lemnicus* (fillet) changes from the sagittal to the coronal plane, and its lateral edges are becoming drawn outward and carry the lateral lemniscus of the regions superior to this. The medial longitudinal fasciculus, left alone by the change in the arrangement of the lemniscus, maintains its dorsal and medial position throughout the pons and into the mesencephalon above. The thalamo-olivary tract appears loosely collected in the dorsal part of the pons, dorsomedial to the nucleus of the superior olive.

The restiform body acquires in this inferior region a more dorsolateral position than in the medulla below. Its fibers are beginning to turn upward in their course to the cerebellum mesial to the brachium pontis. Here the restiform body is nearing completion, and the fibers now contained in it may be summarized as follows:—

(1) The fibers of the dorsal spinocerebellar fasciculus (direct cerebellar tract) of the same side

(2) Fibers from the nuclei of the fasciculus gracilis and fasciculus cuneatus of the same and opposite side (external arcuate fibers).

(3) Fibers to and from the inferior olives of the same and (chiefly) the opposite side (cerebello-olivary fibers).

(4) Sensory cerebellar fibers from the nuclei of termination of the vagus, glossopharyngeal, vestibular and trigeminus, vestibular especially, and from the cells of the reticular formation.

(5) Descending fibers to the motor nuclei of the vagus and glossopharyngeal, and probably some fibers descending into the anterior marginal fasciculus of the spinal cord, the latter, however, being in large part interrupted by cells in the nuclei of the vestibular nerve.

(6) A few fibers arising from the arcuate nuclei. These nuclei are continuous superiorly with the nuclei of the pons and some of their fibers are described as entering the cerebellum by way of the restiform body instead of by way of the brachium of the pons as in the levels above.

The ascending fibers of the restiform body are distributed to the cortex of the vermis, the nucleus of the roof (*fastigii*), the nucleus dentatus, nucleus emboliformis, and nucleus globosus.

Very few if any of the fibers ascending the cord in *Gowers' tract* enter the cerebellum by way of the restiform body. This tract (the superficial anterolateral spinocerebellar fasciculus) ascends the medulla, dispersed in the reticular formation, and therefore in a more ventral position than that of the direct cerebellar tract. In this position it becomes enclosed by the fibers of the pons, and so it passes upward, beyond the pons, around the lateral lemniscus to the brachium conjunctivum, and there turns back to enter the cerebellum by way of this brachium. Certain clinical phenomena, probably purely psychological, have been alleged to indicate that some of the fibers of Gowers' tract pass on to the cerebrum instead of turning in the medullary velum to enter the cerebellum.

The dorsal part of a transverse section through the *upper part* of the pons contains the **superior cerebellar peduncles** [brachia conjunctiva] instead of the restiform bodies or inferior peduncles. Instead of the cerebellum forming the roof of the fourth ventricle, in this region the roof is formed by the anterior medullary velum bridging the space between the two brachia conjunctiva (fig. 696). Adhering upon the medullary velum is the **lingula cerebelli**—the superior and ventral extremity of the superior vermis. This is the only portion of the cerebellum attached to this region.

The lemniscus (fillet) is found more lateral than at the inferior border of the pons, and is divided into the *medial lemniscus* and *lateral lemniscus* proper. The lateral lemniscus has shifted dorsally until in this region it courses in the dorsolateral margin of the section external to the brachium conjunctivum. The mesencephalic root of the masticator nerve occurs in the dorsolateral margin of transverse sections through this region, and this and the trigeminus are the only cranial nerves represented here.

The transverse fibers of the ventral part of the section (pons proper), and therefore the brachia pontis, consist of fibers coursing in opposite directions. Many are fibers which are outgrowths of the Purkinje cells of the cortex of the cerebellar hemispheres, and pass either directly to the cerebellar hemisphere of the opposite side or turn dorsalward in the raphe to course longitudinally in the brain-stem both toward the spinal cord and toward the mesencephalon. Others terminate in the gray substance (nuclei) of the pons. Others are fibers which arise in the gray substance of the pons and pass to the cerebellar hemispheres, and still others are the cerebropontile fibers, from the temporal, occipital and frontal lobes.

The **gray substance of the pons** [nuclei pontis] occurs quite abundantly. At the inferior border of the pons it is found concentrated about the then more accumulated bundles of the emerging pyramids, and serial sections show it to be a direct upward continuation of the arcuate nuclei of the medulla oblongata below. Higher up it is dispersed throughout the central area in the interspaces between the transverse pontile and longitudinal pyramidal fasciculi. A large portion of the nerve-fibers passing through it are thought to be interrupted by its cells, which thus serve as links in some of the neurone-chains represented by the fibers of the pons. Of the more important of such relations, the following are said to exist:—

(1) Fibers which arise in the cortex of one cerebellar hemisphere and terminate about cells of the nucleus pontis of the same and opposite side of the midline. These cells give off axones which pass to the other cerebellar hemisphere. In this relation the nuclei of the pons are analogous to the arcuate nuclei, save that the cerebellar fibers interrupted in the former are connected with the cerebellum by way of the brachia pontis instead of the restiform bodies.

(2) Certain of the descending cerebropontile fibers terminate about cells of the nuclei of the pons. Such cells give off fibers which probably, for the most part, pass to the cerebellar hemispheres, the impulses from the cerebral hemisphere of one side being conveyed to the opposite cerebellar hemisphere. Most of the descending cerebropontile fibers are thought to cross the midline to terminate about cells of the nuclei of the pons of the opposite side, a relation not sufficiently emphasized in the accompanying diagram (fig. 698).

Of the cerebropontile paths, the **frontal pontile path** (Arnold's bundle) is described as arising in the cortex of the frontal lobe (frontal operculum) passing in the anterior portion of the internal capsule down into the medial part of the base of the cerebral peduncle, and terminating in the gray substance of the pons. The descending **temporal pontile path**, (Türk's bundle), arises in the cortex of the temporal lobe, traverses the posterior portion of the internal capsule, lies lateral in the pyramidal portion of the cerebral peduncle, and terminates in the gray substance of the pons. In the posterior part of the internal capsule, the temporal pontile path is joined by a small bundle arising in the occipital lobe and going to the pons nuclei. This, supposedly smaller than the other two, adds an **occipitopontile path.**

The total area in cross section of the pyramidal fasciculi as they enter the pons above is considerably greater than that which they possess as they emerge as the pyramids of the medulla below. The difference is considered very appreciably greater than can be explained as due to the loss of pyramidal fibers supplied to the nuclei of origin of the motor cranial nerves lying within the level of the pons, and the additional difference is explained as due to the termination within the pons of the cerebropontile paths.

THE ISTHMUS OF THE RHOMBENCEPHALON

The isthmus of the rhombencephalon is nothing more than the transition of the metencephalon into the mesencephalon above. It is quite short and comprised of only the structures which run through it, namely, the *brachia conjunctiva* (superior peduncles of the cerebellum), the anterior medullary velum, the lateral sulcus of the mesencephalon, the substantia nigra, the cerebral peduncles, and the inferior end of the interpeduncular fossa. It surrounds the superior extremity of the fourth ventricle. The lateral and medial lemnisci, the superior extension of the nucleus of the trigeminus, the mesencephalic nucleus and root of the masticator nerve and Gowers' tract extend through it. At the midline, just inferior to the inferior quadrigeminate bodies is the **frenulum** of the anterior medullary velum and the trochlear nerves, decussating in this, emerge at its sides and course ventrally around the sides of the isthmus. In the lateral sulcus, the isthmus shows usually a small triangular elevation known as the **trigonum lemnisci** from the fact that the lateral lemniscus tends towards the surface in this region and the nucleus of the lateral lemniscus begins there.

Functions of the cerebellum.—From the above descriptions involving the structures of the metencephalon, it may be noted (1) that a given side of the cerebellum is associated chiefly with the same side of the general body and with the opposite side of the cerebrum. (2) That it receives afferent impulses from the spinal cord (brought into the cord by the dorsal roots of the spinal nerves) by way of the direct cerebellar fasciculus of the same side, and by Gowers' tract, arising in the same and opposite sides of the cord, and from the nuclei of the fasciculus gracilis and cuneatus of the same and opposite sides. It further receives afferent impulses from the nuclei of termination of the trigeminus, glossopharyngeal and vagus of the same side chiefly, and especially does it receive afferent impulses from the nuclei of the vestibular nerve of the opposite and same side. (3) That the cerebellum sends impulses to the red nucleus, the thalamus and the cerebral cortex of the opposite side, and some of its fibers terminate in the nuclei of termination of the vestibular nerve and probably some fibers arising in its roof nuclei descend into the spinal cord direct. (4) That the cerebellum receives impulses from the thalamus of the opposite side by way of the thalamo-olivary tract and the inferior olive, and especially from the cerebral cortex of the opposite side by way of the frontal, temporal and occipital pontile paths and the nuclei of the pons. Further, fibers from the general pyramidal fasciculi are described as terminating about cells of the nuclei of the pons and bearing impulses which are distributed to the opposite side of the cerebellum.

Taking into consideration these known associations of the cerebellum, the anatomically possible paths which in part may distribute cerebellar impulses to the gray substance sending efferent fibers to the peripheral tissues are (1) the general pyramidal fasciculi whose cortex of origin may receive impulses by *fibræ propriæ* from the cortical areas receiving impulses from the cerebellum. The pyramidal fasciculi, decussating, distribute impulses to the gray substance of the medulla and cord of the same side as that from which the cerebellocerebral impulses passed to the cortex. (2) The lateral vestibulospinal and the anterior marginal fasciculi to the ventral horn of the spinal cord of the same side, probably carrying impulses descending from the cerebellum as well as impulses brought in by the vestibular nerve and descending direct from its nuclei of termination into the spinal cord. (3) The rubrospinal tract of the cord and probably some of the thalamospinal fibers (corpora-quadrigemina-thalamus path), the red nuclei and thalami being associated abundantly with the cerebellum. These tracts likewise decussate in descending but likewise do the cerebellar impulses ascending to the red nuclei and thalami.

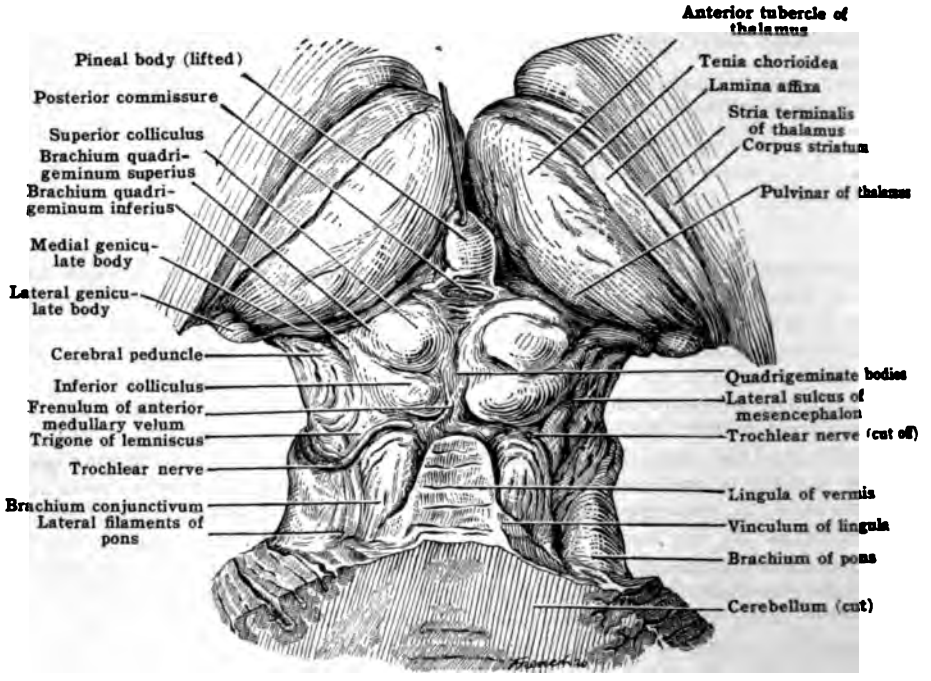
Whatever other functions it may possess, developmental defects and pathologic lesions show that the cerebellum has to do with muscular tone, with the equilibration of the body and the finer coördinations, the adjustive control of contractions of functionally correlated groups of muscles. Making this possible, in part at least, it is seen above that it is associated (1) directly with the special nerve of equilibration, the vestibular; (2) with the optic apparatus by way of the thalamus, and (3) with the afferent impulses from the general body, by way of the direct cerebellar and Gowers' tracts, by way of the nuclei of the fasciculus gracilis and cuneatus, and the nuclei of termination of the trigeminus, glossopharyngeal and vagus. It has been suggested that by way of these latter paths the cerebellum deals especially with those general afferent impulses which arise within the muscles of the body (sensory fiber-terminations on tendons, muscle-sheaths, neuromuscular spindles, etc.), and which are grouped under the name 'Proprioceptive.' Its activities are considered as not entering 'consciousness,' while sensations of 'muscular sense,' and pain from joints, muscles and tendons must reach the *cerebral* cortex and are there recognized as such.

Studies of the comparative anatomy of the cerebellum by Elliot Smith, Bolk and van Rynberk, experimental studies by André-Thomas and Durupt, and clinical studies of symptoms resulting from localized lesions in the human cerebellum by Bárány and others have led to the conclusion that there is a certain amount of localization of function in the cerebellar gray substance. In fig. 699 are indicated some of the functional areas of the cerebellar cortex suggested. It will be seen that the anatomical distinction made between the cerebellar hemispheres and the vermis is not functionally important, especially on the superior surface. Beginning on the superior surface, the following areas may be noted:—The anterior part of the quadrangular lobe, the culmen and the central lobule with its ala comprise an unpaired area for the coördinations of muscular contraction resulting in subconscious movements of the head. The posterior

colliculus, so do some fibers from the optic tract pass into the inferior colliculus. Also some fibers form the optic tract (medial root) are said to terminate in the medial geniculate body. Resting in the broadened medial groove between the superior quadrigeminate bodies lies the non-nervous **pineal body** (epiphysis). This also belongs to the thalamencephalon. Under the stem of the pineal body is a strong transverse band of white substance crossing the middle as a bridge over the opening of the cerebral aqueduct into the third ventricle. This is the **posterior commissure** of the cerebrum, and contains commissural fibers arising in both the thalamencephalon and mesencephalon. The triangular area bounded by the stem of the epiphysis, the thalamus, and the superior colliculus with its brachium, is known as the **habenular trigone.**

Inferiorly, the lamina quadrigemina is continuous with the isthmus of the rhombencephalon by way of the brachia conjunctiva or superior cerebellar peduncles, and the anterior medullary velum which bridges between the medial margins of these peduncles. The narrowed superior end of the velum, the part directly below the inferior quadrigeminate bodies, is thickened into a well-defined white

FIG. 700.—DORSAL SURFACE OF MESENCEPHALON AND ADJACENT PARTS. (After Spalteholz.)



band known as the **frenulum veli.** From the lateral margins of this band on each side and just below the inferior quadrigeminate bodies emerge the **trochlear nerves** (the fourth pair of cranial nerves), and the increased thickness of the band is largely due to the decussation of this pair of nerves taking place within it.

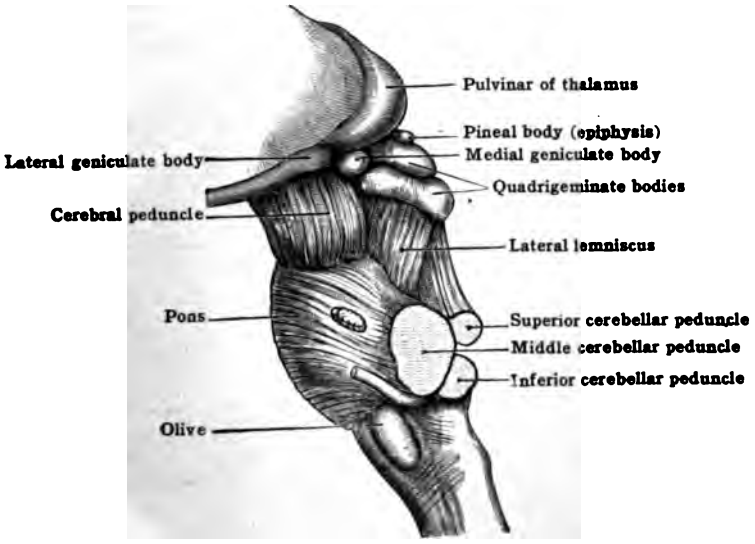
The brachium conjunctivum, together with the inferior and superior colliculi of each side, form a marked ridge which results in the *lateral sulcus* of the mesencephalon, a lateral depression between the base of this ridge and the cerebral peduncle below and continuous into the transverse sulcus at the superior border of the pons. The ridge is thickened laterally by the lateral lemniscus, which is disposed as a band of white substance passing obliquely upward from under the brachium pontis, applied to the lateral surface of the brachium conjunctivum and which enters the lateral margin of the mesencephalon. The region at which the lateral lemniscus approaches nearest the surface and in which the largest portion of its nucleus lies is the slightly elevated **trigone of the lemniscus.**

The **ventral surface** of the mesencephalon is formed by the **cerebral peduncles** (crura), two large bundles of white substance which are close to one another at the superior margin of the pons, but immediately diverge somewhat, producing the **interpeduncular fossa,** and in so doing pass upward and lateralward to disappear beneath the optic tracts (fig. 709). The *posterior recess* of the interpeduncular fossa extends slightly under the superior margin of the pons, while its *anterior*

[redacted] is occupied by the corpora mammillaria of the prosencephalon. The triangular floor of the fossa is the **posterior perforated substance,** a grayish area presenting numerous openings for the passage of blood-vessels. It is divided by a shallow median (oculomotor) groove and is marked off from the medial surface of each peduncle by the lateral furrows, out of which emerge the root filaments of the **oculomotor nerve.** Each oculomotor nerve, formed by assembly of its root filaments makes an impression in the medial surface of the peduncle, the *oculomotor sulcus.* The ventral surface of each peduncle is rounded and has a somewhat twisted appearance, indicating that its fibers curve from above medialward and downward (fig. 709).

Sometimes two small, more or less transverse bands of fibers may be noted crossing the peduncle—an inferior, the *tenia pontis,* and a superior, the *transverse peduncular tract.* The inferior represents detached fibers of the pons; the superior, running from the brachium of the inferior quadrigeminate body and disappearing in the oculomotor sulcus, appears to be derived from the quadrigeminate bodies. Since it is well developed in the cat, dog, sheep, and rabbit, but is absent or little marked in the mole, it is supposed to be concerned with the optic apparatus.

FIG. 701.—DIAGRAM OF LATERAL VIEW OF MESENCEPHALON AND ADJACENT STRUCTURES. (After Gegenbaur, modified.)

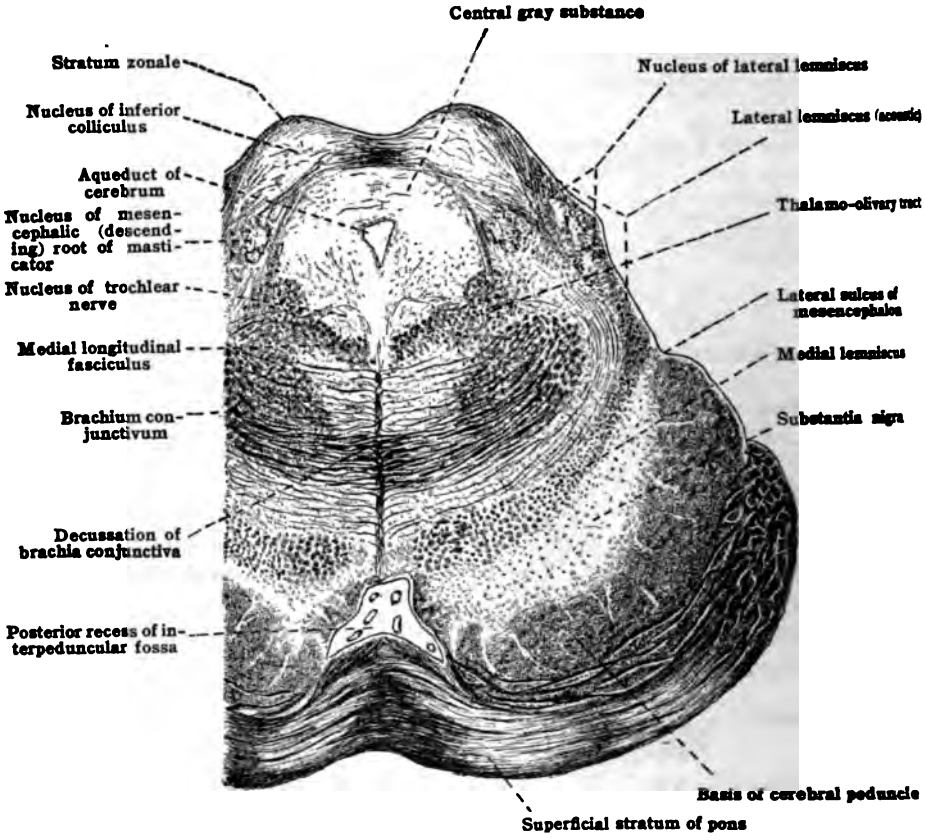


Internal structure.—Transverse sections of the mesencephalon (figs. 702, 703) throughout are composed of—(1) a *dorsal part,* consisting of the lamina quadrigemina or the gray substance of the corpora quadrigemina, with the strata and bundles of nerve-fibers connected with them, and the abundant central gray substance surrounding the aqueduct; (2) a *tegmental part,* consisting of the upward continuation of the reticular formation of the medulla oblongata and that of the dorsal (tegmental) portion of the pons region, to which are added the superior cerebellar peduncles and the red nuclei of the tegmentum in which these peduncles terminate; (3) a paired *ventral part,* the cerebral peduncles, each of which consists of a thick, pigmented stratum of gray substance, the *substantia nigra,* spread upon the large, superficial, and somewhat crescentic tract of white substance known as the *basis* of the peduncle. The bases of the peduncles correspond to the longitudinal or pyramidal fasciculi of the pons and medulla. Likewise the lemniscus and the medial longitudinal fasciculus of the medulla and pons continue through all sections of the mesencephalon, dorsal to the substantia nigra.

The **central gray substance** is a continuation of the central gelatinous substance of the spinal cord and the similar stratum of the medulla and that which immediately underlies the ependyma of the fourth ventricle. As in the spinal cord and medulla, it is largely composed of gelatinous substance. It is much more abundant in the mesencephalon, and in sections appears as a circumscribed area comparatively void of nerve fibers.

The nucleus of the *mesencephalic root of the masticator nerve* and that of the mesencephalic tract of the trigeminus may likewise be traced throughout the mesencephalon. The former consists of a few small bundles of fibers surrounding a thin strand of nerve cells which give origin to its fibers. It courses caudalward close to the lateral margin of the central gray substance, and is quite small at its begining in the extreme superior part of the mesencephalon, but as it descends toward the exit of its fibers from the pons, it increases slightly in size, due to the progressive addition of fibers. Its nucleus also increases slightly in bulk in approaching the region of the chief motor nucleus of the nerve. As mentioned above, the investigations of Johnston and Willems in lower animals suggest that many cells of the mesencephalic nucleus may be sensory instead of motor in character. The sensory nucleus (nucleus of termination) of the mesencephalic tract of the trigeminus tapers rapidly but probably extends throughout the mesencephalon.

FIG. 702.—TRANSVERSE SECTION THROUGH THE INFERIOR QUADRIGEMINATE BODIES.



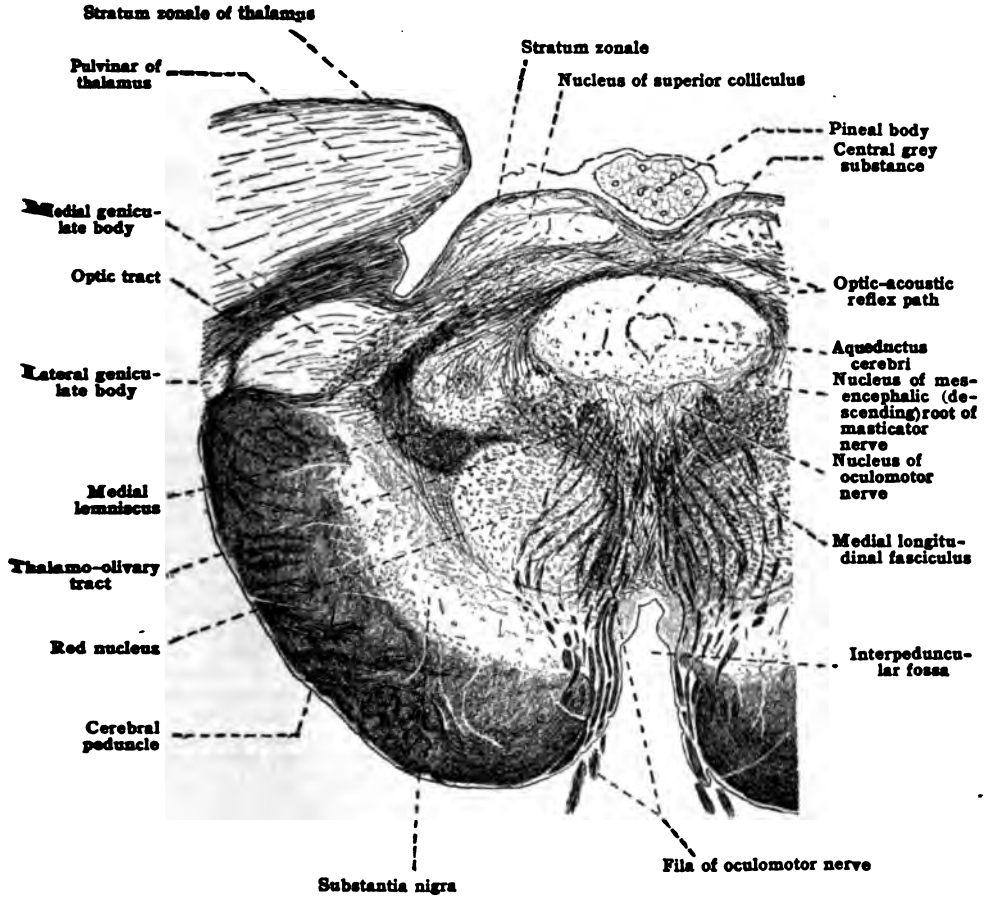
The nuclei of the *trochlear* and *oculomotor* nerves form a practically continuous column of nerve-cells extending close to the midline and ventral to the aqueduct of the cerebrum. They are in line with the nuclei of origin of the abducens and hypoglossus, and, like them, may be regarded as an upward continuation of the ventral group of the cells of the ventral horn of the spinal cord. The portion of the column giving origin to the oculomotor nerve is considerably larger than that for the trochlear.

A transverse section through the inferior quadrigeminate bodies involves a portion of the decussation of the brachia conjunctiva and the nuclei of origin of the trochlear nerves, while a transverse section through the superior quadrigeminate bodies passes through the red nuclei of the tegmentum and the nuclei of origin of the oculomotor nerves. The latter section will also involve the brachia of the inferior quadrigeminate bodies and the medial geniculate bodies connected with them, and, if slanting slightly forward it will involve the pulvinars of the thalami and the lateral geniculate bodies.

The trochlear (or fourth) is the smallest of the cranial nerves, and is the only one which makes its exit from the dorsal surface of the brain, as well as the only one whose fibers undergo a total decussation.

Its nucleus of origin is situated beneath the inferior quadrigeminate bodies in the ventral margin of the central gray substance, quite close to the midline and to its fellow nucleus of opposite side, and it is closely associated with the dorsomedial margin of the medial longitudinal fasciculus. Its root-fibers pass lateralward and dorsalward, curving around the margin of the central gray substance, medial to the mesencephalic root of the masticacor nerve. As the root curves toward the midline in the dorsal region just beneath the inferior quadrigeminate bodies, it turns sharply and courses inferiorly to approach the surface in the superior portion of the anterior medullary velum, the frenulum veli. In this it meets and undergoes a total decussation with the root of its fellow nerve, and then emerges at the medial margin of the superior cerebellar peduncle of the opposite side. Having emerged, it passes ventrally around the cerebral peduncle, and thence pursues its course to the superior oblique muscle of the eye. It receives optic impulses from the superior quadrigeminate bodies and impulses from the cerebral cortex of chiefly the same side, and it is associated with the nuclei of other cranial nerves by way of the medial longitudinal fasciculus.

FIG. 703.—TRANSVERSE SECTION THROUGH LEVEL OF SUPERIOR QUADRIGEMINATE BODIES.



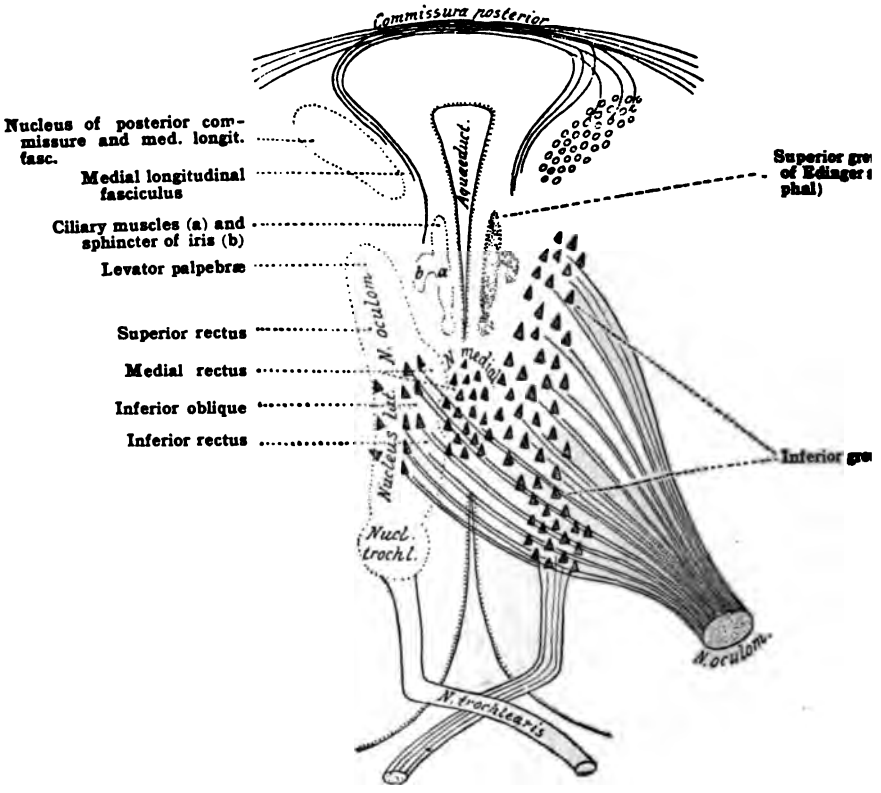
The oculomotor (or third) nerve, like the trochlear, is purely motor. It is the largest of the eye-muscle nerves. It supplies in all seven muscles of the optic apparatus:—two intrinsic, the sphincter iridis and the ciliary muscle (visceral efferent fibers), and five extrinsic (somatic efferent fibers). Of the latter, the levator palpebræ superioris is of the upper eyelid, while the remaining four, the superior, medial, and inferior recti and the obliquus inferior, are attached to the eyeball. As is to be expected, its nucleus of origin is larger and much more complicated than that of the trochlear nerve.

Practically continuous with that of the trochlear below, the nucleus is 5 or 6 mm. in length and extends anteriorly a short distance beyond the bounds of the mesencephalon into the gray substance by the side of the third ventricle. It lies in the ventral part of the central gray substance, and is very intimately associated with the medial longitudinal fasciculus. Its thickest portion is beneath the summit of the superior quadrigeminate body. The root-fibers leave the nucleus from its ventral side and collect into bundles which pass transversely through the medial longitudinal fasciculus and course ventrally to the medial portion of the substantia nigra,

where they emerge in from six to fifteen filaments which blend to form the trunk of the
the oculomotor sulcus of the cerebral peduncles. Those bundles which arise from t
lateral portion of the nucleus course in a series of curves through and around the substan
red nucleus below and, in the substantia nigra, join those which pursue the more direct
The trunk thus assembled passes lateralward around the medial border of the
peduncle.

A portion of the fibers of the oculomotor nerve upon leaving the nucleus decussat
tegmentum immediately below and pass into the nerve of the opposite side, in which
believed to be distributed to the opposite medial rectus muscle. The cells of the nucle
been variously grouped (fig. 704) and subdivided with reference to the different muscles
by the nerve. Perlia has divided them into eight cell-groups. The nucleus may be mo
considered as composed of an inferior and a superior medial group. The inferior group
of a long lateral portion continuous with the nucleus of the trochlear nerve below, and

FIG. 704.—DIAGRAM OF LONGITUDINAL SECTION OF NUCLEUS OF OCULOMOTOR NE
(After Edinger.)



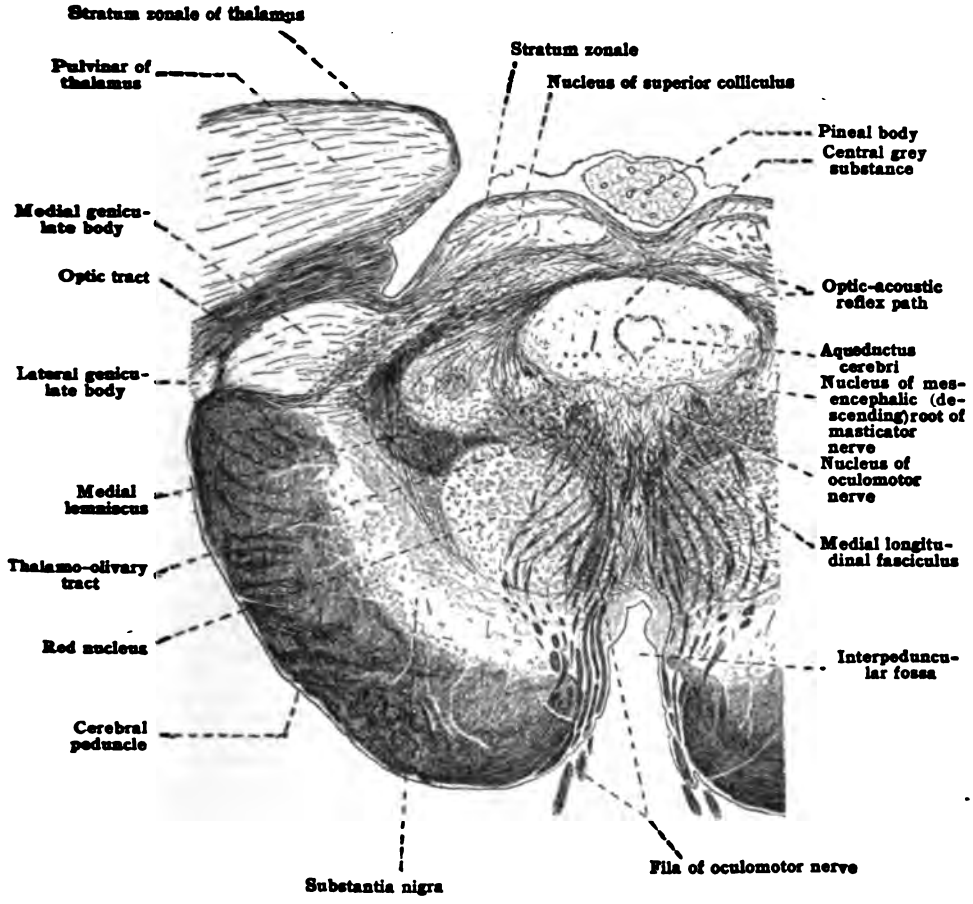
medial portion, situated in the medial plane and continuous across the midline with
of the opposite side. The superior medial group consists of cells of smaller size
inferior, and is known as the *nucleus of Edinger and Westphal*. It is believed to give
the fibers (visceral efferent fibers) which terminate in the ciliary ganglion, axones fr
supply the two intrinsic muscles concerned, viz., the ciliary muscle and the sphincte

The nucleus of the oculomotor is associated with the remainder of the optic appa
by way of the neurones of the superior quadrigeminate body with the optic tract (re
it receives impulses from the occipital part of the cerebral cortex of the same amd th
sides, and probably from the motor cortex of the frontal lobe; (2) by way of the medial
nal fasciculus with the nuclei of the trochlear and abducens (the latter making possit
ordinate action of the lateral and medial recti for the conjugate eye-movements pr
these muscles), and with the nucleus of the facial (associating the innervation of t
palpebræ with that of the orbicularis oculi); (3) with the nuclei of termination of th
nerves, especially the auditory, by way of the lateral lemniscus and medial lo
fasciculus. It is probably associated with the cerebellum by way of the brachia co
and red nuclei.

The eminence representing the **inferior quadrigeminate body proper** of an oval mass of gray substance, the *nucleus of the inferior colliculus*, co numerous nerve-cells, most of which are of small size. A thin superficia of white substance, the **stratum zonale**, forms its outermost bounda fibers from the lateral lemniscus enter it laterally and from below

Its nucleus of origin is situated beneath the inferior quadrigeminate bodies in the ventral margin of the central gray substance, quite close to the midline and to its fellow nucleus of the opposite side, and it is closely associated with the dorsomedial margin of the medial longitudinal fasciculus. Its root-fibers pass lateralward and dorsalward, curving around the margin of the central gray substance, medial to the mesencephalic root of the masticacor nerve. As the root curves toward the midline in the dorsal region just beneath the inferior quadrigeminate bodies, it turns sharply and courses inferiorly to approach the surface in the superior portion of the anterior medullary velum, the frenulum veli. In this it meets and undergoes a total decussation with the root of its fellow nerve, and then emerges at the medial margin of the superior cerebellar peduncle of the opposite side. Having emerged, it passes ventrally around the cerebral peduncle, and thence pursues its course to the superior oblique muscle of the eye. It receives optic impulses from the superior quadrigeminate bodies and impulses from the cerebral cortex of chiefly the same side, and it is associated with the nuclei of other cranial nerves by way of the medial longitudinal fasciculus.

FIG. 703.—TRANSVERSE SECTION THROUGH LEVEL OF SUPERIOR QUADRIGEMINATE BODIES.

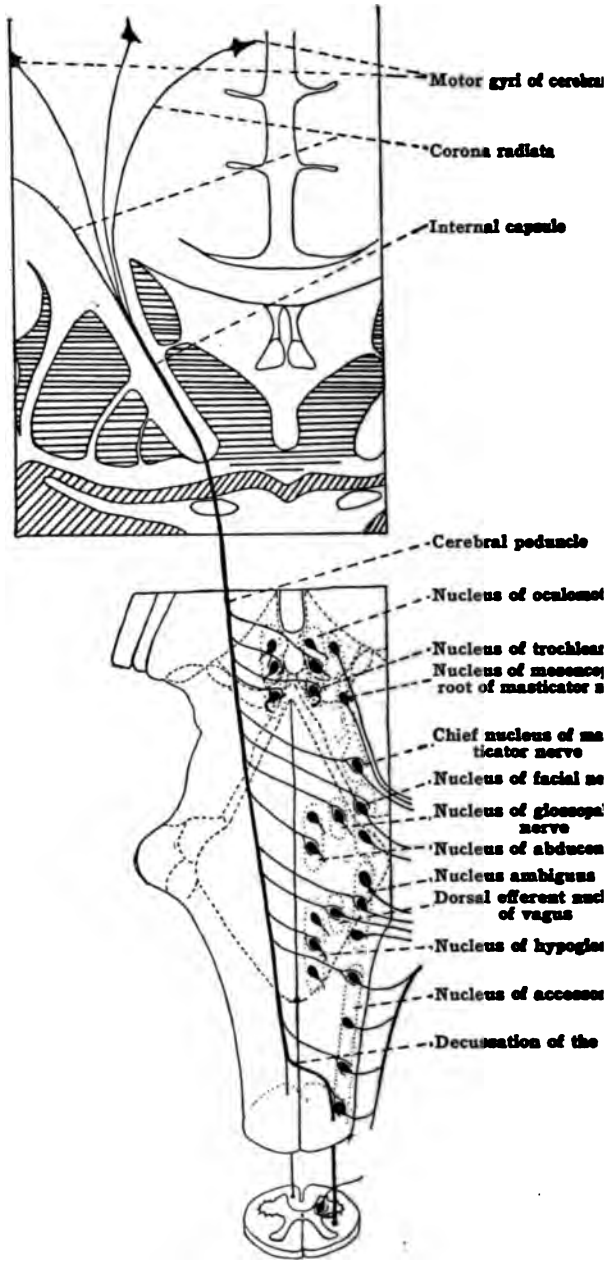


The **oculomotor** (or third) nerve, like the trochlear, is purely motor. It is the largest of the eye-muscle nerves. It supplies in all seven muscles of the optic apparatus:—two intrinsic, the sphincter iridis and the ciliary muscle (visceral efferent fibers), and five extrinsic (somatic efferent fibers). Of the latter, the levator palpebræ superioris is of the upper eyelid, while the remaining four, the superior, medial, and inferior recti and the obliquus inferior, are attached to the eyeball. As is to be expected, its nucleus of origin is larger and much more complicated than that of the trochlear nerve.

Practically continuous with that of the trochlear below, the nucleus is 5 or 6 mm. in length and extends anteriorly a short distance beyond the bounds of the mesencephalon into the gray substance by the side of the third ventricle. It lies in the ventral part of the central gray substance, and is very intimately associated with the medial longitudinal fasciculus. Its thickest portion is beneath the summit of the superior quadrigeminate body. The root-fibers leave the nucleus from its ventral side and collect into bundles which pass transversely through the medial longitudinal fasciculus and course ventrally to the medial portion of the substantia nigra,

hypothalamic region above. Its remarkable abundance begins at the s
border of the pons, and it conforms to the crescentic inner contour of the
the peduncle, sending numerous processes which occupy the interfascicular
of the latter. It contains numerous deeply pigmented nerve-cells, which
fresh specimen give the appearance suggesting its name.

FIG. 705.—SCHEME TO ILLUSTRATE THE PRINCIPAL OR CROSSED RELATIONS OF THE D
ING CORTICAL (PYRAMIDAL) FIBERS TO THE NUCLEI OF ORIGIN OF THE CRANIAL NI



Its anatomical significance is not well understood. It is known that some fib
medial lemniscus terminate about its cells instead of in the hypothalamus highe
Mellus has found in the monkey that a large portion of the pyraidal fibers arising in t
area of the cerebral cortex are interrupted in the substantia nigra. It is probable that o
of the peduncle also terminate here, its cells serving as relays in the descending cortic

The brachia conjunctiva or superior cerebellar peduncles, in passing fr
origin in the dentate nuclei, lose their flattened form and enter the mesen

lemnisci). Near the lateral margin of the central gray substance occurs the beginning of the *inferior brachium*, a bundle containing fibers chiefly from the lateral lemniscus to the medial geniculate body and from the cerebral cortex to the inferior quadrigeminate body.

The lemniscus in the mesencephalon is considered in three parts. The more lateral portion of the lemniscal plate occurring in the pons has here spread dorsolaterally, and occupies a position in the lateral margin of the section, and is known as the **lateral lemniscus**, while the medial portion which remains practically unchanged in the tegmentum is distinguished as the **medial lemniscus** (fig. 702). In the upper portion of the lateral lemniscus occurs a small, scattered mass of gray substance, *nucleus of the lateral lemniscus*, in which a few of its fibers are interrupted. The **trigeminal lemniscus** is described as being detatched from the medial lemniscus throughout the mesencephalon and as coursing in the gray substance, medial to the lateral lemniscus.

The greater portion of the **lateral lemniscus** with its nucleus belongs to the auditory apparatus, bearing impulses from the nuclei of termination of the cochlear nerve, chiefly of the opposite side (fig. 691). A large part of the fibers of this auditory portion terminate in the inferior quadrigeminate bodies. Many of the latter enter at once the nucleus of the body (nucleus of inferior colliculus) of the same side, and disappear among its cells; smaller numbers cross the midline to the quadrigeminate body of the opposite side. In crossing, some pass superficially and thus contribute to the stratum zonale, while others pass either through the nucleus or below it and cross beneath the floor of the median groove between the stratum zonale and the dorsal surface of the central gray substance, forming there an evident decussation with similar fibers crossing from the opposite side. Many fibers arising from the nucleus of the lateral lemniscus are said to pass into the reticular formation, serving in auditory reflexes. Most of the fibers arising from the cells of the nucleus of the inferior quadrigeminate body pass ventrally to terminate in the nucleus of origin of the trochlear nerve, but very few pass forward and laterally to terminate in the cortex of the superior gyrus of the temporal lobe, the cortial area of hearing. A large portion of the lateral lemniscus passes obliquely forward in the inferior brachium, and terminates in the medial geniculate body, the cells of which send fibers to the cortical area of hearing. Thus a large portion of the lateral lemnisci, the inferior quadrigeminate bodies with their brachia and the medial geniculate bodies are concerned with the sense of hearing. The nucleus of the inferior quadrigeminate body receives fibers which arise in the cortex of the superior temporal gyrus of chiefly the same side.

The remaining portions of the lateral lemniscus consist of (1) the spinothalamic part of the spinal lemniscus which, occupies the ventral edge of the lateral lemniscus and courses forward to terminate in the ventral part of the thalamus, and (2) the spinotectal part of the spinal lemniscus, which courses in the extreme dorsal edge of the lateral lemniscus and is dispersed to terminate in the nuclei of the quadrigeminate bodies. In terminating in the nucleus of the superior quadrigeminate body, these spinotectal fibers are joined by some fibers of the auditory portion of the lateral lemniscus of the same and opposite side. Together, the spinal and auditory fibers approach the nucleus from below, and contribute to the well-marked band of fibers coursing on the dorsolateral margin of the central gray substance, and known as the *'optic-acoustic reflex path'* or *stratum lemnisci* (fig. 703).

The **medial lemniscus** arises in the medulla oblongata from the nuclei (of termination) of the funiculus gracilis and funiculus cuneatus of the opposite side, and likewise from the nuclei of termination of the sensory roots of the cranial nerves of the opposite side. It is, therefore, a continuation of the central sensory pathway conveying the general bodily (including the head) sensations into the prosencephalon. Coursing still more laterally than in the pons below, it passes into the inferolateral gray substance of the thalamus, in which most of its fibers terminate. By axones given off from the cells of the inferolateral thalamic gray substance the impulses borne thither by the lemniscus are conveyed by way of the internal capsule and corona radiata to the gyri of the somesthetic area of the cerebral cortex. The trigeimnal lemniscus, here detached from the medial as noted above, arises from the nucleus of termination of the trigeminus of the opposite side and terminates as does the remainder of the medial lemniscus.

The basis (pes) pedunculi comprises the great descending pathway from the cerebral cortex, and thus is continuous with the internal capsule of the telencephalon.

The principal components of each basis pedunculi are as follows:—(1) The *pyramidal fibers*, which occupy the middle portion of the peduncle and comprise three-fifths of its bulk, and which are outgrowths of the giant pyramidal cells of the motor areas of the cerebral cortex, chiefly anterior central gyrus. These supply 'voluntary' impulses to the motor nuclei of the cranial nerves on the opposite side, form the pyramids of the medulla, and are distributed to the ventral horn cells of the spinal cord of the opposite side. (2) The *frontal pontile fibers*, which course in the mesial part of the peduncle from the cortex of the frontal lobe to their termination in the gray substance of the pons. (3) The *occipital and temporal pontile fibers* which run in the lateral portion of the peduncle from their origin in the occipital and temporal lobes to their termination in the gray substance of the pons.

The substantia nigra is continuous with the gray substance of the pons, the arcuate nuclei, and that of the reticular formation below, and with that of the

decussating the fibers turn in spray-like curves downward and soon join the medial longitudinal fasciculus. This is the **'fountain decussation'** of Forel. Decussating fibers which arise in the nucleus of the oculomotor nerve also cross in this decussation and it is said to be augmented by decussating fibers from the two red nuclei.

There is abundant evidence that fibers arising in the corpora quadrigemina descend into the spinal cord. Various studies make it appear that at least part of these are fibers from the fountain decussation, and that these course through the medulla oblongata in the ventral part of the medial longitudinal fasciculus, and thence descend into the cord as the sulcomarginal fasciculus and in the tectospinal path of the opposite side. The termination of some of these fibers about those ventral horn cells of the cervical and upper thoracic cord which send fibers through the rami communicantes probably establishes the pathway by which the superior quadrigeminate bodies are connected with the cervical sympathetic ganglia, and by which may be explained the disturbances in pupillary contraction induced by lesions of the cervical and upper thoracic spinal cord.

The medial geniculate body and the medial root of the optic tract, which runs into the former, probably have nothing to do with the functions of the optic apparatus. Both remain intact after extirpation of the eyes. The medial root of the optic tract is apparently nothing more than the beginning of the *inferior cerebral (Gudden's) commissure*, a bundle passing by way of the optic tract and chiasma, connecting the medial geniculate body of one side with that of the other side, and probably with the inferior colliculus.

The **medial longitudinal fasciculus** (posterior longitudinal fasciculus), continuous into the ventral fasciculus proprius and the sulcomarginal fasciculus of the spinal cord, extends throughout the rhombencephalon and mesencephalon, and is represented in the hypothalamic region of the prosencephalon. Deserted by the lemniscus at the inferior border of the pons, it maintains its closely medial position and courses throughout in the immediate ventral margin of the central gray substance of the medulla and floor of the fourth ventricle, and likewise in the ventral margin of the central gray substance of the mesencephalon.

The two fasciculi constitute the principal of the longer association pathways of the brain stem, and, true to their nature as such, they are among the first of its pathways to acquire medullation. In the mesencephalon they become two of its most conspicuous tracts, and their course in most intimate association with the nuclei of origin of the nerves supplying the eye-muscles suggests what is probably one of their most important functions, viz., that of associating these nuclei with each other and of bearing to them fibers from the nuclei of the other cranial nerves necessary for the co-ordinate action of the muscles of the optic apparatus associated with the functions of these other nerves.

Fibers from each medial longitudinal fasciculus terminate either by collaterals or terminal arborizations about the cells of the motor nuclei of all the cranial nerves, and each nucleus probably contributes fibers to it. It also receives fibers from the nuclei of termination of the sensory nerves especially the vestibular and cochlear. Thus it contains fibers coursing in both directions, and, while it is continually losing fibers by termination, it is being continually recruited and so maintains a practically uniform bulk. Thus, a given lesion never results in its total degeneration. Many of the fibers coursing in it arise from the opposite side of the midline. A special contribution of fibers of this kind is received by way of the fountain decussation from the nucleus of the superior colliculus of the opposite side. As noted above, it is in part continuous into the spinal cord as the ventral fasciculus proprius. It receives some fibers by way of the posterior commissure of the prosencephalon from a small nucleus, common to it and the posterior commissure, situated in the superior extension of the central gray substance of the mesencephalon. Van Gehuchten and Edinger describe for it a special *nucleus of the medial longitudinal fasciculus* situated beyond this commissure in the hypothalamic region. This nucleus may be explained as an accumulation of the gray substance of the reticular formation below and as receiving impulses from the structures of the prosencephalon which are distributed by its axones to the structures below by way of the medial longitudinal fasciculus.

Scattered in the posterior part of the posterior perforated substance, near the superior border of the pons, is a small group of cell-bodies forming the interpeduncular nucleus (interpeduncular ganglion of von Gudden). Fibers arising in the habenular nucleus of the diencephalon curve posteriorly, forming the *fasciculus retroflexus of Meynert*, and terminate about its cells. Fibers arising from its cells course dorsalward and terminate about association neurones in the ventral periphery of the central gray substance. It is concerned with olfactory impulses.

SUMMARY OF THE MESENCEPHALON

1. Quadrigeminate bodies:
   (*a*) Inferior colliculi, their nuclei and brachia.
   (*b*) Superior colliculi, their nuclei and brachia.
2. Peduncles of the cerebrum.
3. Aqueduct of the cerebrum.
4. Central gray substance.
5. Substantia nigra.
6. Decussation of superior cerebellar peduncles; the red nuclei.
7. Medial lemniscus, lateral lemniscus and nucleus of lateral lemniscus.
8. Mesencephalic nucleus and root of masticator nerve, and mesencephalic tract of the trigeminus with its nucleus.
9. Trochlear nerve and its nucleus.

as rounded bundles. In the tegmentum, under the inferior colliculi, the two brachia come together and undergo a sudden and complete decussation. Through this decussation the fibers of the brachium of one side pass forward to terminate, most of them, in the red nucleus [nucleus ruber] of the tegmentum of the opposite side (fig. 703). Some fibers are said to pass the red nucleus and terminate in the inferolateral part of the thalamus.

The red nuclei are two large, globular masses of nerve-cells situated in the tegmentum under the superior quadrigeminate bodies. At all levels they are considerably mixed with the entering bundles of the brachia conjunctiva, and they contain a pigment which in the fresh condition gives them a reddish color, suggesting their name.

They receive in addition descending fibers from the cerebral cortex (frontal operculum) and from the nuclei of the corpus striatum. From the cells of each red nucleus arise fibers which pass—(1) into the thalamus and to the telencephalon (prosencephalic continuation of the cerebellar path), and (2) fibers which descend as the 'rubroreticular' and the 'rubrospinal, tracts, in the lateral funiculus (fig. 661). The latter cross from the red nucleus of the opposite side and descend in the tegmentum. The red nuclei are also in relation with the *fasciculus retroflexus* of Meynert, which belongs to the interbrain.

The thalamo-olivary tract courses in the mesencephalon more dorsally than in the pons region. It runs in the ventrolateral boundary of central gray substance just lateral to the nuclei of the trochlear and oculomotor nerves.

A small *quadrigeminopontile* strand of fibers has been described as arising in the quadrigemina, especially the inferior pair, and terminating in the nuclei of the pons. Impulses carried by these fibers are probably destined for the cerebellar hemisphere of the opposite side.

The superior quadrigeminate bodies (superior colliculi) are phylogenetically more important than the inferior. In certain of the lower vertebrates they are enormously developed and in most of the mammals they are relatively larger and appear more complicated in structure than in man. They are concerned almost wholly with the visual apparatus mediating most of the reflexes with which it is concerned.

The *nucleus* of the superior colliculus is of somewhat greater bulk than that of the inferior. It is capped by a strong *stratum zonale* (fig. 703), which has been described as composed chiefly of retinal fibers, passing to it from the optic tract by way of the superior brachium; but, since Cajal found in the rabbit that extirpation of the eye is followed by very slight degeneration of the stratum zonale, it is probable that it is composed of other than retinal fibers—possibly fibers from the occipital cortex and fibers arising within the nucleus itself. The nucleus is separated from the central gray substance by a well marked band of fibers, the *stratum album profundum*. This contains fibers from two sources:—(1) fibers from the lateral lemniscus which approach the nucleus from the under side, some to terminate within it, others to cross to the nucleus of the opposite side; (2) fibers which arise within the nucleus and course ventrally around the central gray substance, both to terminate in the nucleus of the oculomotor nerve and to join the medial longitudinal fasciculus and pass probably to the nuclei of the trochlear and abducens. The lemniscus fibers often course less deeply than (2) and give the *stratum lemnisci*. The optic fibers proper approach the nucleus by way of the *superior brachium*, and are dispersed directly among its cells; only a small proportion of them cross over to terminate in the nucleus of the opposite side. They consist of two varieties:—(1) retinal fibers which arise in the ganglion-cell layer of the retina and enter the superior brachium at its junction with the lateral root of the optic tract, and (2) fibers from the visual area of the occipital lobe of the cerebral hemisphere. Sometimes the optic fibers in their course within the nucleus of the superior colliculus form a more or less evident stratum near the stratum zonale This is known as the *stratum opticum* (stratum album medium). The portion of the nucleus between this stratum and the stratum zonale is then called the *stratum cinereum*.

The fibers entering the nucleus from the lateral lemniscus probably all represent auditory connections. The stratum album profundum, composed of the lemniscus fibers and fibers from cells of the nucleus, and the stratum opticum together, form the so-called **'optic-acoustic reflex path'** (fig. 703).

The **tectospinal** and the **spinotectal** (spinomesencephalic) paths course together ventrolateral to the nuclei of the colliculi. In the superior quadrigeminate bodies they course in the dorsal edge of the medial lemniscus, between the stratum opticum and stratum album profundum.

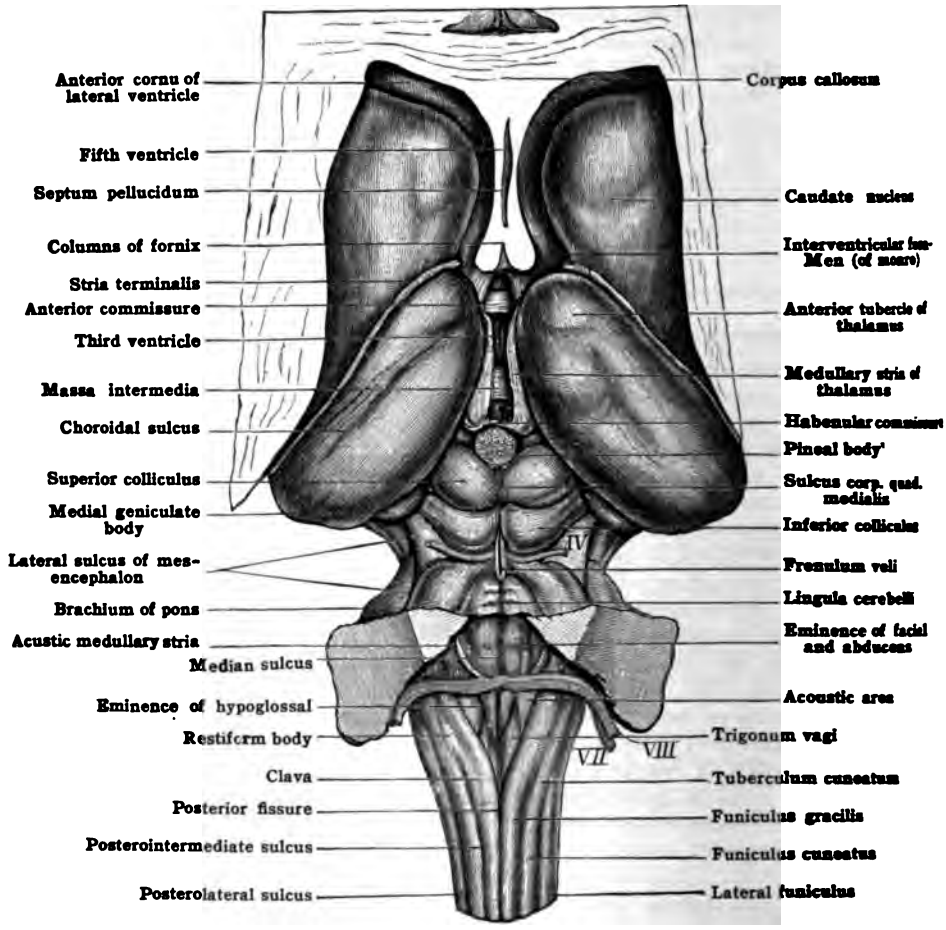
From the various studies that have been made it appears that the superior colliculus of the corpora quadrigemina is merely the central reflex organ concerned in the control of the eye muscles—eye muscle reflexes which result from retinal and cochlear stimulation, and from some general body sensations by way of the spinal cord and trigeminus. Fibers from its nucleus to the visual area of the occipital cortex have been claimed for certain mammals, but in man the superior colliculus may be entirely destroyed without disturbance of the perception of light or color and fibers arising from its nucleus to terminate in the cerebral cortex are denied.

In the level of the anterior part of the superior colliculus the fibers which arise from the cells of its nucleus and course ventrally in the stratum album profundum collect into a strong bundle. This bundle passes ventral to the medial longitudinal fasciculus and, in the space between the two red nuclei, it forms a dense decussation with the similar bundle from the opposite side. In

inferiorly and slightly overhang the level of the quadrigeminate bodies. The projecting portion assumes relations with the optic tract and the metathalamus.

Both the structures of the **metathalamus,** the lateral and medial geniculate bodies, are connected with the optic tract, but it is thought that actual visual axones terminate only in the lateral geniculate body. As the optic tract curves around the cerebral peduncle it divides into two main roots. The *lateral geniculate body* receives a small portion of the fibers of the lateral root of the optic tract; the remainder pass under this body and enter the pulvinar of the thalamus. The *medial geniculate body* is connected with the medial root of the optic tract,

FIG. 706.—DORSAL SURFACE OF DIENCEPHALON WITH ADJACENT STRUCTURES. (After Obersteiner.)



which root consists partly, not of retinal fibers, as does the lateral root, but of the fibers forming Gudden's commissure (the inferior cerebral commissure). The retinal fibers contained in the medial root pass to terminate in the superior quadrigeminate bodies.

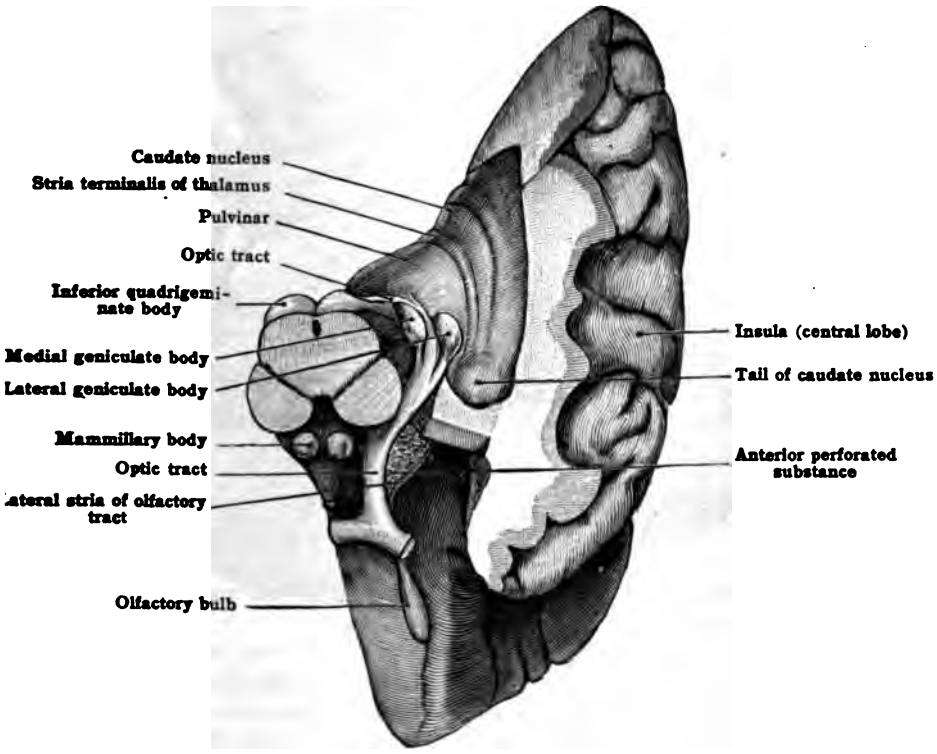
Of the **epithalamus,** the *pineal body* (epiphysis, conarium) is the most conspicuous external feature. This is an unpaired, cone-shaped structure, about 8 mm. long and 4 mm. broad, which also projects upon the mesencephalon so that its body rests in the groove between the superior quadrigeminate bodies. Its stem is attached in the midline at the posterior extremity of the third ventricle and therefore just above the posterior commissure of the cerebrum (fig. 706). It is covered by pia mater, and is involved in a continuation of the tela chorioidea of the third ventricle. Though it develops as a diverticulum of that portion of the anterior primary vesicle which gives origin to the thalamencephalon, it

holly a non-nervous structure, aside from the sympathetic fibers which enter it or the supply of its blood-vessels. (For further details, see p. 1327.)

Apparently arising from the base of the pineal dody, but having practically nothing to do with it, are the **striæ medullares of the thalamus** (striæ pineales, pedunculi conarii, tenia thalami, habenulæ). These are two thin bands of white substance which extend from under the pineal body anteriorly upon the thalamus, along the superior border of each lateral wall of the third ventricle, forming the boundaries between the superior and medial surfac of each thalamus.

They have been called the *habenulæ*, and the habenular nuclei, situated in the habenular trigone, are so called because related to them. They are continuous across the midline in the *habenular commissure*, the dorsal part of the posterior cerebral commissure, just below the neck of the pineal body (figs. 706, 735). It will be seen below that each habenula contains olfactory fibers from the fornix, the anterior perforated substance and the septum pellucidum, as well as fibers out of the thalamus, and that some of its fibers terminate in the habenular nucleus. Most of the thalamic fibers contained cross in the posterior commissure to the thalamus of the opposite side.

FIG. 707.—DIAGRAM OF DISSECTION OF BRAIN SHOWING METATHALAMUS AND PULVINAR WITH ADJACENT STRUCTURES.



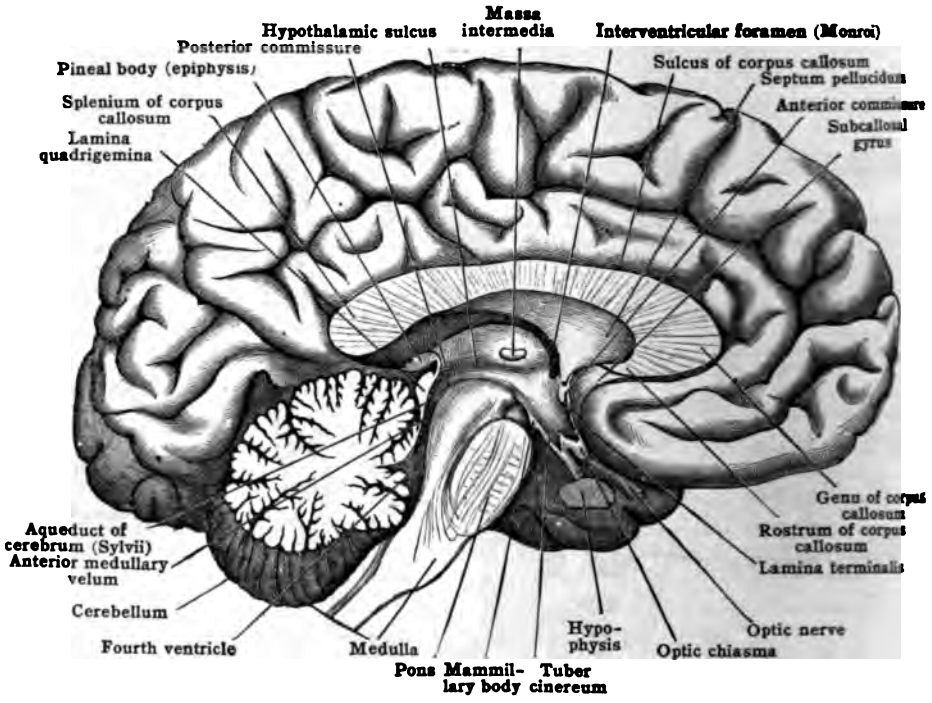
The inferolateral surface of the thalamencephalon is continuous into the hypothalamic tegmental region, the upward continuation of the tegmental gray substance of the mesencephalon. It is also adjacent to a portion of the internal capsule. Both these relationships, as well as the fiber connections of the diencephalon with the structures above and below it, are deferred until the discussion of the internal structure of the prosencephalon.

The **medial surface** of the diencephalon (fig. 708), allows a better view of the shape and relations of the **third ventricle.** Below the line of the massa intermedia the ventricle is usually somewhat wider than it is along the upper margins of the thalami. This greater width is occasioned by a groove in the inferomedial surface of each thalamus, known as the **hypothalamic sulcus** (sulcus of Monro). It is along the line of this sulcus that the third ventricle is continuous with the aqueduct of the cerebrum, and thus with the fourth ventricle below, and, likewise, with the two lateral ventricles of the cerebral hemispheres at its anterior end. The latter junction occurs through a small oblique aperture, the **interventricular**

foramen (foramen of Monro), one into each lateral ventricle. The upper portion of the third ventricle extends posteriorly beneath its choroid tela (velum interpositum) to form a small posterior recess about the pineal body. This is known as the **suprapineal recess.** The anteroinferior extremity of the third ventricle involves the pars optica hypothalami, which belongs to the telencephalon.

B. THE TELENCEPHALON.—External features.—The optic portion of the hypothalamus consists of that small central area of the basal surface of the brain which includes and surrounds the **optic chiasma,** and comprises the structures of the floor of the anterior and inferior portion of the third ventricle. The area belonging to the telencephalon extends anteriorly from the mammillary bodies in the interpeduncular fossa, and includes the **tuber cinereum** and **hypophysis** behind the optic chiasma, and some of the **anterior perforated substance** in front of it.

FIG. 708.—MIDSAGITTAL SECTION OF ENTIRE BRAIN, SHOWING MEDIAL SURFACE OF DIENCEPHALON AND TELENCEPHALON. (After Henle.)



The most anterior portion of the third ventricle is in the form of an inferior extension. The wall of this portion is almost wholly non-nervous and quite thin, and thus the cavity of the ventricle is but thinly separated from the exterior of the brain. The front portion of this wall is the **lamina terminalis** and in the ventricular side of the upper part of this lamina the **anterior commissure** of the cerebrum is apparent.

The **optic chiasma** lies across and presses into the lower portion of the lamina terminalis, and in so doing produces an anterior recess in the cavity of the ventricle known as the **optic recess** (fig. 708). Behind the optic chiasma the floor of the third ventricle bulges slightly, giving the outward appearance known as the **tuber cinereum,** and the cavity bounded by this terminates in the **infundibular recess.**

The **tuber cinereum** then is a hollow, conical projection of the floor of the third ventricle, between the corpora mammillaria and the optic chiasma. Its wall is continuous anteriorly with the lamina terminalis and laterally with the anterior perforated substance.

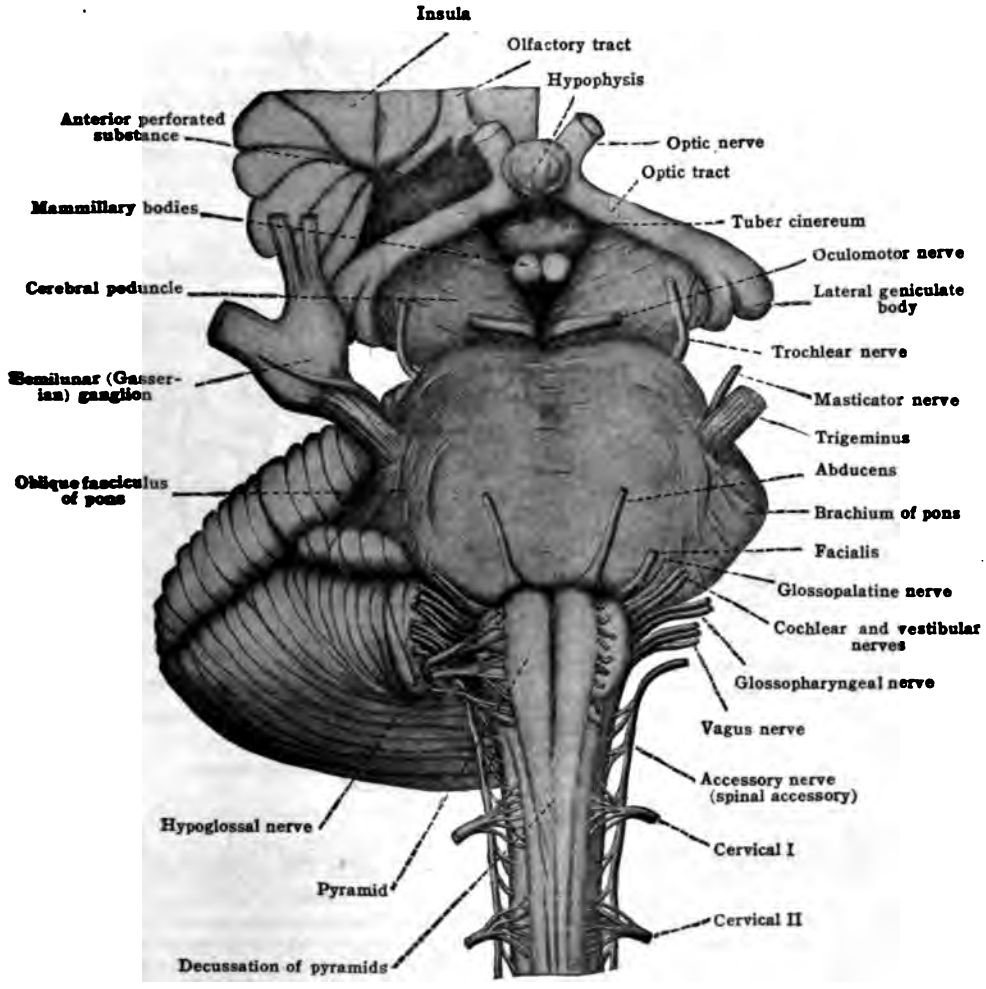
The **infundibulum** is but the attenuated apex of the conical tuber cinereum, and forms the neck connecting it with the hypophysis. It is so drawn out that it is referred to as the stalk of the hypophysis. The cavity of the tuber cinereum (*finundibular* recess) is sometimes maintained throughout the greater part of the

[illegible]gth of the infundibulum, giving it the form of a long-necked funnel. Near the [illegible]ophysis the cavity is always occluded in man.

The **hypophysis cerebri** (pituitary body or gland) (figs. 708, 709) is an ovoid [illegible]s terminating the infundibulum. It lies in the sella turcica of the sphenoid [illegible]e, and consists of two lobes, a large *anterior lobe*, the glandular or buccal lobe, [illegible]d a smaller *posterior* or *neural lobe*. For further details, see GLANDS OF INTER-[illegible]AL SECRETION, p. 1326.

The fundaments of the **optic nerve** are derived from this portion of the telen-[illegible]phalon, though the nuclei of termination of its fibers are located in the thalam-

[illegible]G. 709.—INFERIOR ASPECT OF BRAIN-STEM INCLUDING MAMMILLARY AND OPTIC PORTIONS OF THE HYPOTHALAMUS.



encephalon and mesencephalon. The optic apparatus consists of the retinæ and optic nerves, the optic chiasma, the optic tracts, the superior quadrigeminate bodies with their relations with the nuclei of the eye-moving nerves, the metathalamus, the pulvinar of the thalamus, and the visual area of the cerebral cortex of the occipital lobe. The fibers of the optic nerves arise from the cells of the ganglion-cell layer of the retinæ. The fibers which arise in the mesial or nasal halves of each retina cross in the chiasma to find their nuclei of termination in the gray substance of the opposite side, while those from the outer or lateral halves terminate on the same side (figs. 710, 744).

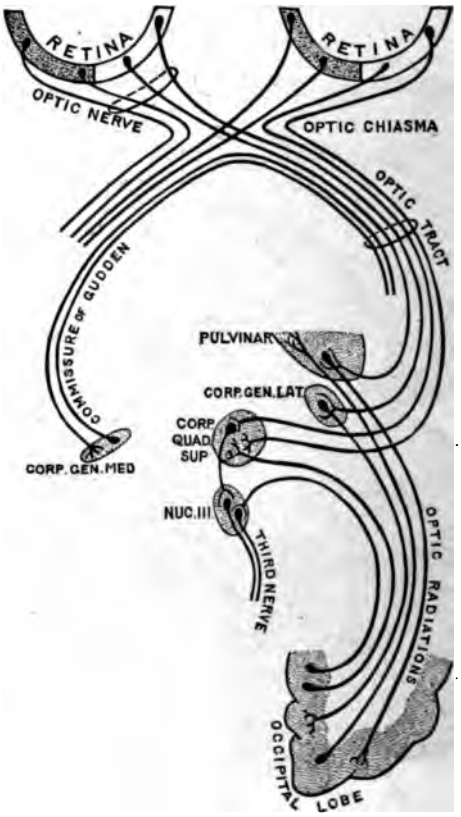
The **optic chiasma** (optic commissure) is adherent upon the structures of the optic portion of the hypothalamus adjacent to it. It is formed by the approach and fusion of the two optic nerves, and is knit together by the decussating fibers

from the nasal halves of each retina, and, in addition, by the fibers of Gud commissure which is contained in it.

Beyond the chiasma the optic fibers continue as the **optic tracts** which c posteriorly around the cerebral peduncles to attain their entrance into the th encephalon and mesencephalon. Upon reaching the pulvinar of the thal each optic tract divides into two roots, a lateral and medial (figs. 707, 709,

The *lateral root* contains practically all of the true visual fibers—fibers arising from the half of the retina of the same side and the nasal half of the retina of the opposite side. fibers are distributed to three localities:—(1) part of them terminate in the lateral geni body; (2) the greater portion pass over and around the lateral geniculate body and ent

FIG. 710.—DIAGRAM OF THE PRINCIPAL COMPONENTS OF THE OPTIC APPARATUS. Cunningham.)



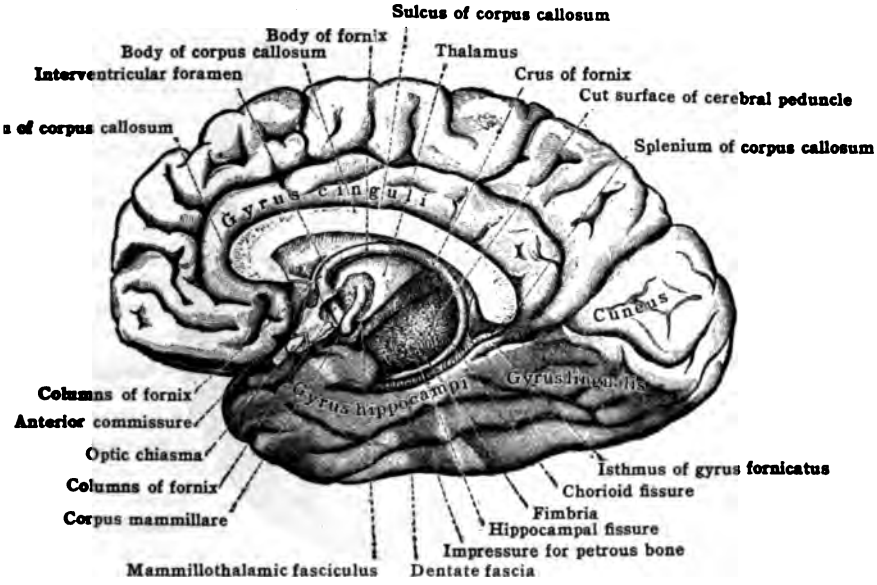
pulvinar; (3) a considerable portion enter the superior quadrigeminal brachium and c it to terminate in the nucleus of the superior quadrigeminate body. The most evident f of this latter portion is to bear impulses which, by way of the neurones of the quadrig body, are distributed to the nuclei of the oculomotor, trochlear, and abducent nerves, s mediate eye-moving reflexes. The cells of the lateral geniculate body and the pulvina which the retinal fibers terminate, give off axones which terminate in the cortex of th area, chiefly the gyri about the calcarine fissure of the occipital lobe. In reaching this a curve upward and backward, coursing in a compact band of white substance known as t radiation (radiatio occipitothalamica, fig. 736). This band also is in part composed arising from the cells of the visual area, which pass from the cortex to the pulvinar, quadrigeminate bodies, and possibly some to the medulla oblongata and spinal cor superior quadrigeminate bodies probably send no fibers to the visual cortex, althou receive fibers from it.

The *medial root* of the optic tract contains few true visual fibers. It runs into th geniculate body, and neither it nor this body are appreciably affected after extirpation eyes. It may be considered as largely representing the fibers of Gudden's commissu rior cerebral commissure). This commissure consists of fibers which correlate the med iculate bodies of the two sides with each other, and which, instead of crossing the through the mesencephalon, course in the optic tracts and cross by way of the posterior of the optic chiasma. It consists of fibers which both arise and terminate in each of th and, therefore, of fibers coursing in both directions. It is also claimed that the fibers of G commissure connect the medial geniculate body of each side with the inferior colliculu opposite side.

THE CEREBRAL HEMISPHERES

he cerebral hemispheres in man form by far the largest part of the central ous system. Together, when viewed from above (fig. 718), they present an d surface, markedly convex upward, which corresponds to the inner surface of vault of the cranium. The greater transverse diameter of this surface lies eriorly in the vicinity of the parietal eminences of the cranium. The outline he superior aspect varies according to the form of the cranium, being more oidal in the brachycephalic and more ellipsoidal in the dolichocephalic. hemispheres are separated from each other superiorly by a deep median slit, **ngitudinal fissure,** into which fits a duplication of the inner layer of the dura er known as the falx cerebri. The posterior or occipital extremities of the ispheres overlap the cerebellum, and thus entirely conceal the mesencephalon thalamencephalon. They are separated from the superior surface of the ellum and the corpora quadrigemina by the deep **transverse fissure.** This upied by the tentorium cerebelli, which is continuous with the falx cerebri also with the tela chorioidea of the third ventricle (figs. 666, 727).

711.—MEDIAL AND TENTORIAL SURFACES OF RIGHT CEREBRAL HEMISPHERE, VIEWED FROM E LEFT. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



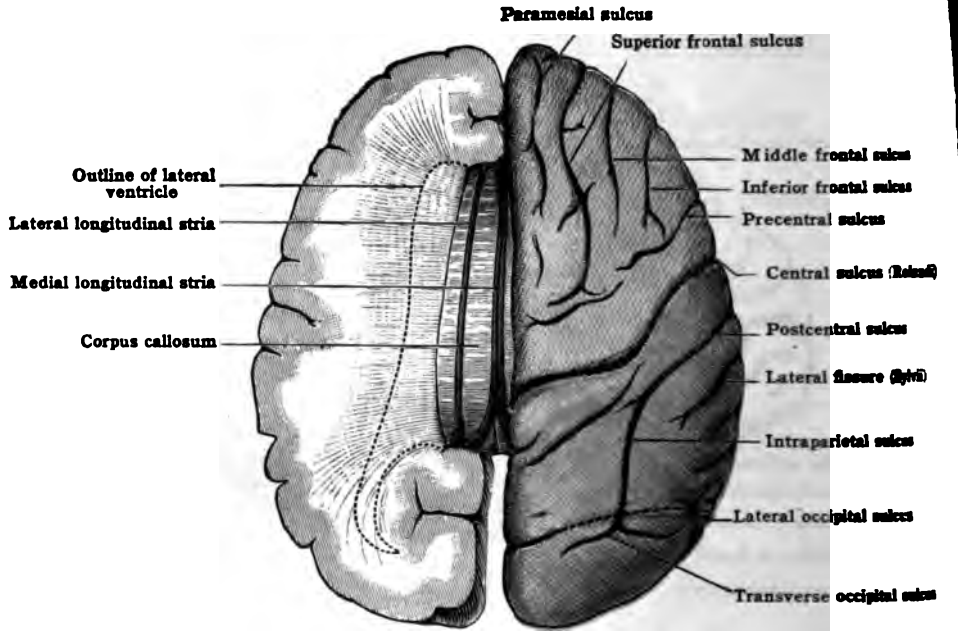
ach of the hemispheres is usually described as having three poles or projecting mities, and three surfaces bounded by intervening borders. The most ior projection is the **frontal pole.** This is near the midline, and with its v of the other hemisphere, forms the frontal end of the ovoid contour of the rum. The **occipital pole** is the most projecting portion of the posterior and ior end, and is more pointed than the frontal pole. The inferolateral por- of the hemisphere is separated anteriorly by the deep **lateral fissure** (fissure lvius) into a distinct division, the temporal lobe, and the anterior portion is lobe projects prominently forward and is known as the **temporal pole.**

he **surfaces** of the hemisphere are—(1) the lateral or *convex surface;* (2) the *al surface;* and (3) the *basal surface.* The convex surface comprises the e rounded aspect of the hemisphere visible previous to manipulation or ction, and is the surface subjacent to the vault of the cranium. The medial ce is perpendicular, flat, and parallel with that of the other hemisphere, the bounding the longitudinal fissure and for the most part in contact with the erebri. The **superomedial border** intervenes between the convex and medial ces, and is thus convex and extends from the frontal to the occipital pole.

he more complex *basal surface* fits into the anterior and middle cranial , and posteriorly rests upon the tentorium cerebelli. Thus it is subdivided —(*a*) an *orbital area,* which is slightly concave, since it is adapted to the

orbital plate of the frontal bone, and is separated from the convex surface by the necessarily arched **superciliary border** and from the medial surface by the medial **orbital border,** the latter being straight and extending from the frontal pole medial to the olfactory bulb and tract; (*b*) a *tentorial area* or surface, which is arched in conformity with the dorsal surface of the cerebellum. This is separated from the convex surface by the **inferolateral border,** which runs from the occipital to the temporal pole; and from the medial surface by the **medial occipital border,** which is a more or less rounded ridge extending from the occipital pole obliquely upward in the angle formed by the junction of the perpendicular falx cerebri and the horizontal tentorium cerebelli. This border is best seen in brains which have been hardened with the membranes *in situ*. The remainder of the basal surface includes the optic portion of the hypothalamus already considered, and the small depressed and punctate area, the anterior perforated substance, which is penetrated by the anterolateral group of the central branches of the anterior and

FIG. 712.—DIAGRAM OF CONVEX SURFACE OF RIGHT CEREBRAL HEMISPHERE AND UPPER SURFACE OF CORPUS CALLOSUM. (Temporal and occipital lobes red, parietal green.)



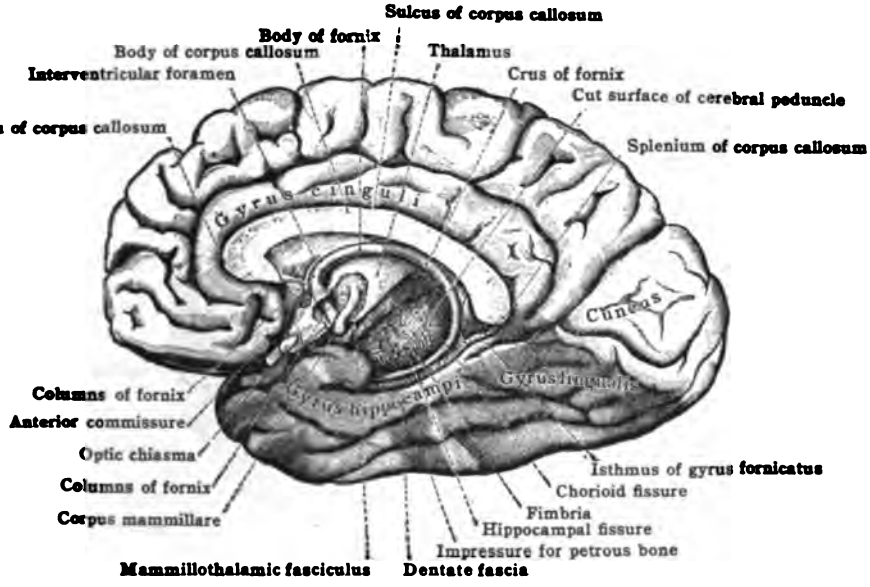
middle cerebral arteries and into which the striæ of the olfactory trigone disappear. In addition to the orbital area, the basal surface of the hemisphere shows signs of the impress of the petrous portion of the temporal bone and of the great wing of the sphenoid.

The corpus callosum.—In their early development as lateral dilations of the anterior primary brain-vesicles, the hemispheres are connected with each other only at the anterior end of the thalamencephalon, where they are both continuous with the unpaired lamina terminalis. As development proceeds and the hemispheres extend upward, backward, forward, and laterally to completely conceal the base, and as the pallium, or cortex, thickens and its folds begin to appear, the two hemispheres become united across the midline above the thalamencephalon and the third ventricle by the intergrowth of the great cerebral commissure, the corpus callosum. After removal of the falx cerebri from the longitudinal fissure, the dorsal surface of the corpus callosum may be exposed by drawing apart the contiguous medial surfaces of the hemispheres (fig. 712). It consists of a dense mass of pure white substance coursing transversely, and arises as outgrowth from the cortical cells of both hemispheres. Thus it is the great pathway which correlates the cortex of the two sides of the telencephalon. Only the smaller middle portion of the body lies free in the floor of the longitudinal fissure, by far the greater part being concealed in the substance of the hemispheres, where its fibers

THE CEREBRAL HEMISPHERES

The cerebral hemispheres in man form by far the largest part of the central **nervous** system. Together, when viewed from above (fig. 718), they present an **ovoid surface**, markedly convex upward, which corresponds to the inner surface of **the vault** of the cranium. The greater transverse diameter of this surface lies **posteriorly** in the vicinity of the parietal eminences of the cranium. The outline **of the superior aspect** varies according to the form of the cranium, being more **spheroidal** in the brachycephalic and more ellipsoidal in the dolichocephalic. **The hemispheres** are separated from each other superiorly by a deep median slit, **the longitudinal fissure,** into which fits a duplication of the inner layer of the dura **mater** known as the falx cerebri. The posterior or occipital extremities of the **hemispheres** overlap the cerebellum, and thus entirely conceal the mesencephalon **and thalamencephalon.** They are separated from the superior surface of the **cerebellum** and the corpora quadrigemina by the deep **transverse fissure.** This **is occupied** by the tentorium cerebelli, which is continuous with the falx cerebri **and also** with the tela chorioidea of the third ventricle (figs. 666, 727).

FIG. 711.—MEDIAL AND TENTORIAL SURFACES OF RIGHT CEREBRAL HEMISPHERE, VIEWED FROM THE LEFT. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



Each of the hemispheres is usually described as having three poles or projecting extremities, and three surfaces bounded by intervening borders. The most anterior projection is the **frontal pole.** This is near the midline, and with its fellow of the other hemisphere, forms the frontal end of the ovoid contour of the cerebrum. The **occipital pole** is the most projecting portion of the posterior and inferior end, and is more pointed than the frontal pole. The inferolateral portion of the hemisphere is separated anteriorly by the deep **lateral fissure** (fissure of Sylvius) into a distinct division, the temporal lobe, and the anterior portion of this lobe projects prominently forward and is known as the **temporal pole.**

The **surfaces** of the hemisphere are—(1) the lateral or *convex surface;* (2) the *medial surface;* and (3) the *basal surface.* The convex surface comprises the entire rounded aspect of the hemisphere visible previous to manipulation or dissection, and is the surface subjacent to the vault of the cranium. The medial surface is perpendicular, flat, and parallel with that of the other hemisphere, the two bounding the longitudinal fissure and for the most part in contact with the falx cerebri. The **superomedial border** intervenes between the convex and medial surfaces, and is thus convex and extends from the frontal to the occipital pole.

The more complex *basal surface* fits into the anterior and middle cranial fossæ, and posteriorly rests upon the tentorium cerebelli. Thus it is subdivided into—(*a*) an *orbital area,* which is slightly concave, since it is adapted to the

the cranium begins to grow more rapidly than the encephalon, and a space is formed b the cerebrum and the inner surface of the cranium. This space allows further expansion pallium, and at the time the space is relatively greatest (during the sixth month) the for direction of the principal gyri and sulci begin to be indicated. As growth proceeds the stricted expansion of the pallium results in the gyri again approaching the wall of the cr and during the eighth month of fetal life they again come in contact with it. Finally, th relative growth of the cranium results in the space found between it and the cortex in the It is obvious that the relation of the cranium may be a factor in the causation of the g the increase of surface area necessitated by the increased amount of cortical gray sul might be limited by a cranial cavity of small size. It is probable that the second contac cortex with the cranium (during the eighth month) may at least cause a deepening and ac tion of the sulci already begun. Evidently the form of the cranium modifies the gyri. a certain extent probably determines their direction, for in long, dolichocephalic crania teroposterior gyri are most accentuated, and in the wide, brachycephalic crania the tra gyri are most marked. At birth all the main fissures and sulci are present, but some smaller sulci appear later. In the growing pallium both the bottoms of the sulci as we summits of the gyri move away from the geometrical center of the hemisphere, the s more rapidly, and hence the sulci or fissures first formed grow gradually deeper as growth continues.

The mechanical factors in the growth processes which result in the more or less arrangement of the gyri of the hemispheres of a given group of animals have not be factorily determined. It has been suggested that the differences in arrangement of the different groups of animals may be in part dependent upon the functional importanc various regions—the amount of gray substance of a region varying with the function tance, and the consequent local increases being accompanied by resultant local folding idea is supported by the fact that while the somesthetic (sensory-motor) area of th varies with the bulk of the body, the frontal gyri, so much developed in man and w one of the chief regions of the associational phenomena, are relatively independent of an vary with the weight of either the body or the brain.

Surface area.—The total surface area of the adult human telencephalon is about cm. Of this area almost exactly one-third is contained on the outer or exposed surfac gyri, while the other two-thirds is found in the walls of the sulci and fissures.

Lobes of the Telencephalon and the Gyri and Sulci

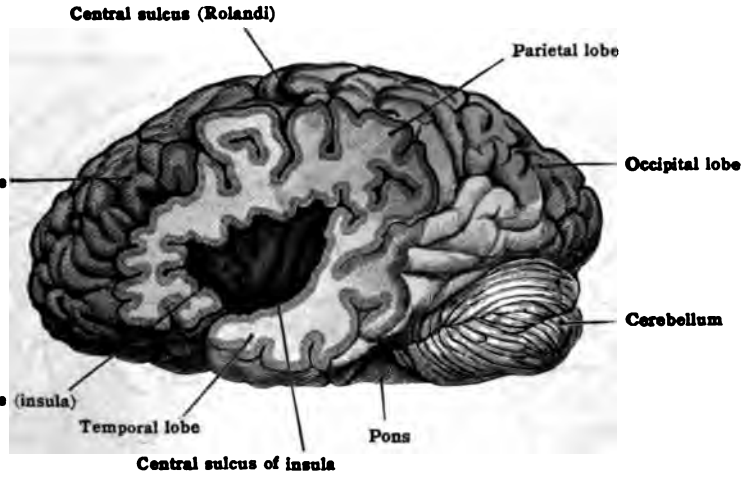
The folded pallium of each hemisphere is arbitrarily divided into lobes by the use of certain of the main fissures and sulci as boundaries and partly use of imaginary lines (figs. 712–714). These divisions are six in number selves subdivided into their component gyri:

(1) Temporal lobe.
(2) Insula (Central lobe or Island of Reil).
(3) Frontal lobe.
(4) Parietal lobe.

ward, the folds which form the margins of the Sylvian fossa increase in size height and begin to overlap and conceal its broad floor, which is the beginning e insula. The overlapping folds thus become the **opercula,** and as their lips roach each other, there results the deep fissure of Sylvius, which marks off riorly an inferolateral limb of the pallium, termed by position the temporal e. As growth proceeds further, the temporal lobe thickens, the temporal pole nds further forward and becomes a free projection, thus lengthening the ure of Sylvius and resulting in the inferior extension or stem of this fissure, ch runs between the temporal pole and the frontal lobe and curves under so as appear on the basal surface of the hemisphere. Finally the cortex of the poral lobe itself is thrown into folds or gyri. Its posterior end is never marked from the lobes above and behind, except by arbitrary lines which will be mened in connection with those lobes.

. 713.—Diagram of the Convex Surface of the Left Cerebral Hemisphere Showing the Five Principal Lobes of the Pallium.

e opercular regions of the frontal, parietal, and temporal lobes are removed to show the central lobe or island of Reil.



The temporal lobe forms part of the lateral convex and tentorial surfaces of the hemisphere, and its anterior portion is adapted to the surface of the middle cranial fossa. It thus has a lateral surface and a basal and tentorial surface. In these surfaces are the following gyri with their intervening and bounding sulci (fig. 714):

The **superior temporal gyrus** is bounded by the posterior ramus of the lateral fissure, and extends from the temporal pole backward into the supramarginal region belonging to the parietal lobe above. The upper margin of this gyrus constitutes the **temporal operculum,** in that it aids in overlapping and enclosing the insula in the floor of the lateral fissure. This margin is for the most part smooth, being occasionally interrupted by a few weak twigs of the lateral fissure. It is separated from the gyrus below by the **superior temporal sulcus,** which is parallel with the posterior ramus of the lateral fissure and is frequently called the ***parallel sulcus.*** The posterior extremity of this sulcus divides the angular gyrus of the parietal lobe, and its anterior end disappears in the temporal pole, sometimes as a continuous groove, sometimes in isolated pieces.

The **middle temporal gyrus** likewise begins in the temporal pole and is continuous backward into the angular gyrus of the parietal lobe.

The **inferior temporal gyrus** forms the inferolateral border of the temporal lobe, and is usually more broken up than the two gyri above it. It usually begins continuous with them in the frontal pole, and extends horizontally backward into the lateral gyri of the occipital lobe. It is separated from the middle gyrus by the **middle temporal sulcus,** which likewise is never so continuous a furrow as the superior temporal sulcus. Frequently this sulcus occurs in detached portions and often terminates within the temporal lobe.

cephalon, due to its rapid growth, closely occupies the cranial capsule. During the fetal
the cranium begins to grow more rapidly than the encephalon, and a space is formed be
the cerebrum and the inner surface of the cranium. This space allows further expansion
pallium, and at the time the space is relatively greatest (during the sixth month) the for
direction of the principal gyri and sulci begin to be indicated. As growth proceeds the
stricted expansion of the pallium results in the gyri again approaching the wall of the cr
and during the eighth month of fetal life they again come in contact with it. Finally, the
relative growth of the cranium results in the space found between it and the cortex in the
It is obvious that the relation of the cranium may be a factor in the causation of the g
the increase of surface area necessitated by the increased amount of cortical gray sub
might be limited by a cranial cavity of small size. It is probable that the second contact
cortex with the cranium (during the eighth month) may at least cause a deepening and ac
tion of the sulci already begun. Evidently the form of the cranium modifies the gyri.
a certain extent probably determines their direction, for in long, dolichocephalic crania
teroposterior gyri are most accentuated, and in the wide, brachycephalic crania the tra
gyri are most marked. At birth all the main fissures and sulci are present, but some
smaller sulci appear later. In the growing pallium both the bottoms of the sulci as well
summits of the gyri move away from the geometrical center of the hemisphere, the s
more rapidly, and hence the sulci or fissures first formed grow gradually deeper as
growth continues.

The mechanical factors in the growth processes which result in the more or less
arrangement of the gyri of the hemispheres of a given group of animals have not be
factorily determined. It has been suggested that the differences in arrangement of the
different groups of animals may be in part dependent upon the functional importanc
various regions—the amount of gray substance of a region varying with the function
tance, and the consequent local increases being accompanied by resultant local folding
idea is supported by the fact that while the somesthetic (sensory-motor) area of th
varies with the bulk of the body, the frontal gyri, so much developed in man and w
one of the chief regions of the associational phenomena, are relatively independent of an
vary with the weight of either the body or the brain.

Surface area.—The total surface area of the adult human telencephalon is about
cm. Of this area almost exactly one-third is contained on the outer or exposed surfac
gyri, while the other two-thirds is found in the walls of the sulci and fissures.

Lobes of the Telencephalon and the Gyri and Sulci

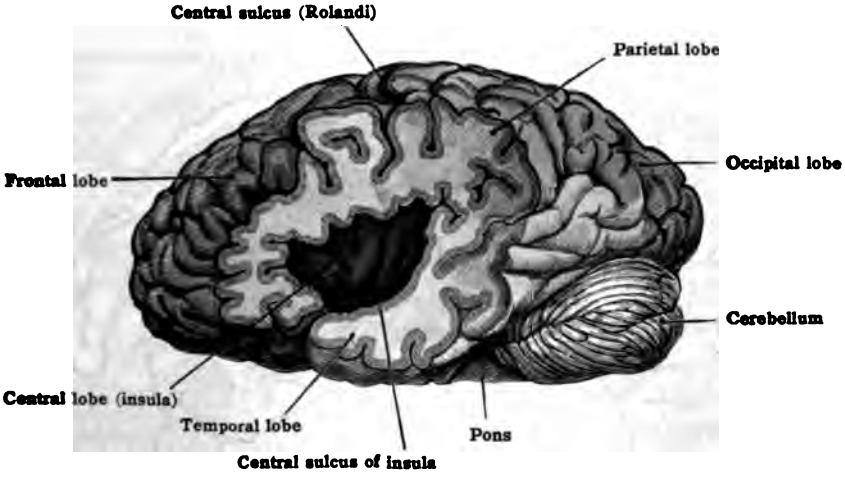
The folded pallium of each hemisphere is arbitrarily divided into lobes
by the use of certain of the main fissures and sulci as boundaries and partly
use of imaginary lines (figs. 712–714). These divisions are six in number
selves subdivided into their component gyri:

(1) Temporal lobe.
(2) Insula (Central lobe or Island of Reil).
(3) Frontal lobe.
(4) Parietal lobe.

[illegible]ward, the folds which form the margins of the Sylvian fossa increase in size [illegible] height and begin to overlap and conceal its broad floor, which is the beginning [illegible]e insula. The overlapping folds thus become the **opercula,** and as their lips [illegible]roach each other, there results the deep fissure of Sylvius, which marks off [illegible]eriorly an inferolateral limb of the pallium, termed by position the temporal [illegible]e. As growth proceeds further, the temporal lobe thickens, the temporal pole [illegible]ends further forward and becomes a free projection, thus lengthening the [illegible]ure of Sylvius and resulting in the inferior extension or stem of this fissure, [illegible]ch runs between the temporal pole and the frontal lobe and curves under so as [illegible] appear on the basal surface of the hemisphere. Finally the cortex of the [illegible]poral lobe itself is thrown into folds or gyri. Its posterior end is never marked [illegible] from the lobes above and behind, except by arbitrary lines which will be men-[illegible]ned in connection with those lobes.

[illegible]. 713.—Diagram of the Convex Surface of the Left Cerebral Hemisphere Showing the Five Principal Lobes of the Pallium.

[illegible] opercular regions of the frontal, parietal, and temporal lobes are removed to show the central lobe or island of Reil.



The temporal lobe forms part of the lateral convex and tentorial surfaces of the hemisphere, and its anterior portion is adapted to the surface of the middle cranial fossa. It thus has a lateral surface and a basal and tentorial surface. In these surfaces are the following gyri with their intervening and bounding sulci (fig. 714):

The **superior temporal gyrus** is bounded by the posterior ramus of the lateral fissure, and extends from the temporal pole backward into the supramarginal region belonging to the parietal lobe above. The upper margin of this gyrus constitutes the **temporal operculum,** in that it aids in overlapping and enclosing the insula in the floor of the lateral fissure. This margin is for the most part smooth, being occasionally interrupted by a few weak twigs of the lateral fissure. It is separated from the gyrus below by the **superior temporal sulcus,** which is parallel with the posterior ramus of the lateral fissure and is frequently called the ***parallel sulcus.*** The posterior extremity of this sulcus divides the angular gyrus of the parietal lobe, and its anterior end disappears in the temporal pole, sometimes as a continuous groove, sometimes in isolated pieces.

The **middle temporal gyrus** likewise begins in the temporal pole and is continuous backward into the angular gyrus of the parietal lobe.

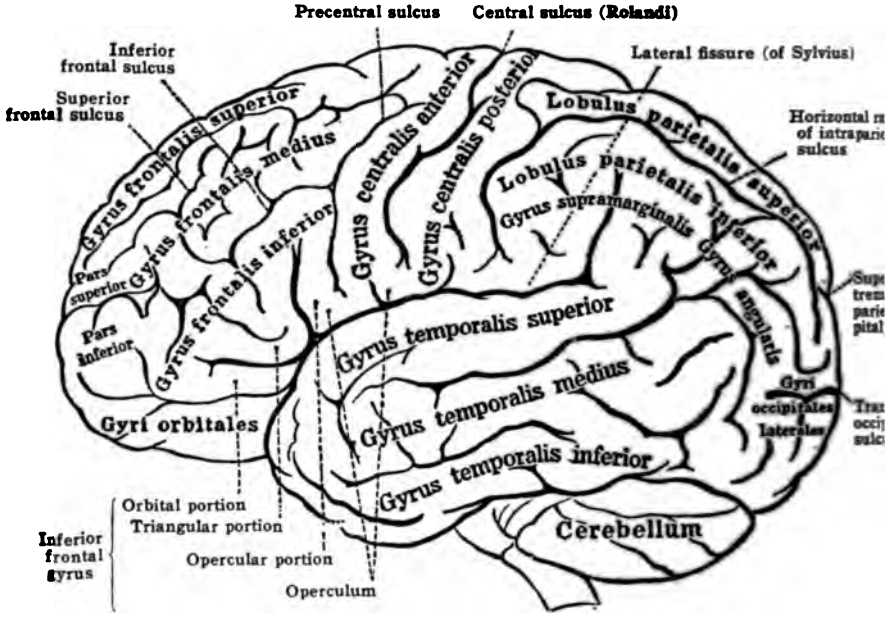
The **inferior temporal gyrus** forms the inferolateral border of the temporal lobe, and is usually more broken up than the two gyri above it. It usually begins continuous with them in the frontal pole, and extends horizontally backward into the lateral gyri of the occipital lobe. It is separated from the middle gyrus by the **middle temporal sulcus,** which likewise is never so continuous a furrow as the superior temporal sulcus. Frequently this sulcus occurs in detached portions and often terminates within the temporal lobe.

The **fusiform gyrus** is in the basal and tentorial surface of the temporal (fig. 716). Its usual somewhat spindle-shape suggests its name, and it is tinuous backward into the occipital gyri, or its posterior end may be compl isolated by a union of the *inferior temporal sulcus* and the **collateral fis** which two furrows separate it from its neighbors on either side. Anteriorly fusiform gyrus runs into the common substance of the other three gyri at temporal pole.

The **lingual gyrus** (fig. 716) is usually included in the tentorial surface o temporal lobe, though some regard it as a part of the occipital lobe. Its la posterior portion lies within the boundaries of the occipital lobe. Bou laterally by the collateral fissure, it is continuous anteriorly into the hippoca gyrus of the rhinencephalon.

All of the sulci give off occasional lateral twigs (*transverse temporal sulci*) w themselves may or may not branch, and which tend to divide the main gyri **transverse temporal gyri.**

FIG. 714.—OUTLINE DRAWING OF CONVEX SURFACE OF LEFT CEREBRAL HEMISPHER (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



The lateral fissure (fissure of Sylvius).—On account of its origin by th lapping and enclosing of the broad floor of the Sylvian fossa by the adjace of the pallium, the lateral fissure is the deepest and most conspicuous fis the cerebral hemisphere (figs. 714–716). Its main divisions are a short st three main branches. The stem lies in the basal surface of the hemisphere it begins in a depression in the anterior perforated substance, the *vallecula* and passes forward and upward between and separating the temporal pole superciliary border of the frontal lobe. It corresponds in direction w posterior border of the lesser wing of the sphenoid bone, which projects ba into it, and it contains the middle cerebral artery, the Sylvian vein, and th alæ parvæ. It appears on the lateral surface at a point known in cranial raphy as the *Sylvian point*, where it divides into its three main branches (fi

(1) The **posterior ramus** is the linear continuation of the fissure, a horizontally backward and upward to terminate in the supramarginal g the parietal lobe.

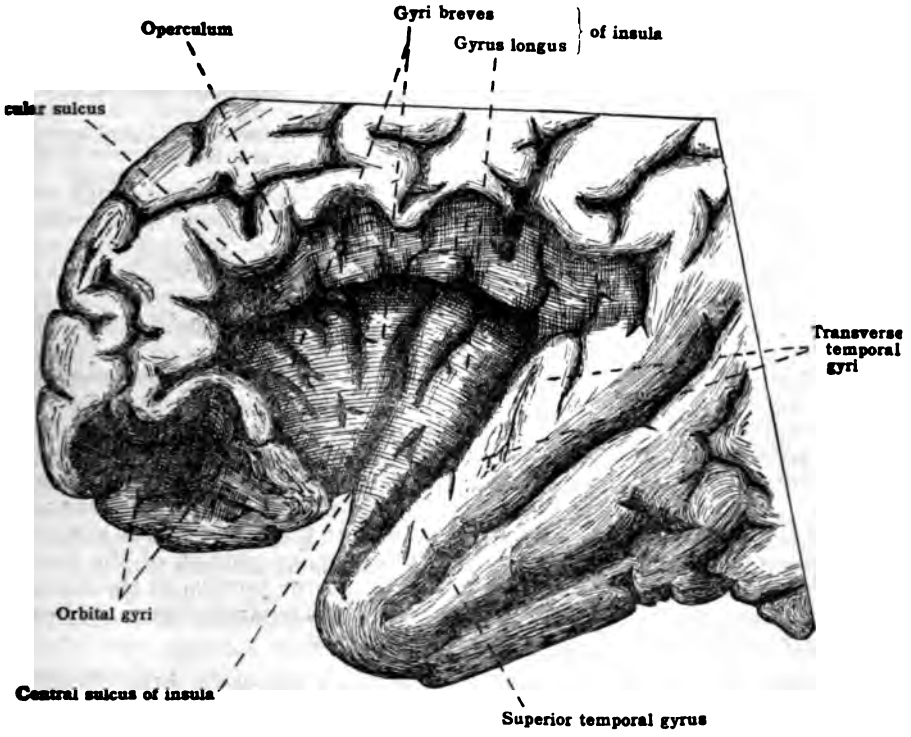
(2) The **anterior ascending ramus** passes upward for about 10 mm dividing the inferior gyrus of the frontal lobe.

(3) The **anterior horizontal ramus** passes forward from the stem of the about 10 mm., and likewise into the inferior frontal gyrus, but parallel w superciliary border.

hese branches, together with certain smaller collateral twigs, divide the over- ng or opercular portions of the adjacent pallium into (*a*) the *temporal opercu-* which lies below the posterior ramus; (*b*) the frontoparietal operculum, or *ulum proper*, which lies above and behind the anterior ascending ramus; (*c*) *rontal operculum*, between the latter and the anterior horizontal ramus; (*d*) he *orbital operculum*, below the anterior horizontal ramus. Collectively the ula are known as the *opercula of the insula*.

he insula (central lobe).—The insula or island of Reil (figs. 713, 715) is a gular area of the cerebral cortex lying in the floor of the lateral fissure, and aled by the opercula. Of these, the temporal operculum overlaps the insula greater extent than either the frontal or parietal. More than half of it may, fore, be exposed, by gently pressing away the temporal lobe. The insula sponds to the broad floor of the Sylvian fossa of the embryonic brain. In leveloped condition its surface is convex lateralward and is itself folded into

15.—THE INSULA WITH ITS GYRI AND SULCI. (Shown by widely separating the opercula.)



The apex of the triangle appears upon the basal surface of the hemisphere 716), and is the only portion which may be seen without disturbing the men. The apex appears as the end of a small gyrus under the temporal pole, in close relation with the anterior perforated substance and the vallecula i, and is known as the **limen of the insula**. In the folding process by which percula accomplish the overlapping and enclosing of the island, there results p sulcus which surrounds its entire area except at the limen insula. This is n as the **circular sulcus**, or limiting sulcus of Reil. The gyri (and sulci) of nsula radiate from the apex of the triangle. The **central sulcus** of the insula e deepest. It runs from below backward and upward, parallel with the al sulcus (of Rolando) above and divides the insula into a larger anterior and aller posterior portion. The anterior portion consists of from three to five irregular **gyri breves** or precentral gyri, separated by **sulci brevis**; the pos- r portion consists of a single, slightly furrowed gyrus, which is long and arched xtends from the apex to the base of the triangle, the **gyrus longus**.

In a thorough study of the insula of more than 200 human brains, including a few of id and paralytics and a series of young fetuses, Nelidoff finds that the left island is more de marked by sulci and averages 11 mm. longer than the right; that, of the sulci in the island, central sulcus is the first to appear, is the most persistent sulcus in defective brains, tho occasionally absent in microcephalic idiots, and that on the average it is more pron in males than in females.

The frontal lobe (figs. 712–719).—This is the most anterior of the lobes of hemisphere, and like the two lobes behind, it has a convex or lateral, a basal, and medial surface. The convex surface begins with the frontal pole, and is boun posteriorly by the *central sulcus* (*Rolandi*). The basal surface extends backw to the stem of the lateral fissure, covered by the frontal pole. The medial surfa is separated from the gyrus cinguli of the rhinencephalon (limbic lobe) by the s frontal part of the **sulcus cinguli** (callosomarginal fissure), and from the pariet lobe by a line drawn perpendicular from the upper extremity of the centr sulcus (Rolandi) to the sulcus cinguli. These surfaces include the following gy and sulci:—

	Gyri.		Sulci.
Convex surface	Anterior central gyrus.		
	Superior frontal gyrus.		Precentral sulcus (Superior. / Inferior.)
	Middle frontal gyrus	Superior portion.	Superior frontal sulcus.
		Inferior portion.	Middle frontal sulcus.
	Inferior frontal gyrus	Opercular portion.	Inferior frontal sulcus.
		Triangular portion.	Anterior ascending ramus of lateral fissure.
		Orbital portion.	Anterior horizontal ramus of lateral fissure.
Basal surface	Orbital gyri	Lateral.	Orbital sulci (Lateral / Medial. / Transverse.)
		Anterior.	
		Posterior.	
		Medial.	
	Gyrus rectus		Olfactory sulcus.
Medial surface	Superior frontal gyrus.		
	Marginal gyrus.		
	Paracentral lobule (anterior part).		Rostral sulci.

Many of the sulci, especially the superior frontal and the rostral sulci, often give off twigs or are broken into short furrows which give rise to small folds [gyri transitivi], too inconstant to be given special names.

The **anterior central gyrus** (ascending frontal convolution) is the only gyrus of the frontal lobe having a vertical direction. It lies parallel to the central sulcus (Rolandi), and thus extends obliquely across the convex surface from the posterior ramus of the lateral fissure (frontal operculum) to the superomedial border, and is continuous on the medial surface with the anterior portion of the *paracentral lobule*. It comprises the larger part of the motor portion of the somesthetic (sensory-motor) area of the cerebral cortex. It is separated from the horizontal frontal gyri in front of it by the **precentral sulcus**.

This sulcus is developed in three parts, but the upper and middle parts in the fetal brain usually fuse together, so that in the later condition it consists of a superior and an inferior segment. The superior cuts the superomedial border of the hemisphere and appears on the medial surface in the paracentral lobule. On the convex surface it is usually connected with the posterior end of the superior frontal sulcus (fig. 714).

The **superior frontal gyrus** is a relatively broad, uneven convolution, comprising the anterior portion of the superomedial border of the hemisphere and therefore extends horizontally from the precentral sulcus to the frontal pole. It is sometimes imperfectly divided into a superior and an inferior part by a series of detached, irregular furrows, spoken of collectively as the *paramedial sulcus*. The resulting transitory gyri are of considerable interest in that they are peculiar to the human brain, and are said to be more marked in the higher than in the lower types.

The **middle frontal gyrus** is likewise a broad strip of pallium extending from the precentral sulcus to the temporal pole. It is separated from the superior frontal gyrus by the **superior frontal sulcus**, which is usually continuous into the superior section of the precentral sulcus and thence extends horizontally to the frontal pole. The middle frontal gyrus is in most cases subdivided anteriorly into a *superior* and an *inferior portion* by a **middle frontal sulcus**. This sulcus begins above and runs into the frontal pole, where, upon reaching the superciliary

border, it frequently bifurcates into a transverse furrow, known as the *fronto-marginal sulcus*.

The **inferior frontal gyrus** forms the superior wall of the lateral fissure, and is separated from the middle frontal gyrus by the **inferior frontal sulcus.** This sulcus usually begins continuous with the inferior section of the precentral sulcus, and extends, very irregularly and frequently interrupted, toward the frontal pole. The gyrus abuts upon the anterior central gyrus, and its posterior portion is divided into three parts (the frontal opercula) by the anterior ascending and horizontal rami of the lateral fissure. The part behind the anterior ascending ramus is the **opercular portion** (a part of the frontoparietal operculum or operculum proper), sometimes referred to as the *basilar portion*. In most brains this part is traversed by a short oblique furrow, the **diagonal sulcus.** The part between the two anterior rami of the lateral fissure is the cone-shaped **triangular portion.** This portion frequently involves one and sometimes two descending twigs of the inferior frontal sulcus. The part below the anterior horizontal ramus is by position the **orbital portion.**

It is seen that the inferior frontal gyrus gives rise to the whole of the frontal operculum and the anterior half of the frontoparietal operculum. The opercular portion is of special interest in that in the left hemisphere it constitutes the celebrated convolution of Broca, the motor area for the function of speech. The area controlling speech, however, involves that part of the triangular portion bounding the anterior ascending ramus of the lateral fissure as well, and both these parts often appear more developed on the left hemisphere. The development of the opercula of the inferior frontal gyrus is a distinctive characteristic of the human brain. This gyrus does not develop opercula even in the highest varieties of apes. The development of the function of speech in man no doubt influences the development of the frontal opercula.

On the *basal surface* (fig. 716) of the frontal lobe is the orbital area and the gyrus rectus. The more pronounced of the **orbital sulci** are often so joined with each other as to form an H-shaped figure standing parallel to the medial plane, and thus they comprise a *medial*, a *lateral* and a *transverse orbital sulcus*. This figure naturally divides the orbital area into four gyri:—(1) The **lateral orbital gyrus** is the basal continuation of the inferior frontal gyrus, and is thus related to the orbital portion of the frontal operculum; (2) the **anterior orbital gyrus** is continuous at the pole with the middle frontal gyrus; (3) the **posterior orbital gyrus** is closely related to the limen insulæ and the stem of the lateral fissure, and its outer part is in relation with the orbital portion of the operculum; (4) the **medial orbital gyrus** is continuous over the superciliary border with the superior frontal gyrus. It frequently contains one or two short, isolated sulci. Its medial boundary is the straight **olfactory sulcus,** in which lies the olfactory bulb and tract of the rhinencephalon. This sulcus marks off a narrow straight strip of cortex between it and the medial border of the lobe known as the **gyrus rectus.** The posterior portion of the gyrus rectus comprises a part of the **parolfactory area** or Broca's area, which functionally belongs to the rhinencephalon. As an area or field, this appears mesially lying between the anterior and posterior parolfactory sulci.

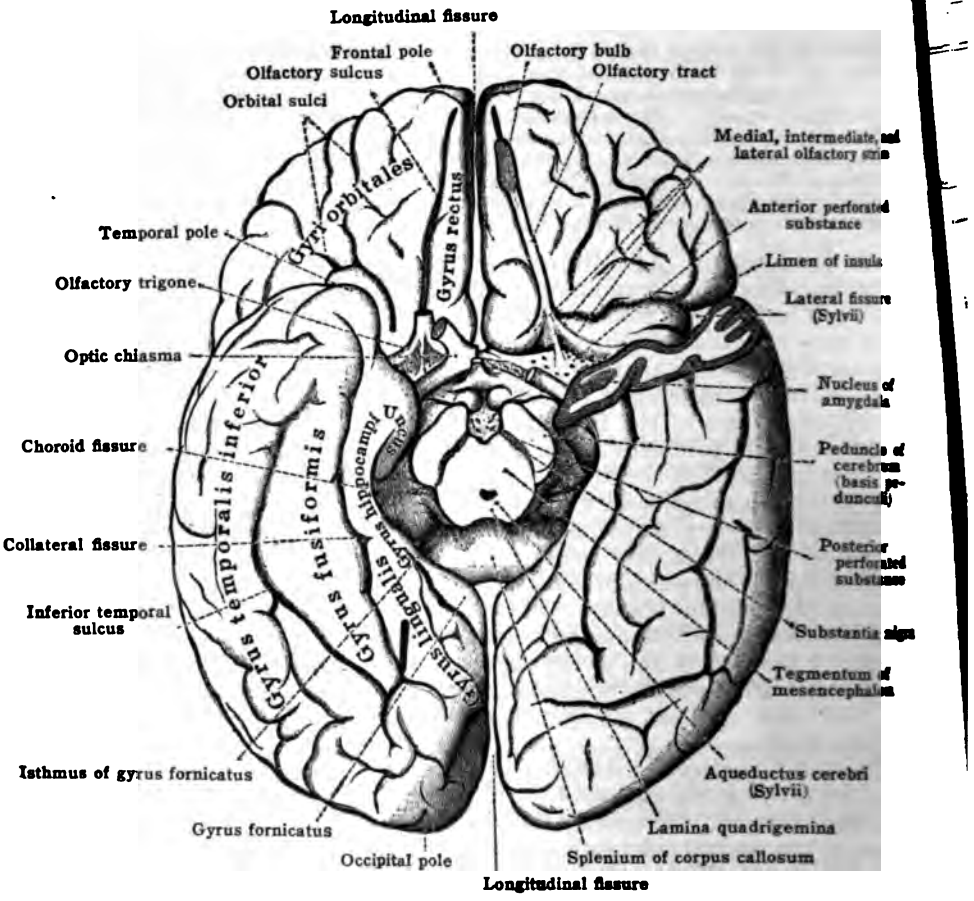
On the *medial surface* (fig. 719) of the frontal lobe the superior frontal gyrus is separated from the gyrus cinguli of the rhinencephalon (limbic lobe) by the well-marked **sulcus cinguli.** Anteriorly the superior frontal gyrus is subdivided by the main stem of the **rostral sulci** into a **marginal gyrus,** and what may be termed a **submarginal gyrus.** The marginal gyrus is usually broken into smaller parts by twigs of the rostral sulci, most of which are perpendicular to the main stem, while the submarginal gyrus is less frequently interrupted. Posteriorly the superior frontal gyrus constitutes the anterior portion of the *paracentral lobule*, a part of the somesthetic area of the medial surface of the hemisphere. This lobule is usually marked off anteriorly by a vertical twig from the sulcus cinguli.

The **sulcus cinguli** (callosomarginal fissure) is the longest and one of the most prominent sulci on the medial surface of the hemisphere. It divides the anrerior portion of the medial surface into a marginal part above and a callosal part below —in other words, it separates the superior frontal gyrus from the gyrus cinguli. Its **subfrontal portion** begins below the rostrum of the corpus callosum and curves forward and upward around the genu, and then turns backward above the body of the corpus callosum. Before it reaches the level of the splenium, it turns upward and cuts and terminates in the superomedial border of the hemisphere, as the next sulcus behind the upper termination of the central sulcus. This upward

turn is the **marginal portion** of the sulcus cinguli. It is sometimes an ab... curve and sometimes curves gradually, but its marginal relation to the upper... of the central sulcus is so constant that it serves as a means by which either of... sulci may be identified. The marginal portion separates the paracentral lo... from the precuneus (quadrate lobule), and is wholly within the parietal l... One of the most constant twigs of the sulcus cinguli is that which marks off... paracentral lobule from the superior frontal gyrus. Another sometimes divi... the paracentral lobule into its frontal and parietal portions.

The sulcus cinguli is developed from two and sometimes three (anterior, middle, and p... terior) separate furrows, which later extend and fuse into continuity. This method of... development may explain the irregularities frequently met with and the fact that sometim... in the adult the sulcus occurs in separate pieces.

FIG. 716.—BASAL SURFACE OF THE CEREBRAL HEMISPHERES. TIP OF LEFT TEMPORAL LOBE REMOVED. (After Toldt, 'Atlas of Human Antomy,' Rebman, London and New York.)



The **central sulcus** (fissure of Rolando) (figs. 714, 717, 718) **is one of the principal** landmarks of the convex surface of the hemisphere. **It separates the frontal** from the parietal lobe, and likewise divides the **somesthetic area of the pallium.** Its upper end terminates in and usually cuts the **superomedial border of the hemisphere** immediately in front of the termination of the **marginal portion of the sulcus** cinguli. Thence it pursues an oblique though sinuous **course forward across the** convex surface of the hemisphere, forming on the **average an angle of about 72°** with the superomedial border (**Rolandic angle**), **and terminates in the fronto**parietal operculum immediately above the posterior **ramus, and about 2.5 cm. be**hind the point of origin of the anterior rami of the **lateral fissure. It rarely cuts** through the frontoparietal operculum. In its **sinuous course, varying from the** line of its superomedial end, two bends are marked (**fig. 717**):—(1) **The superior genu** occurs at about the junction of the upper and **middle thirds of the sulcus and**

is concave forward. It accommodates the greater part of that portion of the cortex which is the motor area for the muscles of the leg and trunk, and the development of this area in man probably aids in producing it. (2) The inferior genu occurs below, is concave forward and is commonly a little more marked than the superior genu. It is probably in part a result of the superior genu—the turn of the sulcus in resuming its general course, but it may further result from the development of the shoulder and arm area of the cortex which occupies its concavity.

The central sulcus (Rolandi) appears in the pallium of the fetus during the latter part of the fifth month. It then consists of a lower longer and an upper shorter part. Usually these two parts become continuous before birth; very rarely do they remain separate in the adult. The point of their fusion is sometimes manifest within the depth of the sulcus. If the lips of the sulcus be pressed widely apart at about the region of the junction of its middle and upper thirds, it will be found that the opposing walls give off a number of protuberances or lateral gyri, which dovetail into each other when the sulcus is closed. Sometimes two of these lateral gyri

appear fused across the floor of the sulcus, so as to form a bridge of gray substance known as the deep annectant gyrus. This interruption of the continuity of the sulcus, when present, represents the point at which the two parts of the sulcus in the fetal brain joined each other without the continuity becoming wholly completed in the adult. The genua of the adult sulcus may often be due to the precedent parts not being in line at the time of their fusion.

From a special study of the central sulcus of 237 normal adult hemispheres, Symington and Crymble (1913) give the following details: (1) that the most common course of the sulcus is that illustrated in fig. 717, above; (2) that it varies in depth both in a given specimen and in different specimens—the greatest variations in depth reported for a given sulcus being from 22 to 12 millimeters, the shallowest part being in the region of the deep annectant gyrus; (3) that the average length from the superomedial border of the hemisphere to the opercular end of the sulcus is about 9 cm. in direct line and 10.4 cm. following the curves of the sulcus. The average length of the curved floor is 7.9 cm. (4) From the superomedial end of the sulcus to the points of junction of the general areas of the precentral gyrus, direct line measurements give averages, (a) to the junction of leg and trunk areas, 3.5 cm.; (b) to junction of trunk and arm areas, 4.5 cm.; (c) junction of arm and face areas, 7.5 cm.

The parietal lobe.—The parietal lobe (figs. 711–714, 718, 719) occupies a somewhat smaller area of the human telencephalon than either the frontal or the temporal lobe. It has a lateral convex and a medial surface, but no basal surface. It is separated from the frontal lobe in front by the central sulcus; from the occipital lobe behind, on the medial surface by the *parietooccipital fissure*, and, on the convex surface, by an arbitrary line drawn transversely around the convex surface of the hemisphere from the superior extremity of this fissure to the inferolateral border, and it is separated from the temporal lobe below by the horizontal part of the posterior ramus of the lateral fissure, and by a line drawn in continuity with this horizontal part to intersect the transverse line drawn to limit it from the occipital lobe.

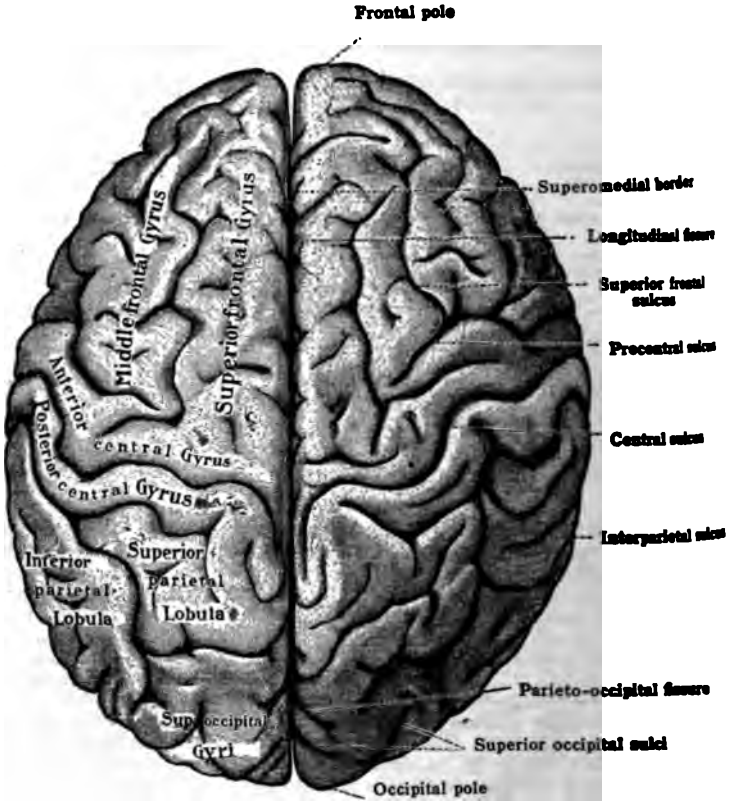
The preoccipital notch.—*In situ*, the inferolateral border of the posterior portion of the hemisphere rests over a small portion of the parietomastoid suture of the cranium, and upon this suture occurs a fold or vertical thickening of the dura mater, which slightly indents the inferolateral border of the hemisphere. This indentation occurs about 4 cm. from the

occipital pole, and is considered one of the points of limitation of the parietal from the occipital lobe, and is therefore called the preoccipital notch. While during late fetal life and early childhood it is well marked, it is usually very slight in the adult brain, and is, as a rule, evident only in brains hardened *in situ*. When it is visible, the arbitrary transverse line from the superior extremity of the parietooccipital fissure, used as a boundary between the convex surfaces of the parietal and occipital lobes, should be so drawn as to bisect the preoccipital notch.

The *convex surface* of the parietal lobe comprises the following gyri and sulci:—

The **posterior central gyrus** (ascending parietal) extends obliquely across the hemisphere parallel with the anterior central gyrus of the frontal lobe, from which it is separated by the central sulcus. Its inferior end is bounded by the posterior ramus of the lateral fissure, and constitutes the posterior or parietal portion of the frontoparietal operculum. Its upper end takes part in the superomedial border

FIG. 718.—CONVEX SURFACE OF THE CEREBRAL HEMISPHERES AS VIEWED FROM ABOVE. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)

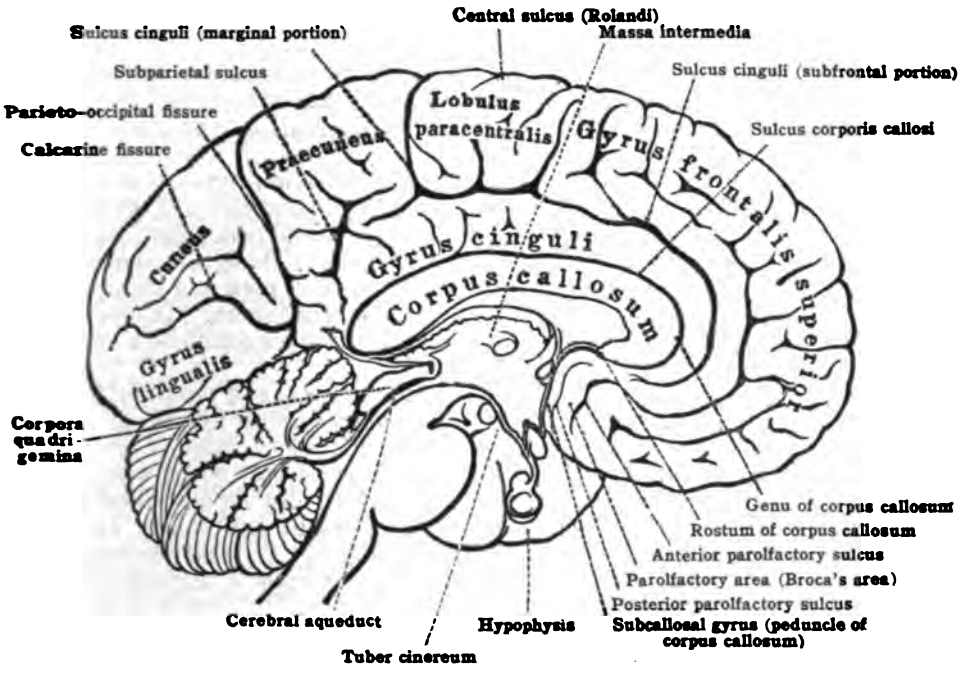


of the hemisphere, and is bounded posteriorly by the tip end of the marginal portion of the sulcus cinguli. Its posterolateral boundary consists of the two more or less vertical rami or factors of the interparietal sulcus, viz., the inferior and superior portions of the *postcentral sulcus*, either continuous with each other or detached.

The **interparietal sulcus** (intraparietal) is often the most complicated sulcus of the pallium. Its development usually begins as four different furrows in the fetal brain, and the difficulty with which it is traced in the adult brain depends upon the extent to which these four factors become continuous in the later development. When continuity of the furrows is well established, the entire sulcus may be described as consisting of an anterior end and a convex ***horizontal ramus***, which gives off a few short collateral twigs and whose either end is in the form of an irregular, reclining ⊣. The transverse bar of the anterior end arises from two of the four factors of the entire sulcus:—(1) an inferior furrow, the ***inferior postcentral sulcus***, commencing above the posterior ramus of the lateral fissure and ascending as the boundary of the lower half of the posterior central gyrus, and (2) a superior furrow, the *superior postcentral sulcus*, lying behind the upper portion

of the posterior central gyrus, and which, upon approaching the superomedial border, may turn backward a short distance parallel with the horizontal ramus, as in fig. 714. When confluent, these two factors form together a continuous **postcentral sulcus.** In the adult the superior of the two is always continuous with the horizontal ramus; when confluent, the two join so as to form the transverse bar of the anterior end of this ramus. The horizontal ramus, which represents the third of the primary furrows, is continued backward past the superior extremity of the parietooccipital fissure into the occipital lobe, where it usually joins the *occipital ramus*, the fourth of the primary furrows. This ramus divides shortly into two branches which run at right angles to the stem, forming the *transverse occipital sulcus*, and thus arises the transverse bar of the posterior end of the interparietal sulcus.

FIG. 719.—OUTLINE DRAWING OF MEDIAL SURFACE OF LEFT CEREBRAL HEMISPHERE. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



The occipital ramus may, however, consist of little more than the transverse bar, which may or may not be joined by the horizontal ramus. The occipital ramus is more frequently separate from the horizontal than is the postcentral sulcus. In their development the inferior postcentral sulcus appears first (during the latter part of the sixth month), the occipital ramus second, the horizontal ramus third, and last, the superior postcentral sulcus.

The superior parietal lobule (*gyrus*) is the area of the superomedial border of the parietal lobe (fig. 714). It is limited in front by the superior postcentral sulcus, below by the horizontal ramus of the interparietal sulcus, and posteriorly it is continuous around the superior end of the parietooccipital fissure into the cortex of the occipital lobe. It is a relatively wide area (lobule), always invaded by collateral twigs of its limiting sulci, and usually contains a few short, isolated furrows. When the parieto-occpital fissure is considerably prolonged over the superomedial border (*external parietooccipital fissure*), the continuation of the lobule about the end of this fissure presents the appearance described as the **parietooccipital arch.**

The inferior parietal lobule is limited in front by the inferior postcentral sulcus, and above by the horizontal ramus of the interparietal sulcus (fig. 714). It is continuous with the cortex of the temporal lobe, and with that of the occipital lobe behind, and is therefore invaded by the ends of the sulci belonging to these lobes. Its anterior portion is separated from the temporal lobe by the horizontal portion of the posterior ramus of the lateral fissure. The upturned end of this

ramus invades the anterior portion of the lobule and the broad fold, arched around this end and continuous behind it into the superior temporal gyrus, is known as the **supramarginal gyrus**—an area to which auditory word- and tone-images are attributed. The **angular gyrus** is the portion which embraces the posterior end of the superior temporal sulcus, and is continuous behind this into the middle temporal gyrus and in front usually with the superior temporal gyrus. It is the area for visual word images. Its shape is usually such as to suggest its name. The most posterior part of the inferior parietal lobule, when arching about the end of the middle temporal sulcus and continuous with the temporal gyri on its either side, is known as the **postparietal gyrus.** This is a smaller area than either of the other two, and, owing to the variability of the end of the middle temporal sulcus, is not always evident.

The *medial surface* of the parietal lobe is divided into two parts by the marginal portion of the sulcus cinguli. The anterior and smaller part is the medial continuation of the posterior central gyrus, and comprises the posterior portion of the **paracentral lobule** (fig. 719). It is limited from the part of this lobule belonging to the frontal lobe by a vertical line drawn from the marginal extremity of the central sulcus. The **precuneus** (*quadrate lobule*) is the posterior and larger part of the medial surface of the parietal lobe. It is separated from the cuneus of the occipital lobe by the parietooccipital fissure, and is imperfectly separated from the gyrus cinguli (limbic lobe) below by the *subparietal sulcus* (postlimbic fissure), branches of which invade it extensively.

The occipital lobe.—This is a relatively small, trifacial, pyramidal segment, comprising the posterior extremity of the hemisphere, its apex being the occipital pole. Though one of the natural divisions of the cerebral hemisphere, it is very indefinitely marked off from the lobes anterior to it. Though it contains the cortical area of the visual apparatus, only in the brains of man and the apes does it occur as a well-defined posterior projection of the hemisphere. In most of the mammalia it is not differentiated at all. Its three surfaces comprise a convex, a medial, and a tentorial surface.

Its *convex surface* is separated from that of the parietal and temporal lobes by the superior and external extremity of the parietooccipital fissure, and by an arbitrary line drawn transversely from this extremity to the inferolateral border of the hemisphere, or so drawn as to bisect the preoccipital notch when this is evident. The sulci which occur on the convex surface may be described as two, though both of these are very variable in their extent and shape, and their branches are inconstant both as to number and length. (1) The **transverse occipital sulcus** is the most constant in shape. It extends a variable distance transversely across the superior portion of the lobe, and, as noted above, it is frequently continuous with the interparietal sulcus through its occipital ramus, and when so, it appears as the posterior terminal bifurcation of this sulcus (fig. 714). When detached, it often occurs merely as a definite furrow with few rami, and sometimes the ramus by which it otherwise would join the interparietal sulcus is entirely absent. (2) The **lateral occipital sulcus** is always short, and has its deepest portion below the transverse sulcus. It usually has a somewhat oblique course toward the superomedial border. Sometimes it occurs in several detached pieces, then known collectively as the *lateral occipital sulci.*

Therefore, the gyri of the convex surface of the lobe are also variable. They are not sufficiently constant to merit individual names. The lateral occipital sulcus or sulci roughly divide them into an inferior and lateral area, known as the **lateral occipital gyri,** and into a superior area, the **superior occipital gyri.** The lateral area is continuous into the gyri of the temporal lobe, while the superior area is continuous into the gyri of the parietal lobe.

The *medial surface* of the occipital lobe is separated from that of the parietal lobe (precuneus) and from the gyrus cinguli of the limbic lobe by the well-marked parietooccipital fissure. It comprises the constantly defined, wedge-shaped lobule known as the **cuneus,** and the posterior and medial extremity of the **lingual gyrus.** Since the greater portion of the length of the lingual gyrus is involved in the basal surface of the temporal lobe, this gyrus as a whole has been considered as belonging to the temporal lobe (see figs. 711, 716). The cuneus is separated from the lingual gyrus by the posterior portion of the **calcarine fissure,** which always terminates in a bifurcation, one limb of which invades the cuneus near the superomedial border. In addition the cuneus may contain

[illegible]er twigs from both the fissures bounding it, and also, when wide, may contain [illegible] or more short, detached **sulci cunei.**

The **calcarine fissure** and the **parietooccipital fissure** are almost invariably joined in the human brain, forming a Y-shaped figure, the prongs of which give the cuneus its shape. The calcarine fissure begins on the tentorial surface in the posterior portion of the hippocampal gyrus of the limbic lobe, below the splenium of the corpus callosum, and extends backward upon the medial occipital border of the hemisphere. It then bends downward and proceeds to its terminal bifurcation in the polar portion of the occipital lobe. The stem or hippocampal portion of the fissure is deeper than the posterior or occipital portion. It produces a well-marked eminence in the medial wall of the posterior cornu of the lateral ventricle, known as the *calcar avis* or *hippocampus minor*. It is developed separately from the posterior portion, which itself first appears as two grooves. All three parts are usually continuous with each other before birth.

The **parietooccipital fissure** usually appears from the first as a continuous groove. It begins in the superomedial border of the hemisphere, rarely extending into the convex surface more than 10 mm. (*external parietooccipital fissure*), thence it extends vertically downward across the mesial surface (*internal parietooccipital fissure*), and terminates by joining the calcarine fissure at the region of the downward bend of the latter, or at about the junction of its anterior and middle thirds. In certain of the lower apes and in the brain of the chimpanzee there is no junction between the two fissures, they being kept apart by a narrow neck of cortex, the **gyrus cunei.** Neither are they joined in the human fetus. If in the adult human brain the region of their junction be opened widely, there will be found a submerged transitory gyrus (**deep annectant gyrus**), which is the gyrus cunei, superficial in the fetus. In the higher apes and in microcephalic idiots this gyrus may be on the surface or partially submerged. Two other transitory gyri (annectant gyri) are to be found by pressing open the calcarine fissure, and they mark the points at which its three original grooves became continuous during its development into a boundary between the cuneus and the lingual gyrus. Of these, the **anterior cuneolingual gyrus** crosses the floor of the calcarine fissure on the posterior side of its junction with the parietooccipital fissure, and therefore near the gyrus cunei. The **posterior cuneolingual gyrus** occurs near the region of the terminal bifurcation of the fissure.

The *tentorial surface* of the occipital lobe is blended intimately with that of the temporal lobe, from which it is separated only by an arbitrary line drawn from the line of demarcation for the convex surface, at the region of the preoccipital notch, and thence to the isthmus of the gyrus fornicatus—the narrow neck of cortex connecting the gyrus cinguli with the hippocampal gyrus, just below the splenium of the corpus callosum (see fig. 711). The gyri blending the occipital and temporal lobes across this line are the *lingual gyrus*, already mentioned, and the **fusiform gyrus** (occipitotemporal convolution). In fact, the tentorial surface of the lobe may be considered as nothing more than the posterior extremity of the fusiform gyrus, and the inferior portion of the same extremity of the lingual gyrus. The former is often somewhat broken up and is then continuous into the lateral occipital gyri. These two gyri are separated by the *collateral fissure* the posterior end of which extends into the occipital lobe. The fusiform gyrus is bounded laterally by the inferior temporal sulcus, which sometimes is continuous by a lateral twig, across the posterior end of this gyrus, with the collateral fissure.

The Rhinencephalon

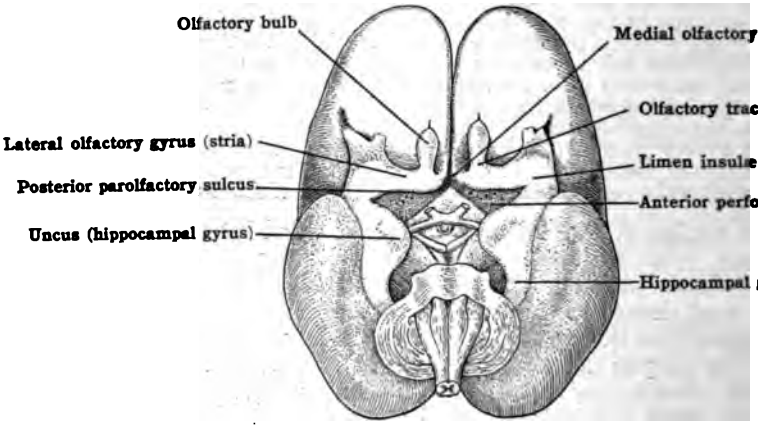
The rhinencephalon or *olfactory brain* includes those portions of the cerebral hemisphere which are chiefly concerned as the central components of the olfactory apparatus. Owing to the preponderant development of the other divisions of the hemisphere, the parts comprising this division appear relatively but feebly developed in the human brain. In most of the mammals the sense of smell is relatively much more highly developed, and in many of the larger mammals the parts comprising the rhinencephalon are of greater absolute size than in man, though their cerebral hemispheres may be considerably smaller. In the human fetus the parts of the rhinencephalon are relatively much more prominent than after the completed differentiations into the adult condition. In the broader sense of the term the rhinencephalon includes those parts of the hemisphere usually classed as comprising two lobes, viz., the **olfactory lobe** and the **limbic lobe.** Neither of these is a 'lobe' in the sense of comprising a definite segment of the hemisphere, as do the other lobes, and therefore the rhinencephalon cannot be called a distinct lobe. It is so strung out that by one or the other of its parts it is either in contact or continuity with each of the other lobes of the hemisphere. Morphologically, the olfactory lobe and adjacent structures form the *anterior division*, and the limbic lobe forms the *posterior division* of the rhinencephalon.

The anterior division.—The *olfactory lobe* proper belongs almost wholly to the base of the encephalon, and consists of the following parts:—

(1) The **olfactory bulb** is an elongated, oval enlargement of gray substance which lies upon the lamina cribrosa of the ethmoid bone, and, practically free, it is pressed into the anterior end of the olfactory sulcus in the basal surface of the frontal lobe. The numerous thin filaments of non-medullated axones of the *olfactory nerve* enter the cranium through the foramina of the lamina cribrosa and pass into the inferior surface of the bulb.

(2) The **olfactory tract** is a triangular band of white substance which arises in the olfactory bulb, and continues backward about 20 mm. to the region of the anterior perforated substance. It appears triangular in transverse section from the fact that its upper side fits into the olfactory sulcus. It becomes somewhat broader at its posterior end. In the human fetus and in the adult of many of the lower vertebrates the tract retains considerable gray substance.

FIG. 720.—BRAIN OF HUMAN FETUS OF 22.5 CM. (BEGINNING OF FIFTH MONTH), SHOWING THE PARTS OF THE DEVELOPING RHINENCEPHALON APPARENT ON THE BASAL SURFACE. (After Retzius.)



(3) The **olfactory trigone** (*olfactory tubercle*) is the small triangular ridge, the posterior continuation of the olfactory tract joining the anterior perforated substance. In it the olfactory tract breaks up into three roots, the *lateral, intermediate,* and *medial olfactory stria* (*gyri*). The lateral olfactory stria emphasizes the lateral portion of the trigone into the **lateral olfactory gyrus,** a portion of which is directly continuous into the *limen insulæ* (figs. 716, 720).

While a few of the fibers of the lateral stria penetrate this region, the greater mass of them pass obliquely lateralward over it and gradually disappear in the anterolateral portion of the anterior perforated substance, in which some of them terminate, but through which most of them pass to curve into the anterior end of the hippocampal gyrus and terminate there, chiefly in the uncus. In most of the mammals the lateral stria is so strong that it appears as a superficial white band passing directly into the uncus. In the early fetus it is seen to enter the uncus in two branches, forming the medial semilunar gyrus and the lateral gyrus ambiens upon the uncus. A portion of the *limen insulæ* belongs to the rhinencephalon.

(4) The **parolfactory area** (Broca's area) involves the mesial extension of the olfactory trigone, and is concerned with the *medial olfactory* stria. On the basal surface of the hemisphere this area involves the posterior extremity of the gyrus rectus—a portion of which is sometimes seperated from the remainder of the gyrus by a ventral prolongation of the *anterior parolfactory sulcus* of the medial surface (figs. 719, 724). This prolongation when present has been called the **fissura serotina.** On the medial surface the parolfactory area appears as a definite gyrus. In front this is separated from the superior frontal gyrus by the *anterior parolfactory sulcus*, and from the subcallosal gyrus behind by the deeper *posterior parolfactory sulcus* (fig. 719). It is continuous above into the gyrus cinguli of the limbic lobe, a portion of the posterior division of the rhinencephalon.

A large portion of the fibers of the medial stria are lost in the parolfactory area, and are known to terminate about the cells there. This stria or root of the olfactory tract forms a slight ridge on the ventral surface of the area, which is frequently prominent enough to retain the name medial olfactory gyrus applied to it in the fetal brain (fig. 720).

(5) The **subcallosal gyrus** (peduncle of the corpus callosum) is the narrow fold of the pallium which lies between the posterior parolfactory sulcus and the rostral lamina and the ventral continuation of the latter into the lamina terminalis. It begins above, in part fused to the rostrum of the corpus callosum, and in part continuous with the gyrus cinguli, and ventrally it goes over lateralward and posteriorly into that portion of the anterior perforated substance known as the *diagonal band* of Broca, and in this way it extends into the uncus. Medially, it approaches its fellow of the opposite side so closely that the groove separating the two is known as the *median subcallosal sulcus* of Retzius Some fibers of the medial olfactory stria disappear in the substance of the subcallosal gyrus.

(6) The **anterior perforated substance** must be considered with the rhinencephalon, but, like the limen insula, it can only be considered as belonging in part to this division of the brain. It comprises the basal region between the optic chiasma and tract and the olfactory trigone. Usually the posterior parolfactory sulcus (*fissura prima* of the embryo) is sufficiently evident to more or less distinctly separate it from the latter. Its posterolateral area is occupied by the *diagonal band* of Broca. A few fibers from the medial stria are known to disappear within its depths, and, as mentioned above, many fibers from the lateral stria also pass into it. The intermediate *olfactory stria* is always much the weakest of the three striæ, and in many specimens is apparently absent The fibers of this stria run almost straight backward and plunge directly into the anterior area of the anterior perforated substance, where some of them are known to terminate, while others continue into the uncus.

On embryological grounds, the subcallosal gyrus and the anterior perforated substance are classed with the posterior part of the 'olfactory' lobe or anterior division of the rhinencephalon. The olfactory bulb and tract arise as a hollow outgrowth from the lower and anterior part of the anterior of the three primary vesicles. It is tubular structure at first, and in many of the mammals the cavity maintains throughout life as the *olfactory ventricle*. In man the cavity becomes occluded and the ependyma and gelatinous substance which surround it become the gray core of the bulb and tract of the adult.

The gray substance persists and develops chiefly in the bulb, and in fact produces it as such. It is much thicker on the inferior surface of the bulb than on the superior surface, and in section shows definite layers. From within outward, the principal of these layers are—(1) the layer of large cells whose shape suggests their name, *mitral cells;* (2) large dendrites of the mitral cells project toward the inferior surface of the bulb and there break up into numerous telodendria which copiously form synapses with like telodendria of the entering fibers of the olfactory nerve, thus forming rounded, much tangled glomeruli and the layer containing these, the *glomerular layer;* (3) the superficial layer, or *olfactory layer*, consists of the fibers of the olfactory nerve which form a dense interlacement with each other on the inferior surface of the bulb before they pass into its interior. The superior surface of the bulb becomes formed almost wholly of the fibers which arise as axones of the mitral cells and pass backward to form the olfactory tract, and thence to their localities of termination, chiefly by way of the three striæ. Along the dorsal, covered, aspect of the olfactory tract the gelatinous substance of the core may show through as a gray ridge.

The posterior division of the rhinencephalon or the so-called **limbic lobe** (a name introduced by Broca in 1878) takes part in both the medial and tentorial surfaces of the hemisphere (fig. 721). Seen from the medial surface, it forms an irregular elliptical figure which encloses the corpus callosum and the extremities of which approach each other at the anterior perforated substance, where they are continous with the structures of the anterior division of the rhinencephalon. The figure is bounded externally by the sulcus cinguli above, by the subparietal sulcus (postlimbic sulcus) and the anterior limb of the calcarine fissure behind, and by the collateral fissure below. These respectively separate it from the frontal, parietal, occipital, and temporal lobes. It comprises the following structures which are either wholly or in part devoted to the functions of the olfactory apparatus:—

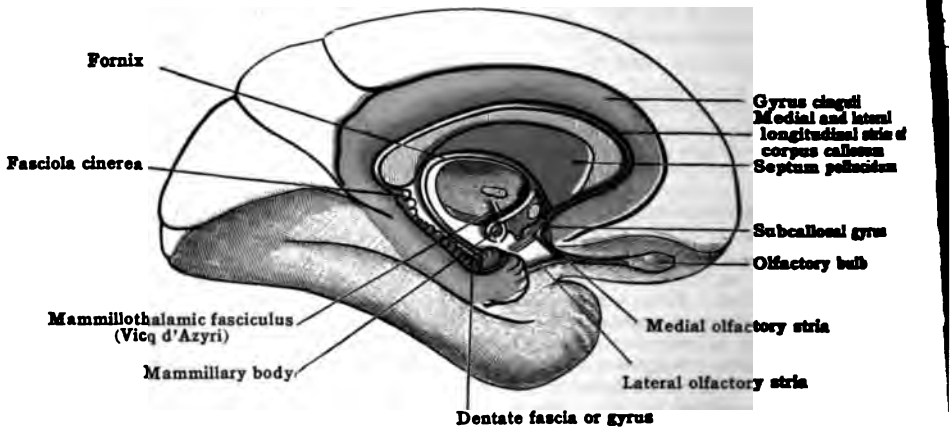
1. Gyrus fornicatus
   - Part of gyrus cinguli and cingulum.
   - Isthmus of the gyrus fornicatus.
   - Hippocampus
     - hippocampal gyrus.
     - uncus.
     - dentate gyrus (fascia).
     - fimbria.
2. The medial and lateral longitudinal striæ upon the corpus callosum.
3. The fornix.

4. The mammillary body, the mammillothalamic fasciculus to the anterior nucleus of the thalamus and the mammillopeduncular fasciculus.
5. Part of anterior cerebral commissure.
6. Part of septum pellucidum.
7. Part of medullary stria of thalamus.
8. Most of habenular nucleus.

The **gyrus fornicatus** comprises the greater mass of the limbic lobe. As seen above, it is a term used to collectively represent a number of conjoined structures. Being an incomplete ellipse in form, its two ends are united to form a closed ring by means of the connection of the parolfactory area with the gyrus cinguli and the connection of the anterior perforated substance with the uncus of the hippocampal gyrus. It is best described in terms of its three component parts indicated above:

The **gyrus cinguli** begins in junction with the area parolfactoria below the anterior end of the corpus callosum, and curves above so as to entirely embrace the upper surface of the latter. It is separated from the frontal lobe by the sulcus

FIG. 721.—DIAGRAM SHOWING POSITION OF STRUCTURES COMPRISING THE LIMBIC LOBE AS SEEN FROM THE MEDIAL ASPECT OF THE CEREBRAL HEMISPHERE.



cinguli (callosomarginal fissure), from the parietal lobe by the **subparietal sulcus**, and from the corpus callosum below by the **sulcus of the corpus callosum**. By the latter it is separated from the longitudinal stria of the upper surface of the corpus callosum.

The gyrus cinguli covers over, and its cells are closely associated with, the **cingulum**, a well-marked arcuate band of white substance, which follows the gyrus in its bend around the rostrum and backward to turn around the splenium of the corpus callosum in the isthmus of the gyrus fornicatus, and then to course forward into the hippocampal gyrus and the uncus. The cingulum is largely an association fasciculus between the gyri of the temporal lobe and those gyri on the medial surface of the cerebral hemisphere in which it runs, its fibers for the most part running short courses, being continually added to it and continually leaving it. However, it contains olfactory axones running in two directions: (1) fibers from the medial olfactory stria and fibers arising in the parolfactory area, the gyrus subcallosus and the anterior perforated substance which course posteriorly for distribution in the cortex of the gyrus cinguli and hippocampal gyrus; (2) fibers arising in the hippocampal gyrus, especially the uncus, to course dorsalward through the isthmus and forward as association fibers. Some fibers arising from the cortical cells of the gyrus cinguli pass inferiorly through the cingulum, through the corpus callosum and, anteriorly, through the septum pellucidum to join the fornix below (*perforating fibers of the fornix*).

The **isthmus of the gyrus fornicatus** is the constricted portion connecting the posterior end of the gyrus cinguli with that of the **hippocampal gyrus** (fig. 711, 716). It is bounded externally by the anterior end of the **calcarine fissure**, and incloses the posterior turn of the cingulum.

The **hippocampus** is the name applied to the curved appearances produced in the floor of the lateral ventricle by the peculiar foldings of this part of the cerebral cortex. The *hippocampal gyrus* (gyrus of the hippocampus) is the main gyrus of the tentorial surface of the limbic lobe. Externally it is separated from the fusi-

m gyrus by the collateral fissure, and it is bounded internally by the **hippo-mpal** or, more inclusive, the **choroid fissure.** Posteriorly it is partially divided the calcarine fissure into the lingual gyrus (of the temporal lobe) and the hmus of the gyrus fornicatus. Its anterior extremity is hooked backward and known as the **uncus** (*gyrus uncinatus*). This is almost entirely separated from e temporal lobe by a groove, the **temporal notch.** If the hippocampal fissure opened up, the **dentate gyrus** or fascia and the *fimbria* will be seen. These lie le by side, separated by the shallow **fimbriodentate sulcus** (fig. 728).

The free edge of the dentate gyrus presents a peculiarly notched appearance, produced by merous parallel grooves cutting it transversely. Its posterior end, sometimes called the *ziola cinerea*, continues backward over the splenium of the corpus callosum, and upon the per surface of the corpus callosum appears as a thin strip of gray substance which contains bedded in it the ends of the *medial* and *lateral longitudinal striæ*. This strip is called the **racallosal gyrus** (*gyrus epicallosus, induseum griseum*), and is thought to represent a ves-ial part of the hippocampal gyrus. Closely beneath the splenium of the corpus callosum, a the superomedial side of the hippocampal gyrus and medial to the dentate gyrus, there metimes occur suggestions of round or oval elevations of the gray substance which have been lled the **'callosal convolutions'** or *gyri Andreæ Retzii*. Rarely are they strongly developed, but hen so they often produce a spiral appearance.

The **fimbria** is but the fimbriated, free border of the posterior end or origin f the fornix, so folded as to project into the hippocampal fissure, parallel with the entate gyrus (fig. 728). It is a conspicuous band composed almost entirely of hite substance, continuous laterally with the thick stratum covering the ven-icular surface of the hippocampus. It begins anteriorly in the hook or recurved ctremity of the uncus. Traced backward, it is seen to curve upward, and within ie ventricle it becomes part of the general accumulation of the white substance *lveus*) of the ventricular surface of the hippocampus, which accumulation is the eginning of the fornix. The free border of the fimbria (seen in section) is known s the *tenia fimbriæ*, or better, *tenia fornicis*. The fimbria is separated from the erebral peduncles by the **choroid fissure,** the thin, non-nervous floor of which one intervenes between the exterior of the brain and the cavity of the lateral entricle within.

The hippocampal fissure attains its greatest depth between the dentate gyrus nd the hippocampal gyrus, and the resulting eminence produced in the floor of ie lateral ventricle is known as the **hippocampus major** (figs. 726, 727), as distin-uished from the lesser eminence produced posteriorly by the end of the calcarine ssure and known as the *hippocampus minor* [calcar avis]. The collateral fissure ay likewise produce a bulging in the wall of the ventricle, the *collateral eminence.* n transverse sections of the hippocampus major, the layers of gray and white sub-ance present a coiled appearance known as the **cornu ammonis.** Externally ie medial surface of the hippocampal gyrus adjoining the dentate gyrus has flected over it a delicate reticular layer of white substance known as the *sub-antia reticularis alba* (*Arnoldi*).

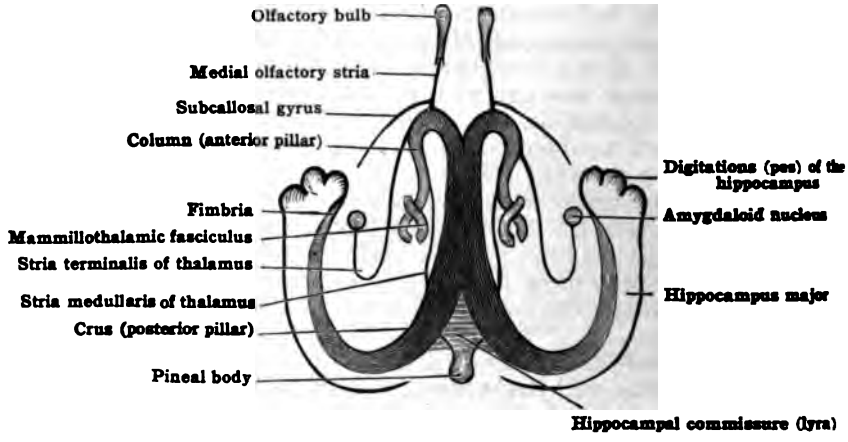
The fornix (figs. 722–724) is the great association pathway of the limbic lobe, nd appears to be wholly concerned in the apparatus of the rhinencephalon. It a bilateral structure arched beneath the corpus callosum, with which it is onnected anteriorly by the septum pellucidum. Posteriorly it passes in contact ith the splenium. It consists of two prominent strips of white substance, one r each hemisphere, the ends of which are separate from each other, while their in-rmediate parts are fused across the midline. These run above the choroid tela of ie third ventricle, and their lateral edges (*teniæ fornicis*) rest, on each side, along ie line of the tenia chorioidea. The posterior, separate ends are known as the osterior pillars or crura of the fornix; the fused, intermediate portion is the body, nd the separate, anterior ends are the anterior pillars or columns of the fornix.

The crura (posterior pillars) of the fornix.—When seen from the medial aspect f the hemisphere, the fused portion of the fornix, in the separation of the hemi-pheres, is split along the midline (fig. 711). The half under examination may be en to course obliquely lateralward under the splenium of the corpus callosum, nd then, continuous into the fimbria, to curve forward and ventralward toward ie uncus. The greater mass of the fibers coursing in the fornix arise as out-rowths of the cells of the uncus, hippocampal gyrus, and dentate gyrus. They ccumulate as a dense stratum on the ventricular surface of these gyri, termed the lveus, which crops outward as the fimbria and which passes backward and up-ard; upon reaching the region of the splenium it turns obliquely forward under

it and approaches the midline, to fuse with the like bundle from the gyri of the hippocampus of the opposite side. The bundles thus arising from the two sides are the crura (posterior pillars) of the fornix. They appear as two flattened bands of white substance which come in close contact with and even adhere to the splenium.

The angle formed by the mutual approach of the crura of the fornix is crossed by a lamina of commissural fibers connecting the hippocampal gyri of the two hemispheres (fig. 722). This lamina is the **hippocampal commissure** or *transverse fornix*. Like those of the fornix, its fibers arise from the cortex of the hippocampal gyri, but they serve as commissural fibers between the hippocampal gyri of the two hemispheres. Being of a different functional direction, it should not be considered a part of the fornix. The angle formed by the two crura of the fornix as traversed by the hippocampal commissure gives a picture named the **psalterium** or **lyra**. Usually the hippocampal commissure and the crura are in close contact with the under surface of the splenium. When occasionally they do not adhere, the space between is known as **Verga's ventricle**. According to recent studies of brains with degenerated corpus callosum (Shimazono), further commissural fibers between the limbic lobes course in the posterior angle of the septum pellucidum, transverse to the body of the fornix.

FIG. 722.—DIAGRAM SHOWING FORNIX AND ITS CONNECTIONS AS SEEN FROM ABOVE.



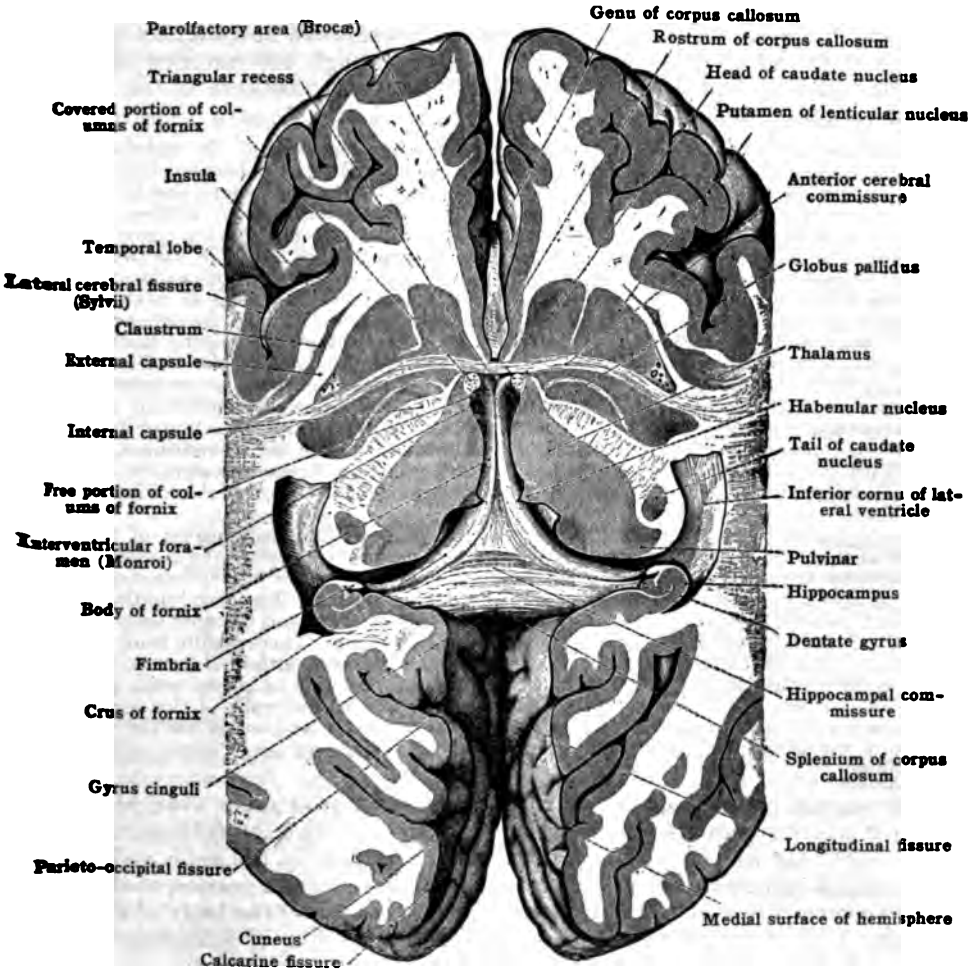
The body of the fornix [corpus fornicis] appears as a triangular plate of white substance produced by the fusion of the pillars. Its base or widest portion is behind. It is not always bilaterally symmetrical. Its upper surface is attached by the septum pellucidum to the lower surface of the corpus callosum. Below, it lies over the choroid tela of the third ventricle, which separates it medially from the cavity of the third ventricle and laterally from the upper surfaces of the thalami. Its sharp lateral edge or margin (tenia fornicis) projects into the lateral ventricle of either side in relation with the choroid plexus of that ventricle, and thus the lateral portion of its upper surface forms part of the floor of the lateral ventricle—an arrangement to be expected, since the crura arise from the floor of the ventricle, viz., the hippocampus. The ventricular portion is covered by a layer of ependyma in common with that lining the rest of the ventricle.

Along its body the fornix receives fibers arising from the cells of the cortex of the gyrus cinguli and fibers from the longitudinal stria upon the dorsal surface of the corpus callosum. These pass through the latter and are the **perforating fibers of the fornix (fig. 724)**. In their ventral course, they pass obliquely forward through the corpus callosum and, anteriorly, through the posterior angle of the septum pellucidum to join the fornix and course in its functional direction. The fibers arising in the cortex of the gyrus cinguli may course short distances in the cingulum before perforating the corpus callosum.

The columns (anterior pillars) of the fornix [columnæ fornicis] are two separate, cylindrical bundles which pass forward from the apex of the body of the fornix and then turn sharply downward along the anterior boundary of the third ventricle, just behind the anterior cerebral commissure. A part of each column, *free portion* [pars libera], forms the anterior boundary of the interventricular foramen (Monroi). Thence the *covered portion* [pars tecta] sinks into the gray substance of the lateral wall of the third ventricle, and passes downward to the base of the brain, where it appears on the exterior as the **mammillary body** [corpus mammillare] (fig. 711).

Some fornix fibers are interrupted in the nuclei of the mammillary body; probably most of them merely double back, forming the genu. From the mammillary body the fibers are disposed at least three ways: (1) The greater part perhaps pass directly upward and are lost in the *anterior nucleus of the thalamus*, where they ramify freely and terminate about its cells. These fibers form the bundle known as the **mammillothalamic fasciculus**, or bundle of Vicq d'Azyr; (2) a portion of the fibers go to form a **mammillomesencephalic fasciculus** (*tegmentomammillary fasciculus, mammillopeduncular fasciculus*). This begins in the mammillary body and passes caudalward into the mesencephalon to terminate about cell-bodies in, or in the region of, the so-called *nucleus of the medial longitudinal fasciculus and posterior commissure.* Fibers given by

FIG. 723.—HORIZONTAL SECTION OF TELENCEPHALON SHOWING BODY OF FORNIX AND HIPPOCAMPAL COMMISSURE AS SEEN FROM BELOW AND THE ANTERIOR COMMISSURE, IN SECTION. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



these cell-bodies may convey impulses by way of the medial longitudinal fasciculus or the general reticular formation to the nuclei in the mesencephalon, rhombencephalon and perhaps into the spinal cord. Some of this portion of the fibers from the mammillary body are said to pass caudalward through the mesencephalon without interruption there. (3) A portion of the fibers decussate in the superior parts of the mamillary bodies and are distributed to both the thalamus and the mesencephalon of the opposite side. This decussation is the **supramammillary commissure.**

As seen above, the fornix as a whole is composed of longitudinally directed fibers, some of which, however, cross the midline in the region of its body and course in the columns of the opposite side. For the greater part, its fibers rise from the cells of the hippocampal gyri, but it is known to contain some fibers which arise in the anterior perforated substance and subcallosal gyrus and course through the fornix to the hippocampal gyri.

The **medial and lateral longitudinal striæ** upon the corpus callosum consist of olfactory fibers coursing in both directions: (1) fibers arising in the parolfactory area, the subcallosal gyrus and the anterior perforated substance (diagonal band of Broca) course posteriorly and then inferiorly in them to the gray substance of the gyri of the hippocampus; (2) and chiefly, fibers from the hippocampal gyri course in them anteriorly and inferiorly around the rostrum of the corpus callosum, through the ventral part of the septum pellucidum, to join the fornix.

It is suggested that the stria, especially the medial, may be considered as a part of the fornix detached upon the dorsal surface of the corpus callosum during the projection of the latter between the cerebral hemispheres. The medial stria is often called the *stria Lancisii*. The two striæ are sometimes called the *dorsal fornix*.

The anterior cerebral commissure is largely concerned in the rhinencephalon; the remainder includes commissural fibers connecting the two temporal lobes. It forms one of the five commissures of the telencephalon, the other four being the corpus callosum, the hippocampal, inferior cerebral, and supramammillary commissures. It is a bundle of white substance with a slightly twisted appearance, which crosses the midline in the anterior boundary of the third ventricle between the lamina teminalis and the columns of the fornix (figs. 711 and 723), just below the interventricular foramen (foramen of Monro). In each hemisphere its main or temporal portion passes lateralward and slightly backward beneath the head of the caudate nucleus and through the anterior end of the lenticular nucleus, and thence is dispersed to the gray substance of the temporal lobe and hippocampal gyrus.

It contains fibers both to and from the temporal lobe of each side. In addition to these fibers the anterior commissure carries in its frontal side three sets of fibers belonging to the olfactory apparatus:—(1) fibers arising in the olfactory bulb of one side, which pass by way of the medial olfactory stria through to it the olfactory bulb of the opposite side; (2) fibers which pass through it from the medial stria (olfactory bulb) of one side to the uncus of the opposite side; 3 commissural fibers between the hippocampal cortex, especially the uncus, of the two sides.

The anterior commissure is a more primitive commissure than the corpus callosum, in that it is present in the lower forms when the latter is absent, and diminishes in relative size and importance as the corpus callosum appears and increases in size. In man the appearance of the anterior commissure precedes but little that of the corpus callosum. During the fifth month the lamina terminalis, which then alone unites the anterior ends of the two hemispheres, develops a thickening of its dorsal portion. In a part of this thickening, transverse fibers begin to appear and their increase in number results in the partial separation posteriorly of the part containing them from the rest of the lamina, and then follows the differentiation of this part into the anterior commissure. The remainder of the thickening of the lamina continues to increase in size with the increase of the hemispheres; its upper edge is directed posteriorly, and fibers begin to appear in it which arise in the cortex of one side and cross over to that of the other side. These fibers form the corpus callosum.

The corpus callosum, a growth of fibers in the upper, expanded portion of the lamina terminalis, thus bridges over a portion of the longitudinal fissure between the hemispheres. In the mean time, the *fornix* arises as two bundles of fibers, one from the hippocampus of each side. In the complex mechanics of the development of the cerebrum these two bundles approach each other under the corpus callosum, fuse for a certain distance, and together arch the cavity of the third ventricle and come to acquire their adult position. There results from these processes of growth a completely enclosed space, a portion of the longitudinal fissure, the roof of which is the corpus callosum, its floor, the body of the fornix, and its lateral walls, portions of the mesial surfaces of the two cerebral hemispheres. The lateral walls of this space do not thicken as do the other regions of the pallium, but remain thin and constitute the *septum pellucidum* of the adult, the space itself being the so-called *fifth ventricle* or cavity of the septum pellucidum.

The **septum pellucidum** is a thin, approximately triangular, vertically placed partition which separates the anterior portions of the two lateral ventricles from each other. Its widest portion lies in front, bounded by the genu and rostrum of the corpus callosum, the rostral lamina, and the anterior portion of the fornix, to all of which it is attached. Prolonged backward under the body of the corpus callosum, it narrows rapidly and terminates at the line of adherence between the posterior portion of the fornix and the splenium of the corpus callosum. It consists of two thin layers, the **laminæ of the septum pellucidum,** arrested developments of portions of the pallium of the hemispheres. The laminæ enclose a narrow median cavity known as the **fifth ventricle** [cavum septi pellucidi]. This cavity is of very variable size, is completely closed, and does not merit the term 'ventricle,' as applied to the other cavities of the brain, in that it has no communication with the ventricular system and has a different lining from the other ventricles.

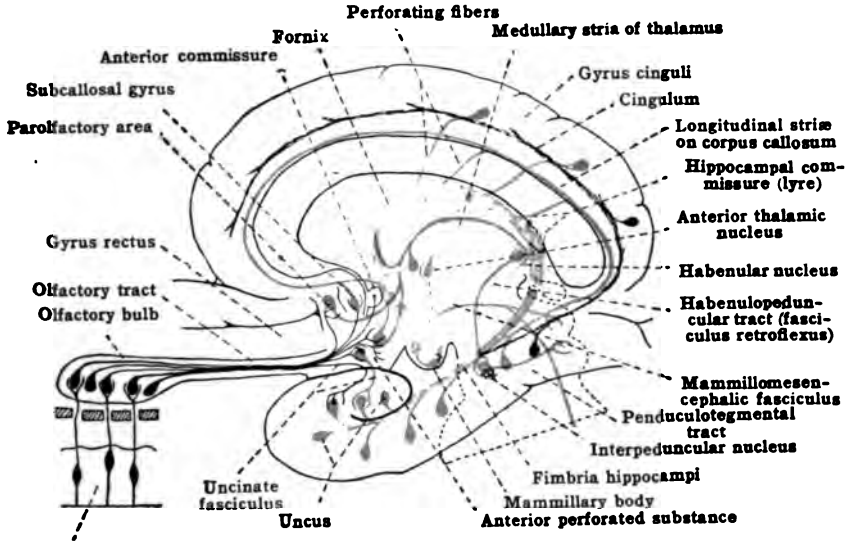
Each lamina of the septum pellucidum consists of a layer of undeveloped gray substance next to the fifth ventricle and a layer of white substance next to the lateral ventricle, the latter covered by a layer of ependyma common to that ventricle. The white substance consists in part of fibers belonging to the general association systems of the hemispheres, and in part of four varieties of fibers concerned with the rhinencephalon:—(1) fibers from each medial olfactory stria are known to reach the septum pellucidum and thence go by way of the fornix to the hippocampus major; (2) fibers are thought to be contributed by the fornix to the septum pellucidum, and through it reach the subcallosal gyrus and perhaps the parolfactory area and even the olfactory bulb; (3) the posterior angle of the septum pellucidum is perforated by some commis-

al fibers passing from the body of the fornix and by some perforating fibers of the fornix, pass- from above through it to the fornix below; (4) anteriorly, some fibers from the longitudinal a upon the corpus callosum pass through its inferior portion to join the fornix.

The medullary stria of the thalamus [stria medullaris thalami] (*stria pinealis, tenia thalami, enula*), already described as to position, receives fibers from three sources, the majority at t of which belong to the rhinencephalon: (1) fibers from the fornix nearby and thus from the rtex of hippocampal gyrus and gyrus cinguli (a corticohabenular tract); (2) fibers from the par- ctory area and the anterior perforated substance, through the septum pellucidum and mina terminalis (a more direct olfactohabenular tract); (3) fibers arising from the cell-bodies the thalamus, supposedly chiefly from its anterior (olfactory) nucleus. These latter fibers ke a thalamohabenular tract.

The majority of the fibers of the medullary stria terminate in the **habenular nuclei**, situated t the two sides of the stalk of the pineal body. Most terminate in the habenular nucles of the me side. Some cross in the *habenular commissure* (dorsal part of the posterior cerebral com- issure) and terminate in the nucleus of the opposite side. A few are claimed to pass to the uclei of the quadrigeminate bodies and a few others to join the association tracts of the mesen- ephalon. Axones given off by the cells of the habenular nucleus curve anteriorly, inferiorly,

FIG. 724.—DIAGRAM SHOWING SOME OF THE PRINCIPAL TRACTS AND SYNAPSES OF THE OLFACTORY APPARATUS.



and then course posteriorly (fasciculus retroflexus) to terminate in the *interpeduncular nucleus* (*habenulopeduncular tract*), and fibers arising in this latter nucleus pass to the cells about the central gray substance of the mesencephalon (an interpedunculotegmental tract). The two mesencephalic paths here noted and the mammillomesencephalic fasciculus noted above give three anatomical possibilities for olfactory reflex activities, visceral (or sympathetic) and somatic, involving the motor cranial nerves and possibly the spinal nerves. Fibers arising in the cortex of the hippocampal gyrus, uncus especially, may pass by way of the cingulum and thence by any suitable association fasciculus of the cerebral hemisphere to the motor area of the cerebral cortex; also fibers may arise from the anterior nucleus of the thalamus and pass to the motor cortex by way of the internal capsule. From the motor cortex, the descending pyramidal fibers give the possibilities for any higher cortical activities induced by smell.

A more direct mesencephalic path has been suggested by Wallenberg, namely, that cells in the olfactory trigone and anterior perforated substance, about which terminate fibers of the olfactory tract, send axones directly posteriorly, around the tuber cinereum, to terminate in the mammillary body and thence the impulses may go to the mesencephalon. Such fibers, if they exist, would form an *olfactomammillary tract*. A path is described in the hedge-hog which arises from cells in the olfactory trigone and passes directly posteriorly to terminate in the gray substance of the mesencephalon—an *olfactomesencephalic tract*.

To the complicated central connections of the sense of smell, Dejerine adds yet another path, namely, a portion at least of the terminal stria [stria terminalis] of the thalamus (tenia semicircularis). This contains fibers arising from cells in the anterior perforated substance and in the septum pellucidum and fibers from the opposite side by way of the anterior commissure. It runs a crescentic course posteriorly, bounding the thalamus from the caudate nucleus, turning downward and then anteriorly in the wall of the inferior cornu of the lateral ventricle to terminate in the amygdaloid nucleus, which latter is a more or less detached bit of the cortex of the extreme anterior portion of the hippocampal gyrus (uncus). The stria is said also to contain fibers which arise in the amygdaloid nucleus and course in it forward to be given off to the thalamus and probably to the internal capsule and thence to the cerebral cortex above. For a more detailed description of what may be called the fornix-system of fibers, the work of Shimazono may be consulted.

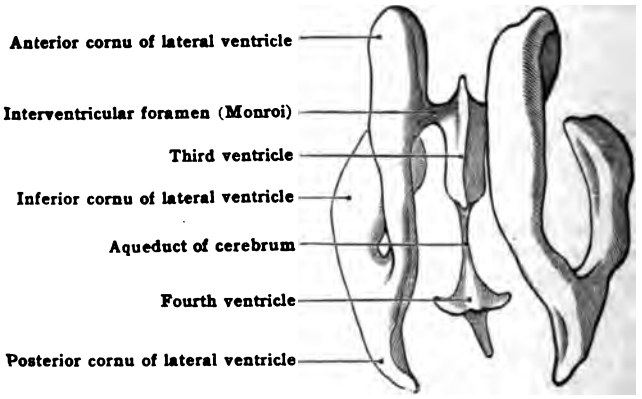
SUMMARY OF THE OLFACTORY APPARATUS

I. Peripheral part.
(1) Olfactory area of nasal epithelium containing the cell-bodies and peripheral p of olfactory neurones (*olfactory ganglion*).
(2) Non-medullated central processes of olfactory neurones, the *olfactory nerve*, pa numerous filaments through the cribriform plate of the ethmoid, to terminate in conta the dendrites of the 'mitral cells' (stratum glomerulosum) in the olfactory bulb.
II. The rhinencephalon.
A. The anterior division.
(1) Olfactory bulb, olfactory tract, olfactory trigone (tubercle), lateral olfact (gryus), medial and intermediate olfactory stria.
(2) The parolfactory area, subcallosal gyrus, anterior perforated substance inclu diagonal band of Broca.
B. The posterior division.
(1) Part of anterior commissure, septum pellucidum, uncinate fasciculus, hipp gyrus (uncus especially), dentate gyrus, gyrus cinguli and cingulum.
(2) Fimbria, hippocampal commissure, fornix, longitudinal striæ upon corpus c mammillary body, mammillothalamic fasciculus, mammillomesencephalic fasciculus.
(3) The anterior nucleus of the thalamus.
(4) The medullary stria of the thalamus, habenular nucleus, fasciculus retroflex peduncular nucleus, and interpeduncolotegmental tract.
(5) Probably an olfactomammillary and an olfactomesencephalic tract, and a pa terminal stria of the thalamus with the amygdaloid nucleus.

THE LATERAL VENTRICLES

Two of the four cavities of the ventricular system of the brain are in th cephalon. From their position, one in each cerebral hemisphere, they are as the **lateral ventricles** (figs. 725–728). They arise as lateral dilation cavity of the anterior of the primary vesicles; and, just as the fourth v remains in communication with the third by way of the aqueduct of the ce

FIG. 725.—A CAST OF THE FOUR VENTRICLES OF THE ENCEPHALON. (After Welc



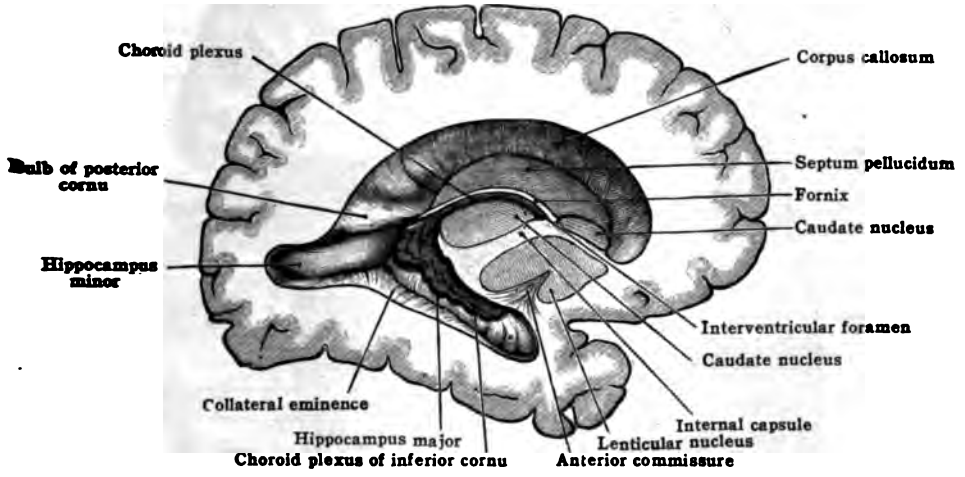
so the lateral are connected with the third by the two interventricular f (Monroi). The whole ventricular system, including the central canal of t cord, is lined by a continuous layer of ependyma and contains a small qu liquid known as the cerebrospinal fluid.

Each lateral ventricle is of an irregular, horseshoe shape. It cons *central portion* or body and three cornua, which correspond to the three the hemisphere. The portion projecting into the frontal lobe is know *anterior cornu*, that projecting into the occipital lobe is the *posterior co* the portion which sweeps anteriorly downward into the temporal lol *inferior cornu*. The ventricles of different individuals vary considerably ity, and the cavity of a given ventricle is not uniform throughout. localities the space may be quite appreciable, while in other places the w be approximate or even in apposition. Each lateral ventricle is a co closed cavity except at the interventricular foramen. However, a str floor of the inferior cornu is separated from the exterior of the brain by thin, non-nervous lamina forming the floor of the choroid fissure.

The interventricular foramen (foramen of Monro), by which the lateral ventricle is continuous with the cavity of the third ventricle, is a small, roundish channel, 2 to 4 mm. wide, which opens into the mesial side of the posterior end of the anterior cornu. It is bounded in front by the free portion of the columns (anterior pillars) of the fornix, and behind by the anterior tubercle of the thalamus. That the greater part of the lateral ventricle is posterior to it is due to the backward extension of the hemispheres during their growth and elaboration. Through the two foramina indirectly, the cavities of the two lateral ventricles are in communication with each other.

The walls of the lateral ventricle.—The **anterior cornu** is a bowl-like cavity, convex forward and extending downward and medialward into the frontal lobe. Above and anteriorly it is bounded by the lower surface of the corpus callosum and the radiations of its genu into the substance of the frontal lobe. Its medial boundary is the septum pellucidum; the head of the caudate nucleus (part of the corpus striatum) gives it a bulging, inferolateral wall, and the remainder of its floor is formed by the white substance of the orbital part of the frontal lobe.

FIG. 726.—DIAGRAM OF SAGITTAL SECTION THROUGH LATERAL PART OF RIGHT HEMISPHERE SHOWING LATERAL VENTRICLE FROM THE MESIAL SIDE OF THE SECTION.



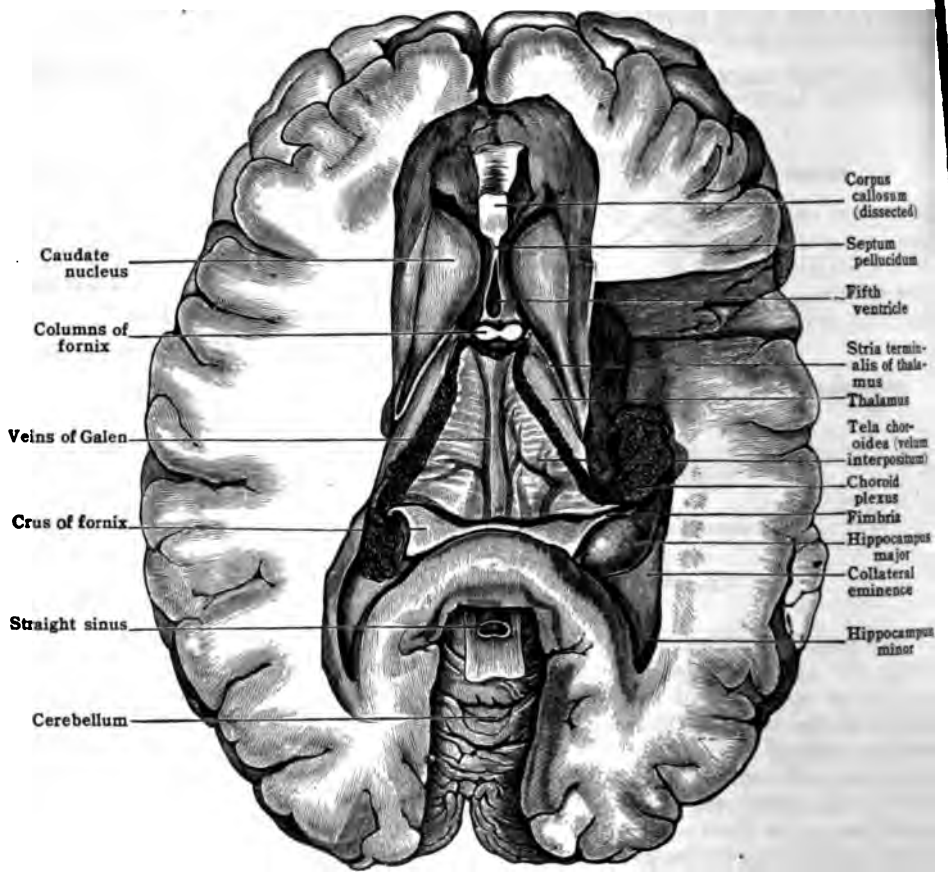
The **central portion** or body of the ventricle is more nearly horizontal. It lies within the parietal lobe and extends from the interventricular foramen to the level of the splenium of the corpus callosum. Its roof is formed by the inferior surface of the body of the corpus callosum, and its medial wall consists of the posterior part of the septum pellucidum, attaching the fornix to the lower surface of the corpus callosum. Like the anterior horn, it is given an oblique, inferolateral wall by the narrower, middle part of the caudate nucleus. Several structures contribute to its floor:—(1) the stria terminalis of the thalamus, a line of white substance conforming to the genu of the internal capsule within, and constituting the boundary between the caudate nucleus and the thalamus, and containing (2) the vena terminalis (vein of the corpus striatum); (3) the lamina affixa, a medial continuation of the stria terminalis upon the surface of (4) the lateral part of the thalamus; (5) the medial edge of the lamina affixa, the tenia chorioidea, and the choroid plexus continuing under (6) the edge (tenia) of the body and the beginning crura (posterior pillars) of the fornix (fig. 727).

The choroid plexus of the lateral ventricles (figs. 727, 760) is continuous with that of the third ventricle. The choroid tela of the third ventricle (velum interpositum) continues under the tenia of the fornix into the lateral ventricle, and there, along the line of the tenia chorioidea, becomes elaborated into a varicose, convoluted, villus-like fringe, rich in venous capillaries and lymphatics. This fringe is the choroid plexus. It is continuous anteriorly, at the interventricular foramen, with the corresponding plexus of the opposite lateral ventricle and with the choroid plexus of the third ventricle. The latter consists of two similar but smaller fringes, which project close together into the cavity of the third ventricle

from the medial portion of the ventral surface of the choroid tela. Behind, the choroid plexus of the lateral ventricle curves posteriorly and inferiorly into the inferior cornu, being especially well developed at the region of its entrance into the latter, into what is called the **choroid glomus.** It extends into neither posterior nor anterior cornu.

Though apparently lying free in the ventricle, the choroid plexus is invested throughout by a layer of ependyma, the **epithelial choroid lamina,** which is adapted to all its unevenness of surface and which is a continuation of the ependymal lining of the remainder of the ventricle —continuous, on the one hand, with that of the lamina affixa and thalamus, and, on the other, with the epitheloid covering upon the upper surface of the tenia of the fornix and fimbria.

FIG. 727.—HORIZONTAL DISSECTION OF THE CEREBRAL HEMISPHERES.
The fornix has been removed to show the relation of the tela chorioidea of the third ventricle to the choroid plexus of the lateral ventricles. (From a mounted specimen in the Anatomical Department of Trinity College, Dublin.)

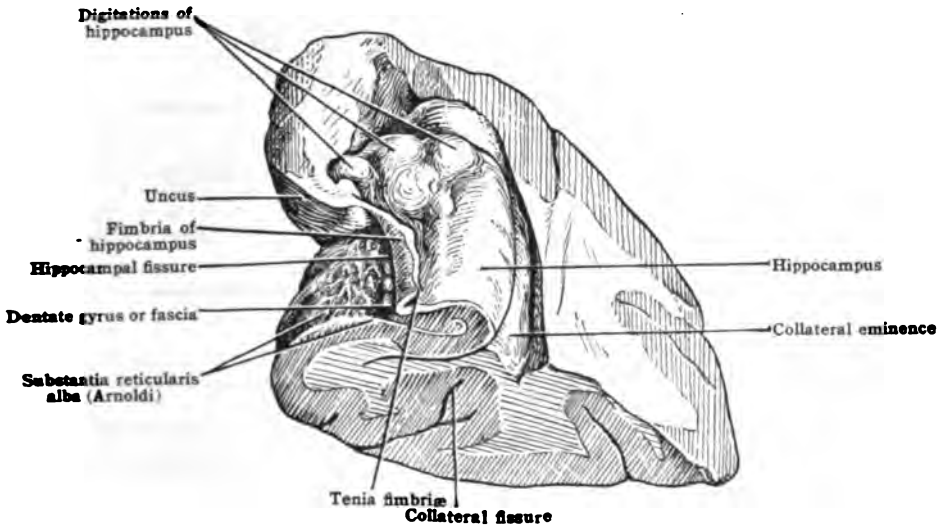


The **posterior cornu** of the lateral ventricle is a crescentic cleft of variable length, convex lateralward, which is carried backward from the posterior end of the body of the ventricle and, curving medialward, comes to a point in the occipital lobe. Its *roof* and *lateral wall* are formed by a portion of the posterior radiation of the corpus callosum, which forms a layer, from its appearance known as the **tapetum.** In transverse sections of the occipital lobe (fig. 736) the tapetum appears as a thin lamina of obliquely cut white substance immediately bounding the cavity, while lateral to the tapetum occurs a thicker layer of more transversely cut fibers, the occipitothalamic radiation. In the medial or *inner wall* of the posterior cornu run two variable longitudinal eminences:—(1) The superior of these is the **bulb of the posterior cornu,** and is formed by the occipital portion of the radiation of the corpus callosum (splenium), which bends around the impression of the deep parieto-occipital fissure, and, hook-like, sweeps into the occipital lobe. In horizontal sections these fibers, together with the splenium and the

similar fibers into the opposite occipital lobe, form the figure known as the **forceps major.** (2) The inferior and thicker of the eminences is the **hippocampus minor** [**calcar avis**] (cock's spur), and is due to the anterior part of the calcarine fissure, by which the wall of the hemisphere is projected into the ventricle. The posterior cornu, like the anterior, is not entered by the choroid plexus.

The inferior cornu.—In its inferior and slightly lateral origin from the region of junction between the body of the ventricle and the posterior cornu, the inferior cornu aids in producing a somewhat triangular dilation of the cavity known as the **collateral trigone.** Beginning as a part of the trigone, the cavity of this cornu at first passes posteriorly and lateralward, but then suddenly curves anteriorly and inferiorly into the medial part of the temporal lobe nearly parallel with the superior temporal sulcus. Above, it follows the curved crura (posterior pillars) of the fornix and fimbria; below, it does not extend to the temporal pole by from 2 to 3 cm. The *roof* and *lateral wall* are, for the most part, like those of the posterior cornu, being formed by the tapetum, but medialward a strip of the roof is formed by the attenuated, inferior prolongation, or tail, of the caudate nucleus, together with the inferior extension of the stria terminalis of the thalamus.

FIG. 728.—DISSECTION OF RIGHT TEMPORAL LOBE SHOWING THE MEDIAL WALL OF THE END OF THE INFERIOR HORN OF THE LATERAL VENTRICLE. (From Spalteholz.)



At the end of the inferior cornu the roof shows a bulging, the **amygdaloid tubercle,** situated at the termination of the tail of the caudate nucleus. This bulging is produced by the *amygdaloid nucleus,* an accumulation of gray substance continuous with that of the cortex of the hippocampal gyrus, and which gives origin to part of the longitudinal fibers coursing in the stria terminalis of the thalamus.

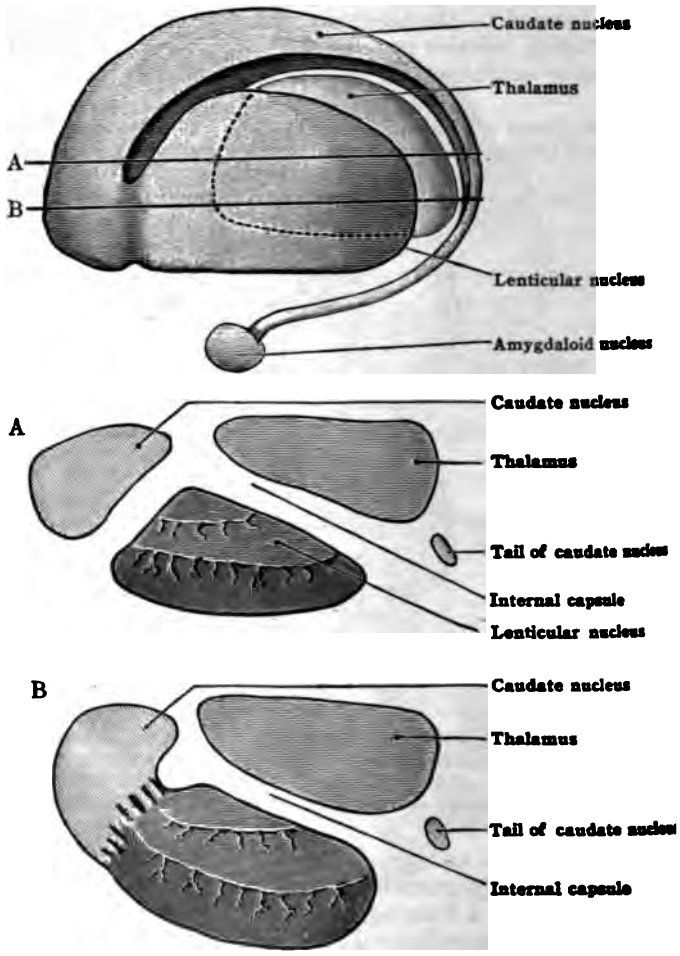
In the *medial wall* and floor of the inferior cornu the following structures are shown:—(1) In the posterior or trigonal part of the floor is the longitudinal **collateral eminence,** a bulging, very variable in development in different specimens, produced by the collateral fissure. This is often pronouncedly in two parts, a posterior prominence corresponding to the middle portion of the collateral fissure and an anterior prominence (less frequent) produced by the anterior part of the fissure. (2) Medial to this eminence lies the inferior extension of the **choroid plexus,** usually more voluminous than the part in the body of the ventricle. (3) Partly covered by the choroid plexus is the **hippocampus major,** a prominent, sickle-like ridge corresponding to the indentation of the hippocampal fissure. It begins as a narrow ridge posteriorly, at the end of the body of the ventricle, as the extension of the crus of the fornix, and expands anteriorly as the ventricular surface of the uncus. Its surface is not regular, but shows a concave medial margin as distinguished from a wider, convex, lateral surface. Its termination in front (*pes hippocampi*) is divided by two or three flat, radial grooves into a corresponding number of short elevations known as the *hippocampal digitations.* It is covered by a thick stratum of white substance, the *alveus,* arising from its

depths and continued mesially into the fimbria. (4) The **fimbria** is so fol that its margin, *tenia fimbriæ*, lies in the cavity of the inferior cornu attac to the choroid plexus and the thin, non-nervous floor of the choroid fissure.

The caudate nucleus (fig. 729).—As realized in the study of the lateral v tricle, the caudate nucleus is a comma-shaped mass of gray substance wit long, much-curved, and attenuated tail. Its *head* forms the bulging lateral w of the anterior cornu; thence it proceeds posteriorly in the lateral wall of the b of the ventricle and, at the collateral trigone, curves downward and its *tail* comes a medial portion of the roof of the inferior cornu. It is separated from

FIG. 729.—DIAGRAMS OF LATERAL VIEW AND SECTIONS OF THE CORPUS STRIATUM WI THE INTERNAL CAPSULE.

A and B below represent horizontal sections along the lines A and B in the figure above. figure also shows the relative position of the thalamus and the amygdaloid nucleus.



thalamus adjacent to it by the stria terminalis of the thalamus (tenia se cularis). The end of its tail extends anteriorly below to the level of the an horn of the ventricle above. Owing to its much curved shape, both hori and vertical sections of the hemisphere passing through the inferior cornu contain the nucleus cut at two places (figs. 731, 735).

The caudate nucleus is the intraventricular of the two masses of gray sub which together are sometimes referred to as the **basal ganglia.** The ext tricular of these masses is the *lenticular nucleus*, which is buried in the sub of the hemisphere, laterally and inferior to the caudate nucleus. The two a are separated by the *internal capsule*, a thick band of nerve-fibers continuou the cerebral peduncles, and connecting the gray cortex of the hemisphere w structures inferior to it. Anteriorly and below, the two nuclei become conti

hite substance of the internal capsule, in separating them posteriorly, butes to the striated appearance in sections, known collectively as the *corpus m* (figs. 730–735). The corpus striatum as such is described below.

INTERNAL STRUCTURE OF THE PROSENCEPHALON

om the above examinations of their external and ventricular surfaces, it is nt that the cerebral hemispheres consist of a folded, external mantle of bstance, the cortex cerebri, spread more or less evenly over an internal mass te substance which contains embedded within it certain masses of gray sub-, the chief of which are known as the caudate and lenticular nuclei of the striatum. In addition, the hemispheres of the telencephalon overlie and functional connection with the structures of the diencephalon below, the f which are the thalamencephalon and the bases of the cerebral peduncles.

e gray substance of the telencephalon.—The gray substance is in intimate n with the white substance, and in fact its cells give origin to the greater f the fibers composing the white substance. The accumulations of gray nce to be considered are the cerebral cortex, with its variations in thickness rrangement, the corpus striatum, the claustrum, and the amygdaloid s.

e cerebral cortex [substantia corticalis] is distributed over the entire surface hemisphere except the peduncular region of the base and the region of the callosum and fornix of the medial surface. Numerous measurements een made to determine its average thickness. These have shown that the e is not uniformly distributed:—(1) that it is thicker on the convex surface n the basal and medial surfaces; (2) that on the convex surface it is thicker central region of the hemisphere, somesthetic area, than at the poles; (3) the average normal specimen it averages somewhat thicker on the left than right hemisphere; (4) that its average thickness varies greatly in different luals, and that the thickness decreases with old age; (5) that it is probably hat thicker in males than in females, and (6) that in a given specimen it es thicker on the summits of the gyri than in the floor of the corresponding

he normal adult conditions it averages about 4 mm. thick on the anterior and posterior gyri, in the somesthetic area, while it attains its mimimum thickness of about 2.5 mm. basal surface of the occipital and frontal lobes. Its total average thickness is about 2.9 The lamina of the septum pellucidum and the practically non-nervous floor of the third le and that of the choroid fissure are very much thinner. The cortex of the (more) rhinencephalon is termed the *archipallium;* while the remaining cortex of the telence- is the *neopallium.*

cerebral cortex consists of layers of the cell-bodies of neurones, chiefly of the pyramidal g. 647), which receive impulses from the structures below and from other regions of the by way of fibers reaching them through the internal mass of white substance, and which contribute fibers to the white substance. Certain fibers of shorter course and numerous al branches of fibers passing out of the cortex are devoted to the association of the region origin with the cortex of the immediate vicinity of their origin, and most of these course the gray cortex itself. In certain gyri, such as the anterior central gyri and those of the surface of the occipital lobe, these short association fibers accumulate into strata, and cal sections give the cortex a stratified appearance. Two such strata of white substance noted in the above localities, one lying about midway in the thickness of the cortex and htly internal to this. They are known as the inner and outer **stripes of Baillarger.** In n, a thin, superficial or *tangential layer* of fibers may often be distinguished lying in the of the cortex. Transverse sections through the anterior end of the hippocampus show l arrangement of the layers of white substance, to which has been given the name *cornu is.* The peculiar structure and appearance of the olfactory bulb and tract, parts of tex, have already been mentioned.

e corpus striatum is so called on account of the appearance in section of nponent parts, the caudate and lenticular nuclei (basal ganglia) and the al capsule between them. The two nuclei are directly continuous with ther at their anterior ends (fig. 729), and in addition they are connected by ous small bands of gray substance which pass from one to the other through ternal capsule, especially its anterior part. Also each nucleus contributes ous fibers to, and receives fibers from, the internal capsule. These bundles rs both arising and terminating within the nuclei, together with the gray nce among the fibers of the capsule, produce the ribbed and striped appear- uggesting the name, corpus striatum. The **caudate nucleus**—the intra-

ventricular part of the corpus striatum—lies with its thicker anterior part (he... closely related to the internal capsule, but its tail passes posteriorly around t... posterior border of the capsule and curves downward and anteriorly into the ro... of the inferior cornu of the lateral ventricle.

The lenticular nucleus [nucleus lentiformis]—the extraventricular part o... the corpus striatum—is embedded in the white substance of the cerebral hemi... sphere. It is somewhat pyriform in shape, not being so long as the caudate... nucleus, and neither having a tail nor extending so far anteriorly. Its lower sur... face is separated from the inferior cornu of the lateral ventricle by the white sub... stance of the roof of that cornu and by the tail of the caudate nucleus, and, fur... ther forward, the anterior commissure passes through its base. Its lateral sur... face is rounded and conforms both in extent and curvature with the surface of the insula, from which it is separated by the fibers of the external capsule and the intervening claustrum. Its oblique superior and medial surface is adapted to the lateral surface of the internal capsule, and it comes to a rounded apex in the angle formed by the internal capsule and a plane parallel with the base of the hemi... sphere. In both horizontal and coronal (transverse) sections through its middle it resembles a compound biconvex lens. Internally this appearance is produced by two vertically curving lamina of white substance, an **external** and an **internal medullary lamina,** which divide its substance into three zones:—the two medial zones together form an area, triangular in section, known as the **globus pallidus;** the lateral, larger and more gray, concavoconvex zone is the **putamen** (figs. 730–732). Radiating fibers from the medullary lamina extend into the zones, especially those of the globus pallidus. These zones disappear in transverse sections of the anterior portion of the lenticular nucleus on account of the fact that the larger putamen alone comprises this portion and alone becomes continuous with the caudate nucleus. (See figs. 729, 733.)

Connections.—Both nuclei of the corpus striatum become continuous with the cortex in the region of the anterior perforated substance, and the putamen of the lenticular nucleus may blend with the anterior part of the base of the claustrum. The following are the principal fiber connections:—(1) Fibers arising in the nuclei which join the internal capsule to reach the cerebral cortex, and fibers arising in the cortex which descend by the same course to the cells of the nuclei. (2) Fibers which pass in both directions between the thalamus and the corpus striatum (caudate nucleus especially). These are more abundant anteriorly, and necessarily pass in the internal capsule. (3) The **ansa lenticularis,** or striosubthalamic radiation, a usually distinct lamina, composed largely of fibers passing inferiorly between the thalamus and lenticular nucleus. It passes from the basal aspect of the anterior tubercle of the thalamus and curves below through the internal capsule to the basal surface of the lenticular nucleus, and there its fibers are distributed upward through its medullary lamina to the globus pallidus and putamen. Some enter the internal capsule and reach the cortex, chiefly that of the temporal lobe. The ansa lenticularis also contains fibers from the cortex of the temporal lobe to terminate in the inferior and medial parts of the thalamus. The fibers associating the thalamus with the temporal lobe belong to the so-called *inferior peduncle of the thalamus.* (4) Fibers connecting both nuclei (chiefly the lenticular) with the red nucleus and substantia nigra of the mesencephalon. These pass through the hypothalamic region and along the cerebral peduncle.

No definitely localized functions have been with certainty ascribed to either nucleus of the corpus striatum. They serve as relays in the pathways associating the cortical gray substance with the structures below. It is held that some of the descending motor fibers arising from the cells of the cortex give off collaterals, in passing, to the cells of the nuclei and these give fibers which join the internal capsule and cerebral peduncles, increasing the number of fibers bearing impulses from the cortex to the mesencephalon, rhombencephalon and spinal cord. This would make the functions of the nuclei subsidiary to those of the cerebral cortex. In lower vertebrates, the corpus striatum is an important reflex center. Phylogenetically, the globus pallidus is the most primitive portion, and in mammals fibers arising therein may descend to exert control over skeletal muscular activity (S. A. K. Wilson), via the red nucleus (striorubral tract).

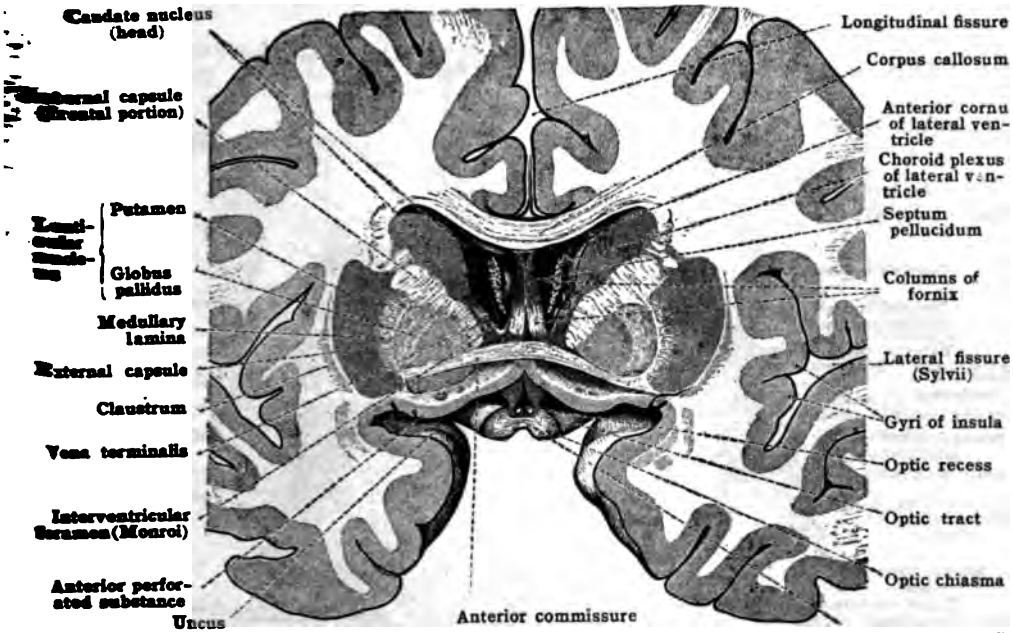
The claustrum is a triangular plate of gray substance which is embedded in the white substance between the lenticular nucleus and the cortex of the insula. Its medial surface is concave, conforming to the convexity of the putamen. The sheet of white substance intervening between it and the putamen is known as the **external capsule.**

The lateral surface of the claustrum shows ridges in section which conform to the neighboring gyri of the insula, and it is spread through a region which quite closely coincides with the area of the insula. Below and anteriorly it becomes continuous with the cortex of the anterior perforated substance and with the lenticular nucleus at the region of the junction of these. Above and posteriorly it gradually becomes thinner, and finally disappears in the white substance about it. In origin it is thought to be a detached portion of the cortical gray substance of the insula.

The amygdaloid nucleus [nucleus amygdalæ] is represented by the amygdaloid tubercle, which has already been described in the extremity of the inferior horn of the lateral ventricle (figs. 707 and 729). It is an almond-shaped mass of gray joined to the tail of the caudate nucleus, continuous above with the putamen and anteriorly continuous with the cortex of the hippocampal gyrus.

The chief connections of the amygdaloid nucleus by way of the *stria terminalis of the thalamus* are noted above under the description of the posterior division of the rhinencephalon. The amygdaloid nucleus, like the claustrum, is thought to represent a detached portion of the cortex, having detached from the uncus. Considering this and its chief connections, it, with the stria terminalis of the thalamus, are concerned in the central portion of the olfactory apparatus.

FIG. 730.—CORONAL SECTION OF TELENCEPHALON THROUGH THE ANTERIOR COMMISSURE, OPTIC CHIASMA AND BODY OF CORPUS CALLOSUM. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



The thalamus and hypothalamus.—The external features of these portions of the prosencephalon have been described previously, but inasmuch as they contain the chief relays between the telencephalon and the divisions of the nervous system caudal to the prosencephalon, the consideration of their internal structure has been deferred until now. The principal gray masses to be considered are the thalamus and the hypothalamic nucleus. The structures comprising the metathalamus and epithalamus have already been mentioned in their relations with the mesencephalon and the optic and auditory apparatus.

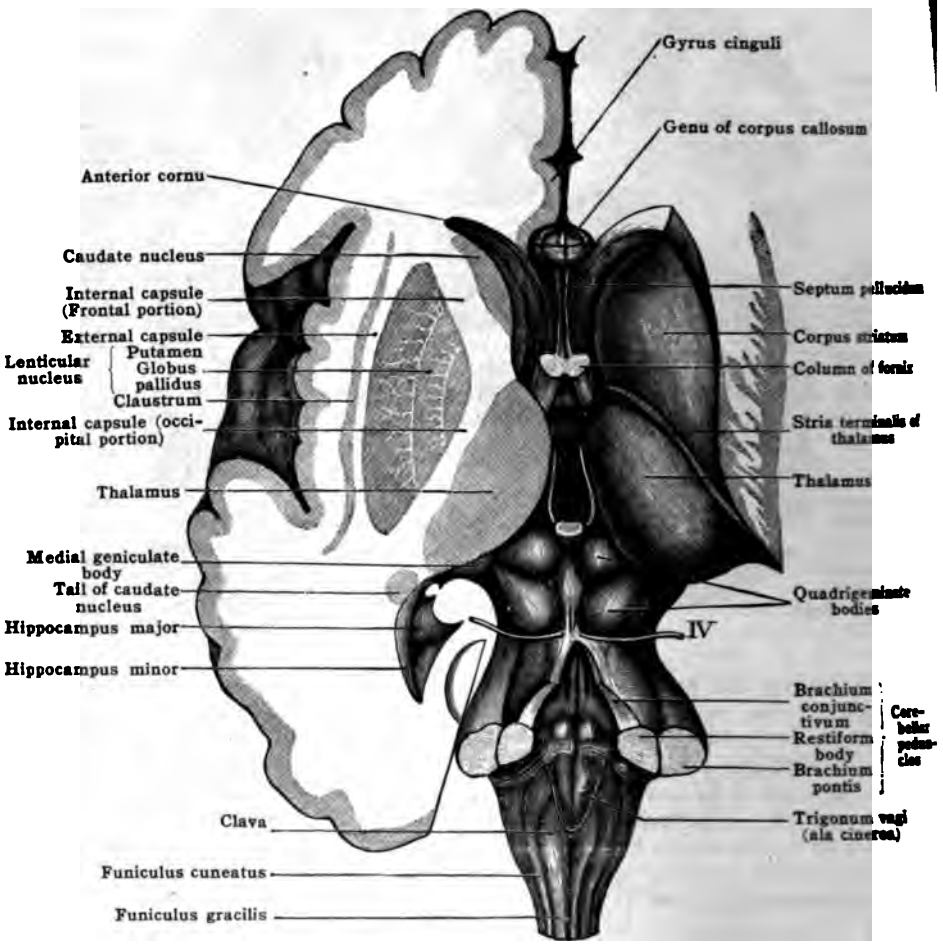
The thalamus has upon its upper surface, under its ependyma, a thin **stratum zonale** of white substance, derived in part from the incoming fibers but chiefly from its own cells. Its oblique lateral surface conforms to the medial surface of the internal capsule; its vertical medial surface forms the lateral wall of the third ventricle, and below it is continuous into the hypothalamic (tegmental) region and the hypothalamic nucleus. Its upper surface shows a middle, an anterior, and a posterior prominence or tubercle. The **anterior tubercle** (nucleus) forms the posterior boundary of the interventricular foramen; the posterior tubercle is the cushion-like **pulvinar** which projects backward over the lateral geniculate body and the brachium of the superior quadrigeminate body.

A horizontal section through the superomedial edge, splitting the stria medullaris of the thalamus and thus passing above the massa intermedia, shows the gray mass of the thalamus divided into segments or nuclei by a more or less distinct **internal medullary lamina.** This extends the whole length of the thalamus, dividing its middle and posterior portion into the medial and the **lateral nucleus.**

Anteriorly the lamina bifurcates into a medial limb, extending to the medial face of the thalamus, and a lateral limb, extending forward to join the genu of the internal capsule (figs. 732, 733). This bifurcation results in a cup-like sheet of white substance which encloses the **anterior nucleus.** On the lateral surface of the section, next to the internal capsule, there may usually be distinguished the **external medullary lamina,** separated from the white substance of the capsule by a *reticular layer* of mixed white and gray substance.

The anterior nucleus, lying partially encapsulated in the bifurcation of the internal medullary lamina, is somewhat wedge-shaped and points backward between the anterior portions of the lateral and medial nuclei.

FIG. 731.—HORIZONTAL DISSECTION SHOWING THE GRAY AND WHITE SUBSTANCE OF THE TELENCEPHALON BELOW THE CORPUS CALLOSUM AND THE RELATIVE POSITION OF THE THALAMENCEPHALON. (After Landois and Stirling.)



It is composed chiefly of large cells, and constitutes the anterior tubercle of the superi aspect. Its principal connection from below is with the nuclei of the mammillary body of t same and opposite sides, and chiefly with uninterrupted fibers derived from the form The fibers from both sources enter it by way of the *mammillothalamic fasciculus* (figs. 711 a 732). The significance of this connection is mentioned in the description of the limbic lob

The lateral nucleus, lying between the external and internal medullary lam inæ, extends posteriorly to include the **pulvinar, which latter, however, is oft** called the posterior nucleus of the thalamus.

The neurones of the anterior portion of the lateral nucleus (**lateral nucleus proper**), togeth with the entire inferolateral gray substance of the thalamus, receive the terminations of t spinal, medial and trigeminal lemnisci and thus serve as the third links in the neurone cha bearing sensory impulses from the general body to the cerebral cortex. The lateral nucle also especially receives fibers inferiorly from the red nucleus and from the brachium conju

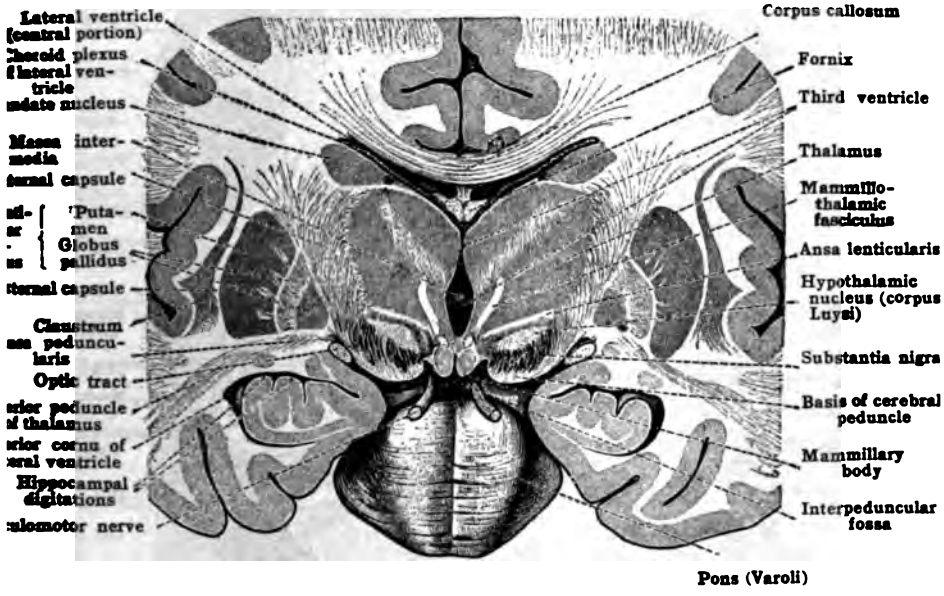
direct. The pulvinar, as already noted, together with the lateral geniculate body, con- the prosencephalic nucleus of termination of the optic tract, and the stratum zonale the surface of this nucleus might be called the stratum opticum.

The medial nucleus lies medial to the internal medullary lamina and forms the erior portion of the lateral wall of the third ventricle. It is shorter than the ral nucleus, and is less extensively pervaded by fibers.

s inferior part is thought to receive fibers from the three lemnisci, trigeminal especial y, to send fibers to the cortex. Its dorsal part receives fibers from the olfactory areas of the x and contributes fibers to the medullary stria of the thalamus and probably some to the x. It is usually continuous across the third ventricle with the opposite medial nucleus by massa intermedia.

In comparative anatomy, the nuclei of the thalamus have been variously subdivided by different investigators. All the nuclei are connected with the lenticular nucleus by fibers ing between the two through the internal capsule directly, and by fibers curving from below, fly from the anterior, lateral and medial nuclei, and passing in the ansa lenticularis.

. 732.—Coronal Section of Prosencephalon through Thalamencephalon at Region of Corpora Mammillaria. (Seen from in front.) (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



The cortical connections of the thalamus are abundant. They consist of fibers th to and from the cortex of the different lobes of the hemisphere, the greater rt arising in the thalamus and terminating in the cortex. These fibers collect the internal and external medullary lamina and the stratum zonale; most of em enter the internal capsule and thence radiate to the different parts of the rtex. Carrying sensory impulses to the cortex received from sensory neurones low, these thalamocortical fibers are the *sensory projection fibers* of the brain.

They form the so-called peduncles of the thalamus, which have been distinguished both by Flechsig method of investigation and by the degeneration method. The anterior or **frontal luncle** passes from the lateral and anterior part of the thalamus through the frontal portion the internal capsule, and radiates to the cortex of the frontal lobe (fig. 737). The idle or **parietal peduncle** passes from the lateral surface of the thalamus through the inter- diate part of the internal capsule, and upward to the cortex of the parietal lobe. The pos- ior or **occipital peduncle** passes chiefly from the pulvinar, through the occipital portion of the ernal capsule, and radiates backward to the occipital lobe by way of the occipitothalamic otic) radiation (fig. 736). The **inferior peduncle** passes from the medial and basal surface the thalamus (from the anterior and medial nuclei chiefly), turns outward to course beneath lenticular nucleus, and radiates to the cortex of the temporal lobe and insula. The fibers this peduncle course chiefly in the ansa lenticularis (fig. 732). Some turn upward in the ernal capsule to reach the cortex above the insula; others pass upward through the medullary ainæ of the lenticular nucleus.

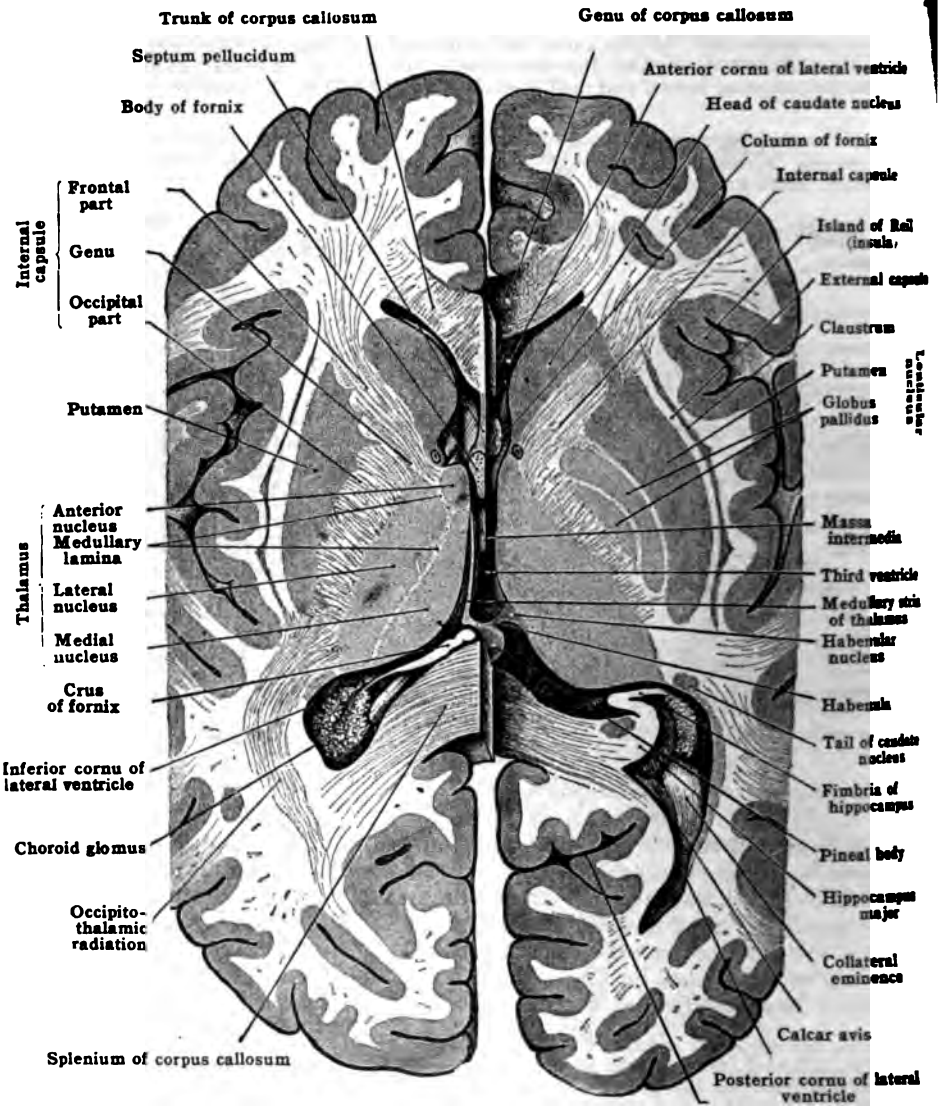
The nuclei of the thalamus without doubt serve chiefly as relays in the sensory paths, both neral and special, from the periphery of the body to the cerebral cortex. By the several minal branches of each of the visiting fibers making synapses with the thalamic neurones,

the sensory impulses are not only reinforced by the transfer but also the number of neuro bearing them to the cortex is increased in the thalamus.

From the viewpoint of comparative anatomy, the larger, lateral portion of the thalam or *neothalamus*, including the pulvinar and the lateral and medial geniculate bodies (detach portions of the thalamus), is considered especially concerned in such relays. In the lower fo having little or no cerebral cortex, the medial portion of the thalamus persists and serves for t mediation of primitive reflex activities. In man, clinical evidence collected by Head a

FIG. 733.—HORIZONTAL SECTIONS OF THE PROSENCEPHALON THROUGH THE THALAMUS AN CORPUS STRIATUM.

The plane of the section of the left hemisphere splits the medullary stria of the thalamus abo 15 mm. above the plane through which the right hemisphere is cut (After Toldt.)



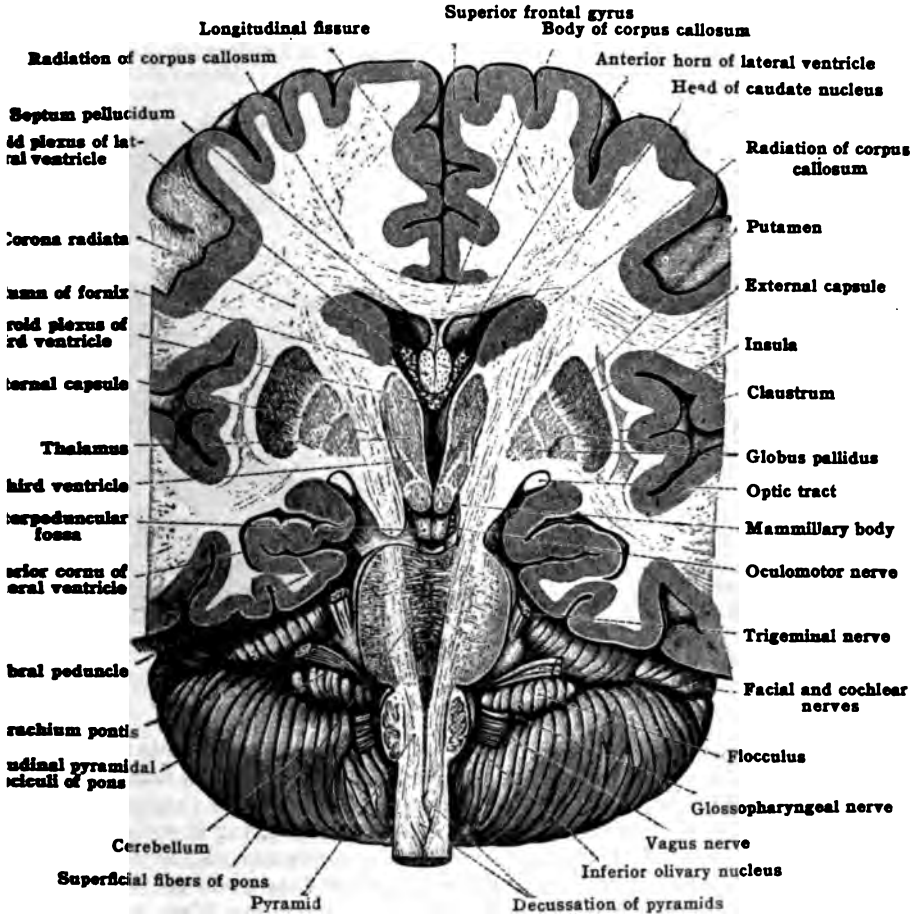
Holmes and others seem to suggest that some of these primitive reflex functions may be r tained in the medial portion; but further, the interesting inference is possible that some acti ities usually classed as conscious may be mediated by the thalamus, the cerebral cortex b being essential for them. In other words, the thalamus divorced from the cerebral cortex b destructive lesions, seems able to mediate activities in response to sensations of pleasure a pain. The participation of the cerebral cortex, however, seems especially necessary for analytical, or so-called intellectual and voluntary activities. Such functions of the thalam give the thalamospinal fasciculus greater functional significance than is usually attributed to

The hypothalamic nucleus (body of Luys, subthalamus) **(fig. 732) is a biconv** plate of gray substance situated on the basal aspect of the lateral and anteri

ei of the thalamus, and between these and the basis of the cerebral peduncle. the anterior continuation of the substantia nigra, which is spread upon the al surface of the peduncle, and which, though greatly diminished, extends into hypothalamic region. It is referred to as the hypothalamic nucleus as far eriorly as the posterior commissure. It presents a brownish-pink color esh material, due to pigment in its cells and to its abundant blood-capillaries.

is enclosed by a thin capsule of white substance, some of the fibers of which seem to decuss- ith those of the opposite side in the floor of the third ventricle, above and just behind the of the corpora mammillaria. It is said to receive fibers descending from the cortex and from the thalamus and nuclei of the corpus striatum. Most of the fibers arising from

734.—Oblique Frontal Section through the Brain in the Direction of the Cerebral Peduncles and the Pyramids. (Seen from in front.) (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



n the cerebral peduncle. Such relations would suggest that the hypothalamic nucleus s as a relay in certain paths from the cortex and striate body to the structures below. On ther hand, until recently it was considered the chief nucleus of termination of the medial iscus.

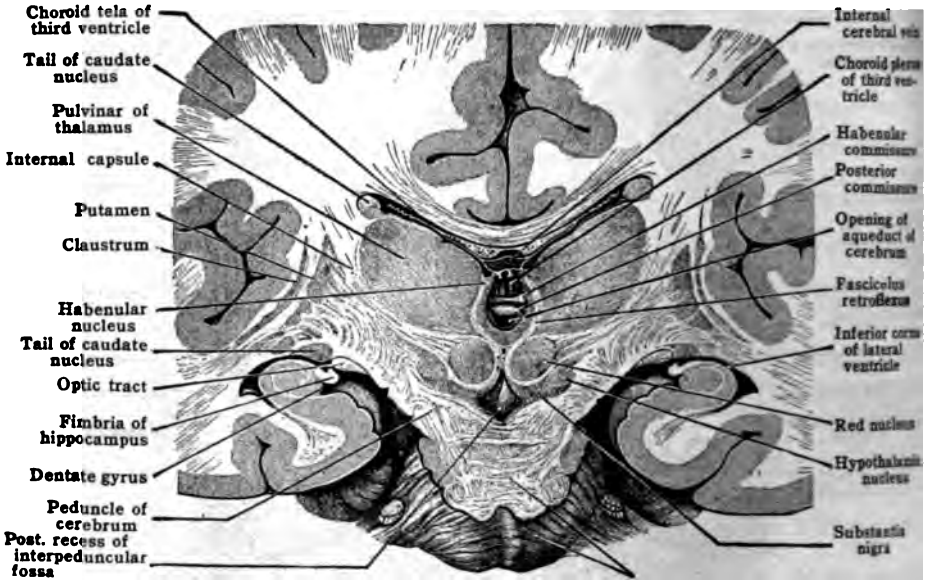
he *habenular nucleus* and the *fasciculus retroflexus* of Meynert have been noted in the de- tion of the rhinencephalon. The **habencular nucleus**, a part of the epithalamus, is a small of nerve cells situated in the habenular trigone just inferolateral to the pineal body. Some of the medullary stria of the thalamus (habenula) terminate about its cells. A small le of fibers crossing the midline under the pineal body in the superior aspect of the posterior ral commissure is called the *commissure of the habenulæ*, from the fact that it contains fibers lating the habenular nuclei of the two sides.

he **fasciculus retroflexus** (**Meynerti**) (tractus habenulopeduncularis) is a relatively strong le of fibers which runs downward and then turns caudalward from the habenular nucleus rd the inferior portion of the interpeduncular fossa. It has been shown that many, at of the fibers of this bundle arise from the cells of the habenular nucleus. In its slightly al course, the bundle passes obliquely through the red nucleus, entering the medial superior t and making its exit from the medial side of the inferior extremity of this nucleus. In the

animals in which it has been studied, the bundle ends in the *interpeduncular nucleus* (ganglion), a group of nerve cells lying in the floor of the interpeduncular fossa at the level of the inferior quadrigemina. In man, the interpeduncular nucleus is not definitely assembled and the bundle seems to disappear in the posterior perforated substance. However, the microscope shows nerve cells dispersed among the fibers of the bundle and these cells probably represent the nucleus. Impulses borne by the fasciculus are presumably transmitted to the cranial and spinal nerves.

The white substance of the telencephalon.—A horizontal section through the upper part of the body of the corpus callosum will pass above the basal gray substance of the corpus striatum, and, aided by the corpus callosum, each hemisphere in such a section will appear as if consisting of a solid, half-oval mass of white substance, bounded without by the gray layer of the cortex (fig. 712). As seen at this level, the white substance of each hemisphere is known as the **centrum semiovale.** Horizontal sections passing below the body of the corpus callosum involve the corpus striatum and thalamus, and the appearance of the white substance is modified accordingly (fig. 731).

FIG. 735.—CORONAL SECTION OF BRAIN PASSING THROUGH THE PULVINAR OF THE THALAMUS AND THE UNCUS OF THE HIPPOCAMPAL GYRUS. (After Toldt.)



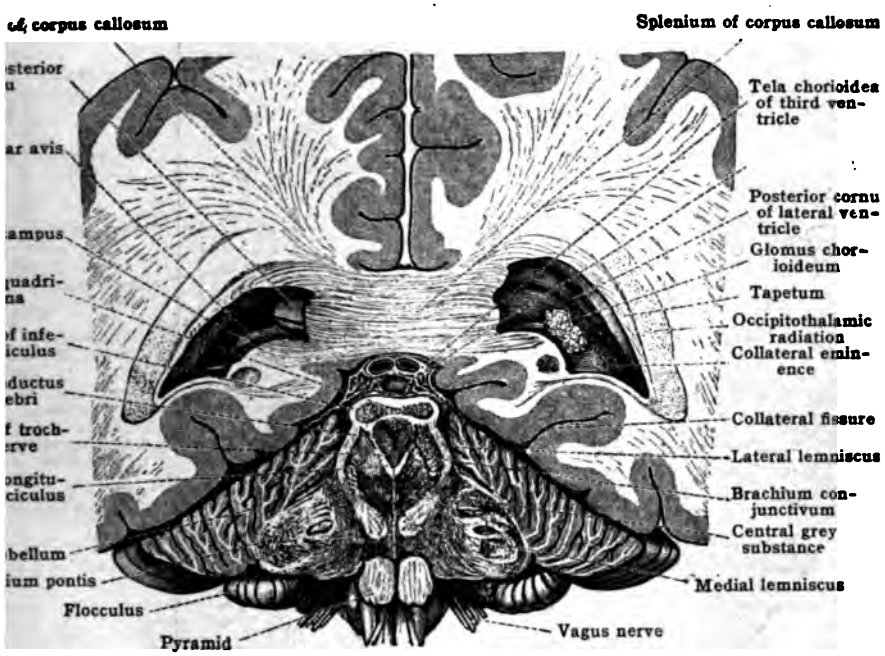
In the white substance of the cerebral hemispheres as a whole three main systems of fibers are recognized:—projection fibers, commissural fibers, and association fibers. The *projection fibers* are those of a more or less vertical course, which pass to and from the cortex of the hemisphere, associating it with the structures below the confines of the hemisphere. The *commissural fibers* are those of transverse or horizontal course, which cross the midline and functionally correlate the two hemispheres with each other. The *association fibers* are those which neither cross the midline nor pass beyond the bounds of the hemisphere in which they arise, but instead associate the different parts of the same hemisphere—lobe with lobes and gyri with gyri. The fibers which associate the cortex with the nuclei of the corpus striatum must also be classed as association fibers, since the masses of gray substance are a part of the telencephalon, while by definition those which associate the thalamus and hypothalamus with the cortex belong to the projection system. Some of the fiber bundles of the above systems have already been described in connection with the parts with which they are concerned.

The projection fibers of the hemisphere comprise both ascending and descending fibers between the cerebral cortex and structures below the bounds of the hemisphere proper, i.e., some arise in the structures below and terminate in the cortex, others arise from the cortical cells and terminate in the structures below, including the gray substance of the thalamencephalon, mesencephalon, rhombencephalon and spinal cord. The projection fibers are given different names in the hemi-

according to their arrangement and the appearances to which they con- in the dissections. Beginning with the pyramidal fasciculi and the basis peduncle, they contribute fibers (both sensory and motor)—(1) to the *l capsule* and some to the *external capsule* and (2) to the *corona radiata.*

internal capsule [capsula interna] is a band of white substance, consisting scending fibers from the nuclei of the thalamus, hypothalamus, and corpus n, reinforced by the descending fibers from the cortex to these nuclei and e descending in the cerebral peduncle to terminate in the mesencephalon, ncephalon and spinal cord. It is a broad, fan-like mass of fibers, which es in width from the base of the hemisphere upward, and which is spread n the lenticular nucleus on its lateral aspect and the caudate nucleus and us on its medial side. To reach the cortex above, the course of its fibers rily intersects that of the radiations of the corpus callosum, and thus,

5.—Coronal Section through the Splenium of the Corpus Callosum and the terior Cornua of the Lateral Ventricles. (Viewed from behind.) (After Toldt, as of Human Anatomy,' Rebman, London and New York.)



er with the corpus callosum, the fan-like bands of the two hemispheres form ile containing the thalami, the third ventricle, the caudate nuclei, and the r and central portions of the lateral ventricles. In horizontal sections, ternal capsule appears bent at an angle, the **genu,** which approaches the of the lateral ventricle along the line of the boundary between the thalamus e caudate nucleus. Along the genu runs the stria terminalis of the thala- nd through the genu the capsule receives fibers from the internal medullary of the thalamus, from the stratum zonale of the thalamus and from that caudate nucleus. At the genu each capsule is separable into two parts:— **anterior (frontal) portion,** spreading between the caudate and lenticular (2) the **posterior (occipital) portion,** between the lenticular nucleus and the us (fig. 737).

tionally, the internal capsule may be divided into a frontal, a frontoparietal and an l part.

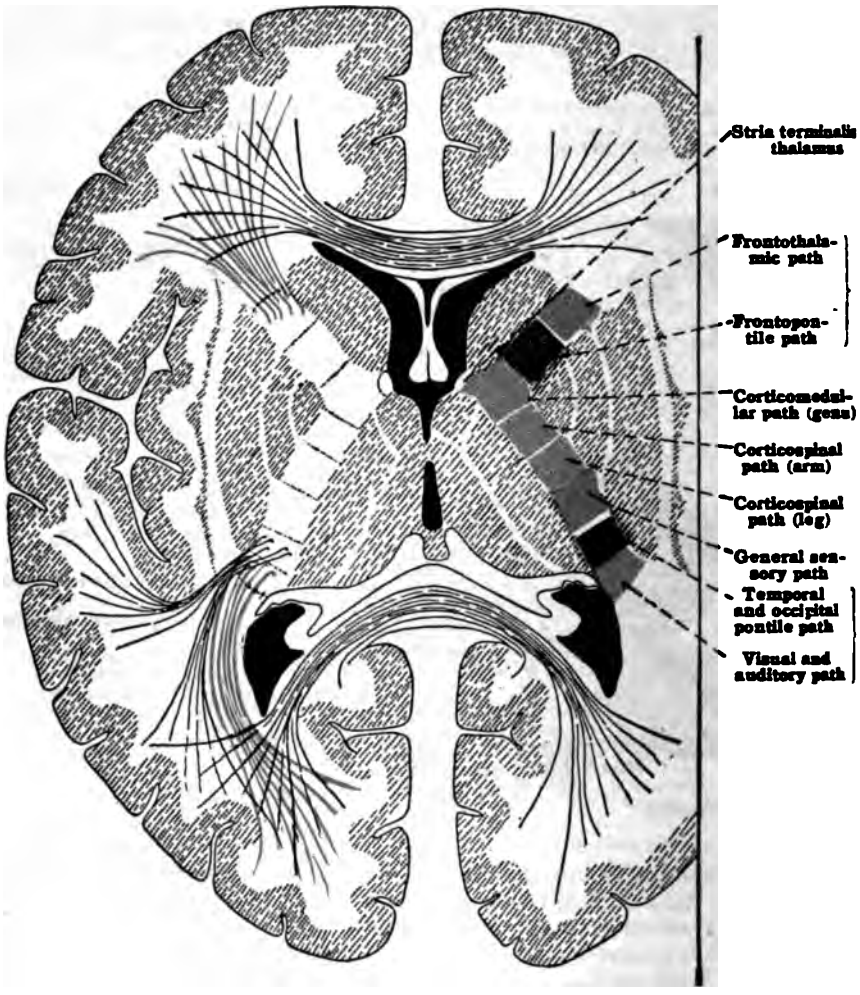
frontal part consists of (1) an *anterior segment,* carrying chiefly fibers coursing in both s between the thalamus and the cortex of the frontal lobe, and (2) a *posterior segment* the frontopontile tract.

frontoparietal part may be considered in four segments:—(1) An anterior segment, , carrying impulses from the cortex to the nuclei of the motor cranial nerves; (2) pos- this is the *corticospinal segment for the arm and thorax,* descending cortical fibers to the ord; also the *corticorubral tract;* (3) next is the *corticospinal segment for the lower*

extremity; (4) a posterior segment carrying the *general sensory path* ascending from th lateral part of the thalamus and the red nucleus to the cortex. All the segments of t parietal part carry in addition, fibers in both directions between the cortex above thalamus and the nuclei of the striate body.

The occipital part consists (1) of an anterior segment which carries the descending *and occipital pontile paths*, and (2) a posterior segment carrying the *visual fibers* be occipital cortex and the nuclei of termination of the optic nerve. This segment also c *auditory fibers* passing to the cortex of the superior temporal gyrus from the r termination of the lateral lemniscus. Thus this segment carries a visual and an audit

FIG. 737.—DIAGRAM TO INDICATE THE TOPOGRAPHY OF THE PROJECTION FIBERS IN TH NAL CAPSULE. (In part after Villiger.)



The corona radiata.—Above the corpus callosum and laterally jo radiations, the fibers of the internal capsule are dispersed in all directio appearance known in coronal sections of the hemispheres as the corona produced by the ascending and descending fibers of the internal capsule with the radiations of the corpus callosum. The radiations related to th capsule may be divided into a frontal, a parietal and an occipital pa sponding to the frontal, parietal and occipital peduncles of the thalamus parts of the internal capsule.

The radiation derived from the posterior segment of the occipital pa internal capsule, the visual path, accumulates into a well-defined band which passes posteriorly into the occipital lobe, spreading in the lateral w posterior cornu of the lateral ventricle immediately lateral to the tapetu band consists for the most part of fibers arising in the pulvinar of the thal in the lateral geniculate body and going to the visual area of the occipit

and of fibers arising in this cortex to terminate in the thalamus and mesencephalon. Being thus concerned with the optic apparatus, it is known as the **occipitothalamic radiation** or **optic radiation** (fig. 736).

The external capsule is, as already noted, a thin sheet of white substance spread between the claustrum and the lenticular nucleus.

It owes its appearance as such to the presence of the claustrum. It joins the internal capsule at the upper, posterior, and anterior borders of the putamen, and below the claustrum it is continuous with the general white substance of the temporal lobe. Thus it contributes to an encapsulation of the lenticular nucleus by white substance. Most of the fibers contained in it belong to the association system. Its projection fibers consist of those of the inferior peduncle of the thalamus, which pass from the basal surface of the thalamus and, instead of continuing below to the cortex of the temporal lobe and insula, turn upward, around the lenticular nucleus to the cortex above the insula. Some of these thalamic fibers are known to pass upward through the lamina of the lenticular nucleus instead of through the external capsule.

The ascending projection fibers arise mostly from the cells of the nuclei of the thalamus; some arise from nuclei in the mesencephalon and from the red nucleus. They may be summarized as follows:—

(1) *The terminal part of the general sensory pathway of the body.* The portion of the medial lemniscus which arises in the nuclei of the fasciculus gracilis and cuneatus, of the opposite side, and the 'spinal lemniscus' (thalamospinal fasciculi), arising in the opposite side of the spinal cord, terminate in the ventral and lateral gray substance of the thalamus. The projection fibers given off by this pass chiefly through the posterior segment of the frontoparietal part of the internal capsule and radiate to and terminate in the somesthetic area of the cortex, chiefly in the posterior central gyrus. Some few may pass outside around the lenticular nucleus, and ascend by way of the external capsule.

(2) *The terminal part of the general sensory pathway of the head and neck.* The nuclei of termination of the sensory portions of the crainal nerves of the rhombencephalon (except the nuclei of the cochlear nerve) give fibers which course upward in the medial lemniscus (fillet) and reticular substance of the opposite side and terminate in the inferolateral portions of the thalamus. Thence arise projection fibers which ascend to the somesthetic area by practically the same route as those of the general sensory system for the body. A large portion of this part of the medial lemniscus arises from the nucleus of termination of the trigeminal nerve and is known as the *'trigeminal lemniscus.'*

(3) *The terminal part of the auditory pathway.* The ventral and dorsal nuclei of termination of the cochlear nerve send impulses which, by way of the lateral lemniscus, are distributed to the inferior quadrigeminate body, the medial geniculate body, and the nucleus of the lateral lemniscus of the opposite side. These nuclei send projection fibers through the posterior segment of the frontoparietal part of the internal capsule, and thence by the temporal portion of the corona radiata to the cortex of the superior temporal gyrus (auditory area). Probably some of these fibers pass by way of the inferior peduncle of the thalamus. Some of the fibers arising in the nuclei of termination of the vestibular nerve convey impulses which reach the somesthetic area, but the origin of the terminal portion of this system is uncertain.

(4) *The terminal part of the visual pathway.* The cells of the pulvinar and the lateral geniculate body, serving as nuclei of termination of the optic tract, give off projection fibers which pass by way of the posterior segment of the occipital portion of the internal capsule and the occipitothalamic radiation to the cortex of the occipital lobe, chiefly the region about the posterior end of the calcarine fissure—the visual area.

(5) *The terminal ascending cerebellar pathway.* The fibers of the brachium conjunctivum, after decussating, terminate both in the red nucleus and in the lateral nucleus of the thalamus. Some fibers from the red nucleus become projection fibers direct, others terminate in the medial and anterior portion of the lateral nucleus of the thalamus. From the thalamus the projection fibers of this system pass in the peduncles of the thalamus to the somesthetic area and general cortex, that of the frontal lobe especially.

The descending projection fibers arise as outgrowths of the pyramidal cells of the cerebral cortex. Practically all of them cross to the opposite side in their descent to the structures of the rhombencephalon and spinal cord. The majority of them arise near and within the gyri in which the respective ascending fibers terminate. Those transmitting cortical impulses to the cells giving origin to the motor fibers of the cranial and spinal nerves arise chiefly from the giant pyramidal cells of the precentral (anterior central) gyrus, the paracentral lobule and the posterior ends of the superior, middle, and inferior frontal gyri. These latter occupy nearly three-fourths (the anterior three segments) of the frontoparietal part of the internal capsule and the middle three-fifths of the basis of the cerebral peduncle, and are usually called *pyramidal* fibers (fig. 737).

The principal descending projection fibers may be grouped as follows:

(1) **The pyramidal fibers to the spinal cord** (corticospinal or pyramidal fasciculi proper). These arise from the giant pyramidal cells of the upper two-thirds of the precentral gyrus, the anterior portion of the paracentral lobule and the posterior third of the superior frontal gyrus. Those for the lumbosacral region of the spinal cord arise nearest the superomedial border of the cerebral hemisphere. The tract descends through the two middle segments of

the frontoparietal part of the internal capsule. Those carrying cortical impulses f muscles of the arm and shoulder course in the segment anterior to the course of those muscles of the leg. Both continue through the cerebral peduncles and the pons and th the pyramids of the medulla, and then decussate, passing down the spinal cord to ter about the ventral horn cells (the origin of the motor nerve roots) of the opposite side.

(2) **The pyramidal fibers to the nuclei of origin of the motor cranial nerves** aris the pyramidal cells in the inferior third of the precentral gyrus, the posterior end of the i frontal gyrus, the opercular margin of the posterior central gyrus, and probably some (movements) in the posterior end of the middle frontal gyrus. The locality of the or the pyramidal fibers terminating in the nuclei of the facial and hypoglossal nerves only h determined with certainty. The general tract passes in the genu of the internal c through the cerebral peduncle, and gradually decussating along the brain stem, termi the nuclei of the motor cranial nerves of the opposite side.

(3) **The frontal pontile path** (Arnold's bundle) arises in the cortex of the fronta anterior to the precental gyrus, descends through the frontal part of the corona radia posterior segment of the frontal portion of the internal capsule into the frontomedial por the cerebral peduncle, and terminates in the nuclei of the pons.

(4) **The temporal pontile path** (Türk's bundle) arises in the cortex of the superior and temporal gyri, passes through the posterior segment of the occipital part of the internal c enters the cerebral peduncle posterolateral to its pyramidal portion, and terminates nuclei of the pons. An occipitopontile path is described as arising in the occipital cor joining the temporal pontile path in the internal capsule to pass to the nuclei of the

(5) **The occipitomesencephalic path** (Flechsig's secondary optic radiation) arises cortex of the visual area of the occipital lobe (cuneus and about the calcarine fissure). forward through the occipitothalamic radiation, downward in the posterior segment occipital portion of the internal capsule, and terminates in the nucleus of the superior geminate body and the lateral geniculate body. It is probable that some of its fibers ter directly in the nuclei of the eye-moving nerves.

Those **fibers of the fornix** which arise in the hippocampus and terminate in the mammillare or pass through to the anterior nucleus of the thalamus of the same and c side (mammillothalamic fasciculus) or pass into the mesencephalon and probably to str lower down.

In the frontal part of the internal capsule fibers are said to course in both directions b the medial nucleus of the thalamus and the cortex of the frontal lobe. And in the fronto part of the capsule a tract is claimed to descend from the motor area of the cortex to term the red nucleus—a *'corticorubral tract.'* As noted in preceding paragraphs, some of th descending from the cortex are thought to make synapses in the corpus striatum, hypo nucleus and substantia nigra.

The commissural system of fibers.—The commissural fibers of the telen lon serve to connect or correlate the functional activities of one hemi with those of the other. They consist of three groups:—The corpus cal the anterior commissure and the hippocampal commissure.

(1) The **corpus callosum,** the great commissure of the brain. A general descri this with the medial and lateral striæ running over it has already been given. It is a thi of white substance, about 10 cm. wide, which crosses between the two hemispheres at the of the longitudinal fissure. Its shape is such that in its median sagittal section its p given the names *splenium, body, genu,* and *rostum* (figs. 708 and 719). Its lower su medially joined to the fornix, in part by the septum pellucidum and in part directly. L it is the tapetum of the roof of the lateral ventricle of either side. The majority of it arise from the cortical cells of the two hemispheres and terminate in the cortex of opposite that of their origin. In dissections, its fibers are seen to radiate toward all the cortex—the radiation of the corpus callosum. These radiations may be divid frontal, parietal, temporal and occipital parts. The occipital parts curve posteriorly strong bands from the splenium into the occipital lobes, producing the figure known forceps major. Anteriorly, the frontal parts are two similar but lesser bands whic from the genu forward into the frontal lobe, producing the **forceps minor.**

(2) The **anterior commissure** has been described in connection with the rhinenc In addition to the olfactory fibers coursing through it from the olfactory bulb and part area of one hemisphere to the uncus and olfactory bulb of the opposite hemisph commissural fibers between the two hippocampal gyri, comprising its greater p also carries fibers which arise in the cortex of the temporal lobe, the uncus chiefly, of and terminate in that of the opposite side. It crosses in the substance of the anterior b of the third ventricle, and through the inferior portions of the lenticular nuclei, and can only in dissections (figs. 723, 730). It is a relatively small, round bundle, and its mi between its terminal radiations presents a somewhat twisted appearance.

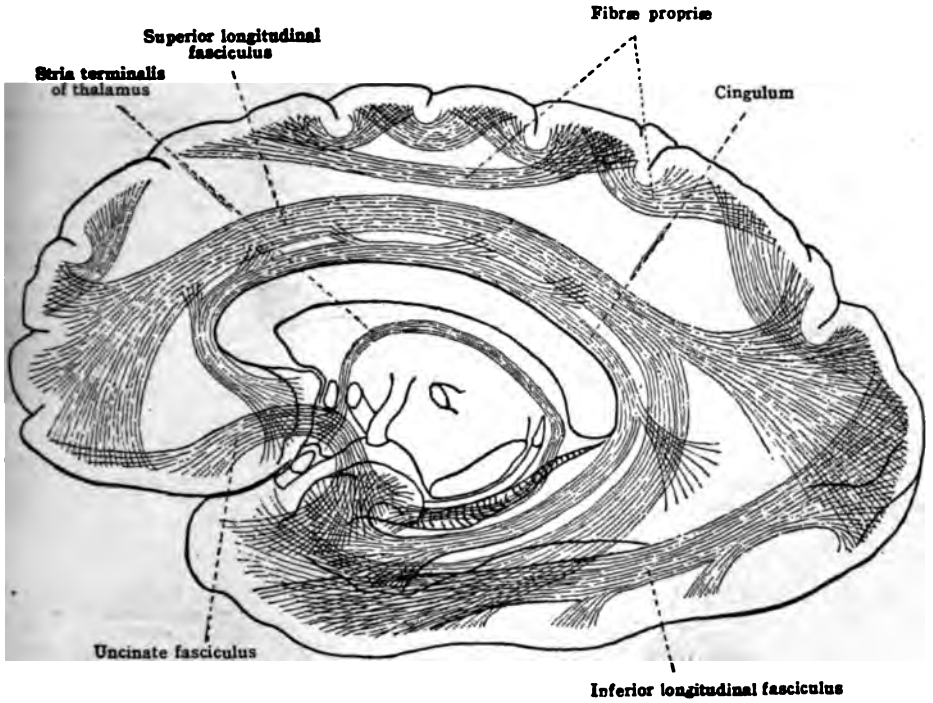
(3) The **hippocampal commissure** (*transverse fornix*) belongs wholly to the lim (rhinencephalon), and has been described there. It connects the hippocampal gyr two sides, and crosses the midline under and usually adhering to the inferior surfac splenium of the corpus callosum. Crossing the body of the fornix, it thins anteriorly an in the posterior angle of the septum pellucidum.

With these three commissures of the telencephalon, the three other commissures prosencephalon should be called to mind. The **inferior cerebral commissure** (C commissure), while occurring in the optic chiasma and allotted by position to the telenc really belongs to the diencephalon since it connects with each other the medial ge bodies of the two sides. The **supramammillary commissure, connecting the nuclei of th**

...ry bodies of the two sides, is allotted to the diencephalon (hypothalamus). The posterior ...al commisure, situated just below the stalk of the pineal body, belongs to both the dien... ...lon and mesencephalon. Its superior part, the *habernular commissure*, connecting the two ... of the habenulæ, belongs wholly to the diencephalon. In its inferior part, the fibers ...ng in the thalamus of one side and terminating in that of the other side belong likewise to the ...cephalon, but those passing between the superior quadrigeminate bodies of the two sides and ...en the so-called nuclei of the medial longitudinal fasciculi belong to the mesencephalon.

The association system of the hemisphere.—The possibilities for association-...dles connecting the different parts of the same hemisphere with each other are ...merable, and a large number are recognized. They serve for the distribution ...diffusion of impulses brought in from the exterior by the ascending projection ...tem, and it is by means of them that the different areas of the cortex may

FIG. 738.—SCHEMATIC REPRESENTATION OF CERTAIN OF THE ASSOCIATION-PATHWAYS OF THE CEREBRAL HEMISPHERE.



function in harmony and coördination. Most of the association-bundles are supposed to contain fibers coursing in both directions. Several of them have already been described in company with the gray masses with which they are concerned. They may be summarized as follows (see fig. 738):—

(1) Those of short course, the **fibræ propriæ**, which associate contiguous gyri with each other. These arise from the cells of a gyrus and loop around the floor of a sulcus, continually receiving and losing fibers in the cortex they associate. The stripes of Baillarger within the gray cortical layer might be included among the short association-bundles.

(2) The **cingulum** (girdle) lies in the gyrus cinguli and is shaped correspondingly. It extends from the anterior perforated substance and the subcallosal gyrus around the genu of the corpus callosum, then, under cover of the gyrus cinguli and around the splenium, and thence downward and forward in the hippocampal gyrus to the uncus. It is chiefly an aggregation of fibers of short course—fibers which associate neighboring portions of the cortical substance beneath which they course, and which, by continually overlapping each other, form the bundle.

(3) The **uncinate fasciculus** is a hook-shaped bundle which associates the uncus and anterior portion of the temporal lobe with the olfactory bulb, parolfactory area and anterior perforated substance and perhaps the frontal pole with the orbital gyri. Its shape is due to its having to curve medialward around the stem of the lateral cerebral fissure.

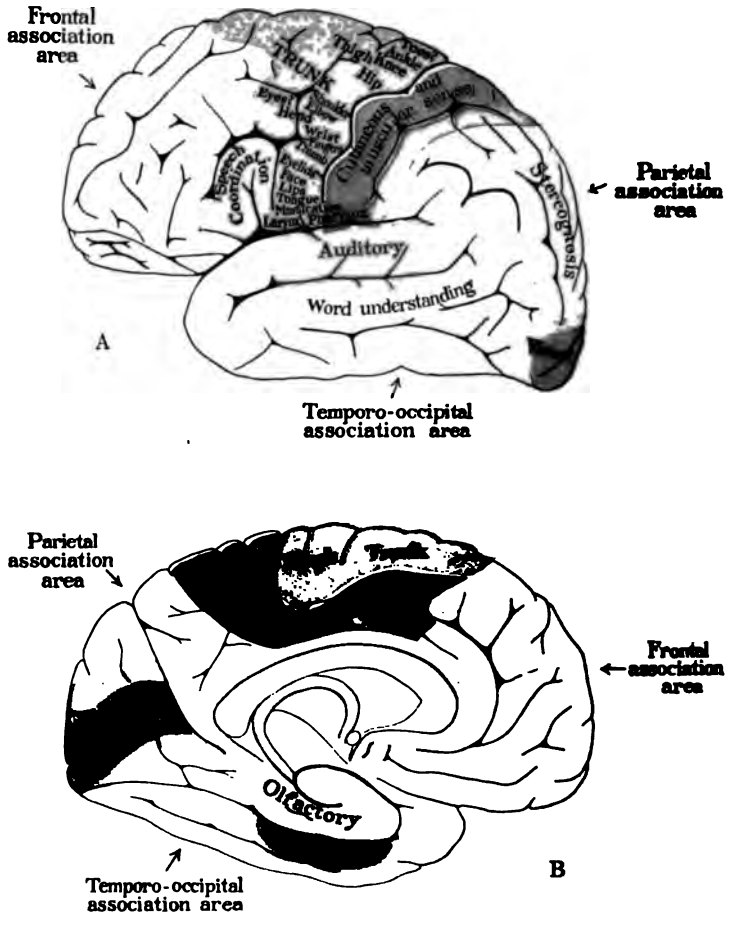
(4) The **superior longitudinal fasciculus** is the longest of the association-paths, and associates the frontal, occipital, and temporal lobes. From the frontal lobe it passes latreally in the frontal and parietal operculum, transverse to the radiations of the corpus callosum and the lower part of the corona radiata, and above the insula to the region of the posterior end of the lateral fissure, and thence it curves downward and forward to the cortex of the temporal lobe. Some of its fibers extend to the cortex of the temporal pole. The occipital portion consists

of a loose bundle given off from the region of the downward curve, which radiates the the occipital cortex.

(5) The inferior longitudinal fasciculus associates the temporal and occipital lobe extends along the whole length of these lobes parallel with their tentorial surfaces. Post it courses lateral to the lower part of the occipitothalamic radiation, from which it diff the fact that its fibers all arise within the hemisphere and are less compactly arrange associates the lingual and fusiform gyri and the cuneus with the temporal pole.

(6) A vertical or transverse occipital fasciculus (not included in fig. 738) associat tentorial surface of the occipital lobe with the superomedial and lateral parts of thi and adjacent portions of the parietal lobe.

FIG. 739.—DIAGRAMS SUGGESTING THE GENERAL MOTOR, GENERAL AND SPECIAL SE AND THE ASSOCIATION AREAS OF (A) THE CONVEX AND (B) THE MEDIAL SURFACE C CEREBRAL HEMISPHERE.



(7) The medial and lateral longitudinal striæ of the upper surface of the corpus c may be considered among the association pathways, since most of their fibers associate substance of the hippocampal gyrus with the subcallosal gyrus and the anterior pe substance of the same hemisphere. Their significance as parts of the rhinencepha already been given.

(8) Likewise the longitudinal fibers in the stria terminalis of the thalamus (ten circularis) may be considered among the association pathways, since these connect th daloid nucleus with the anterior perforated substance.

(9) The numerous fibers passing in both directions between the cerebral cortex nuclei of the corpus striatum belong to the association system. These do not form a bundle, though they contribute appreciably to the corona radiata. However, a described as the occipitofrontal fasciculus probably consists largely of the more running fibers of this nature. The existence of this fasciculus has been noted in degen and in cases of arrested development of the corpus callosum. Its fibers are describe tributing greatly to the tapetum, and as coursing beneath the corpus callosum imm next to the ependyma of the lateral ventricle. As a mass, they appear in intimate cor with the caudate nucleus, and are spread toward both the frontal and the occipital lobes

the latter), in the mesial part of the corona radiata of those lobes. It is described as also containing fibers in both directions associating the occipital with the temporal lobe. *Vertical association-fibers* pass through the caudate and lenticular nuclei between the cortex above and that of the temporal lobe below.

(10) Since the olfactory bulb is a part of the hemisphere proper, the *olfactory tract* may be considered an association pathway connecting the olfactory bulb with the parolfactory area, the subcallosal gyrus, the anterior perforated substance, and the uncus. As already shown, a portion of the fibers of the tract belongs to the commissural system.

THE FUNCTIONAL AREAS OF THE CEREBRAL CORTEX

The definitely known areas of specific function of the human cerebral cortex are relatively small. They comprise but little more than a third of the area of the entire hemisphere. They are—(1) the general sensory-motor or somesthetic area, and (2) the areas for the organs of special sense. They represent portions of the cortex in which terminate sensory or ascending projection-fibers bearing impulses from the given peripheral structures, and in which arise motor or descending projection-fibers bearing impulses in response.

Knowledge of the location of the areas has been obtained—(1) by the Flechsig method of investigation, and to a considerable extent by Flechsig himself; (2) from clinicopathological observations, largely studies of the phenomena resulting from brain-tumors, cerebral thrombi and traumatic lesions; (3) by experimental excitation of the cortex of monkeys and apes, the resulting phenomena being correlated with the anatomical findings and compared with the observations upon the human brain. The remaining larger and less known areas of the cortex are referred to as 'association-centers' or areas of the 'higher psychic activties.'

In development, the sensory fibers to the specific areas acquire their medullary sheaths first, before birth, and then the respective motor fibers from each become medullated. It is not until a month after birth that the association-centers show medullation and therefore acquire active functional connection with the specific areas.

In defining an area it is not claimed that all the fibers bearing a given type of impulse terminate in that area, nor that all the motor fibers leading to the given reaction originate in the area. It can only be said that of the fibers concerned in a given group of reactions, more terminate and arise in the areas cited than in any other areas of the cortex. The corresponding motor fibers arise both in the region of the termination of the sensory fibers (sensory area) and also in a zone (motor area) either partially surrounding or bordering upon a part of the region of the termination.

There is yet much lack of agreement among observers both as to the number of localized functional areas and as to the exact position of certain of the areas claimed. The following are considered the more generally accepted of the areas:—

(1) **The somesthetic (sensory-motor) area,** the area of general sensibility, and the area in which arise the larger part of the cerebral motor or pyramidal fibers for the cortical control of the general muscular system. As is to be expected, it is the largest of the specific areas. It includes the anterior central gyrus, posterior central gyrus, the posterior ends of the superior, middle, and inferior frontal gyri, the paracentral lobules, and the immediately adjacent part of the gyrus cinguli. The ascending or sensory fibers are found to terminate most abundantly in the part posterior to the central sulcus (Rolandi), the posterior central gyrus being the special *area of cutaneous sensibility* (see Cushing, 1909, and Head, 1918, for human cortex), and the adjacent anterior ends of the horizontal parietal gyri have been designated as the area of '*muscular sense.*' Both these areas are carried over upon the medial surface to involve the lower part of the paracentral lobule and a part of the gyrus cinguli. The anterior central gyrus gives origin to relatively more motor fibers than the other portions of the somesthetic area. In distribution, the muscles furthest away from the cortex are innervated from the most superior part of the area, the leg area being in the superomedial border of the hemisphere, while that for the head is in the anterior and inferior part of the area (fig. 739). The muscles of mastication and the laryngeal muscles are controlled from the frontoparietal operculum. Broca's convolution, the opercular portion and part of the triangular portion of the inferior frontal gyrus, of the left hemisphere, constitutes the especial motor coördination-area of speech, and Mills has extended this area to include the superoanterior portion of the insula below. The various authorities differ considerably as to the exact locations of many of the areas for the cortical control of given sets of muscles. Further observations must be skillfully made for localization of areas of the human cortex in detail and further correlations must be determined between the experiments upon the cortex of anthropoid apes and the functions of that of man. The accompanying diagrams (figs. 739, 740) are compiled from several of the diagrams more usually given and must be considered as only approximately correct.

(2) **The visual area.**—The especial sensory portion of this area is that immediately bordering upon either side of the posterior part of the calcarine fissure. The entire area, motor and sensory overlapping each other, includes the whole of the cuneus. The motor visual area proper is described as the more peripheral portion of the entire area. In addition, an area producing eye movements is described as situated in the posterior end of the middle frontal gyrus.

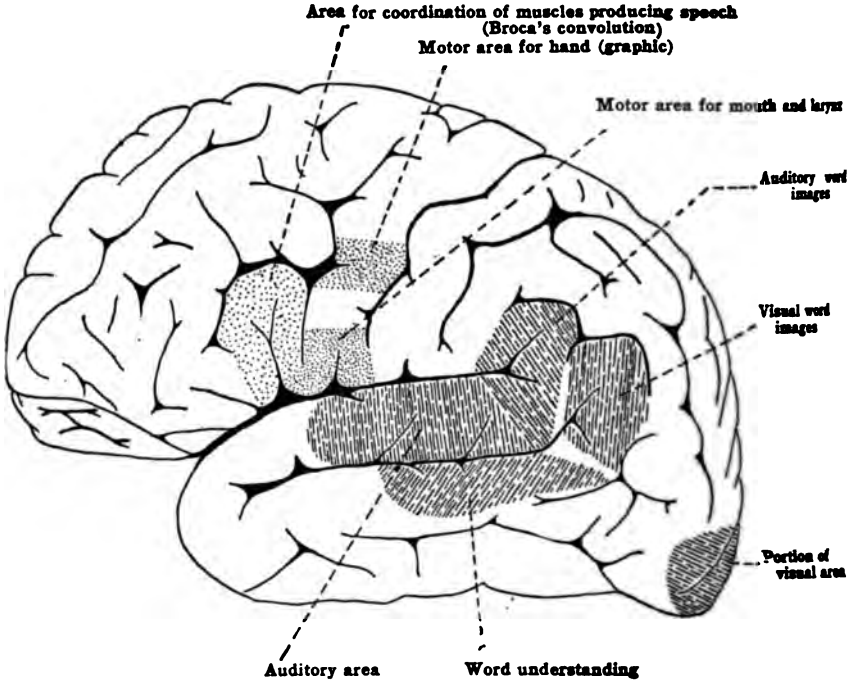
(3) **The auditory (cochlear) area** comprises the middle third of the superior temporal gyrus and the transverse temporal gyri of the temporal operculum. The motor portion of this area lies in its inferior border. The fibers arising in the area course downward in the temporal pontile path to the motor nuclei of the medulla.

(4) **The olfactory area** consists of the olfactory trigone, the parolfactory area, the subcallosal gyrus, part of the anterior perforated substance, the hippocampal gyrus (especially the uncus), and the callosal half of the gyrus cinguli. Its motor or efferent area lies chiefly in the hippocampal gyrus, the fibers from which pass out from the telencephalon by way of the fornix and cingulum

(5) **The gustatory area** is supposed to comprise the anterior portion of the fusiform gyrus and the zone (motor portion) about the anterior extremity of the inferior temporal sulcus. This area has been claimed to extend through the isthmus of the gyrus fornicatus to include a part of the callosal margin of the gyrus cinguli.

(6) **The association-areas.**—The relatively large areas allotted at present to the so-called higher psychic activities are indicated in fig. 739. The great relative extent of these is one of the characteristics of the human brain. They probably merely represent the portions of the cortex of which little is known, and may eventually be subdivided into more specific areas. They are considered to be connected with the structures below by fewer projection fibers than are the recognized areas named above, while, on the other hand, they are rich in association fibers. By means of the latter they are in intimate connection with the specific areas and have abundant means of correlating and exercising a controlling influence upon the functions of these areas. According to Flechsig, they consist of—(1) a *parietal association-area*, comprising that part of the parietal cortex between the somesthetic area and the visual area; (2) an *occipito-temporal association-area*, including the unspecified portions of the temporal lobe and the adjoining portion of the occipital lobe not included in the visual area; (3) a *frontal association-area*

FIG. 740.—CONVEX SURFACE OF LEFT CEREBRAL HEMISPHERE WITH DIAGRAMMATIC PRESENTATION OF THE AREAS SUGGESTED AS CONCERNED WITH SPEECH.



including all the frontal lobe anterior to the somesthetic and olfactory area. A large frontal area is especially distinctive of man. In the folds of the inferior parietal lobule of the parietal association-area such intellectual activities as the optic discrimination of words, letters, numbers, and objects generally are supposed to take place, while the superior parietal lobule continued into the posterior part of the præcuneus is the general region for the perception of form and solidity of objects—the stereognostic center.

The *insula* is suggested as the area in which auditory, olfactory and gustatory impulses are associated with the motor areas beginning in the operculum dorsolaterally adjacent to it.

Observations of symptoms and the position of lesions accompanying them have made it possible to arrive at some trustworthy conclusions regarding the cortical areas controlling speech. Broca announced in 1861 that the inferior frontal gyrus of the *left* hemisphere was peculiarly concerned with speech. This area was later confined to the posterior end or opercular portion of this gyrus and the name 'Broca's Convolution' was given it. It is now known that Broca's convolution and the adjacent portion of the triangular part of the inferior frontal gyrus as well comprise the *motor* area or *emissive speech-area*—the area especially devoted to the control of that coördinated action of the muscles concerned which makes possible articulate speech. Patients in whom this area is impaired are unable to give utterance to words though they may understand them both written and spoken, and though they may give utterance to sound. This inability is known as *motor aphasia*. Results of observed lesions have further shown that the area in which the *auditory images* of words are retained (word memories) comprises the posterior end of the superior temporal gyrus and the adjoining portion of the supramarginal gyrus. Injury to this area is accompanied by inability to recognize spoken words although the patient hears them and may recognize and understand written words, a phenomenon known as 'word-deafness' or auditory *sensory aphasia*. This area may be considered

as continuous with the superior portion of the posterior end of the middle temporal gyrus which has been suggested as the area of 'word-understanding,' or *'lalognosis.'* On the other hand, the area in which visual images of words are retained is located as the angular gyrus. Injury to this results in an inability to recognize printed or written words although the patient may hear, understand and speak them. This is called *'word-blindness,* (visual sensory aphasia). This area is nearest the special area of vision on the one hand and on the other hand, is continuous into the area to which word-understanding is attributed. For purposes of writing, it must be associated with the motor area for the muscles of the hand in the precentral gyrus.

While the motor area for speech is most functional in the left hemisphere of right-handed individuals, and *vice versa,* the remaining areas concerned are probably equally functional in the two hemispheres.

III. GENERAL SUMMARY OF SOME OF THE PRINCIPAL CONDUCTION-PATHS OF THE NERVOUS SYSTEM

In the following summary the arabic numerals indicate the nuclei or ganglia containing the cell-bodies of the neurones interposed in the chains; the letters in parenthesis indicate the different names given to the different levels of the pathways through which their fibers run. For detailed descriptions of either nuclei or pathways see pages describing them. Only the more common neurone-chains are followed here.

I. The Spinocerebral and Cerebrospinal System

A. The ascending path of neurones (fig. 741).

1. Spinal ganglion—neurone of first order.
   (*a*) Terminal corpuscles and peripheral process of T-fiber.
   (*b*) Dorsal or afferent root of spinal nerve.
   (*c*) Ascending branch of bifurcation of dorsal root fiber in fasciculus gracilis or fasciculus cuneatus of spinal cord.
2. Nucleus of fasciculus gracilis or nucleus of fasciculus cuneatus in medulla oblongata —neurone of second order.
   (*a*) Internal arcuate fibers.
   (*b*) Decussation of lemniscus.
   (*c*) Interolivary stratum of lemniscus of opposite side.
   (*d*) Medial lemniscus.
3. Inferior and lateral nuclei of thalamus—neurone of third order.
   (*a*) Internal capsule, posterior segment of frontoparietal portion.
   (*b*) Corona radiata, frontoparietal part.
4. Posterior central gyrus of somesthetic area of cerebral cortex.
   (*a*) Association and commissural fibers of cortex.

1*x*. Spinal ganglion—neurone of first order.
   (*a*) Terminals, especially in skin, and peripheral process of T-fiber.
   (*b*) Dorsal or afferent root of spinal nerve.
   (*c*) Collaterals and terminal branches of bifurcation of dorsal root-fiber within spinal cord.

2*x*. Gray substance of spinal cord, dorsal horn especially—neurone of second order.
   (*a*) Decussation of fibers to opposite side within spinal cord.
   (*b*) Thalamospinal and tectospinal paths (*spinal lemniscus*).

3*x*. Inferolateral nuclei of thalamus—neurone of third order.
   (*a*) Internal capsule (medial side of frontoparietal portion).
   (*b*) Corona radiata.

4*x*. Posterior central gyrus of cerebral cortex—neurone of fourth order.
   (*a*) Association and commissural fibers of cortex.

B. Descending path of neurones (fig. 742).

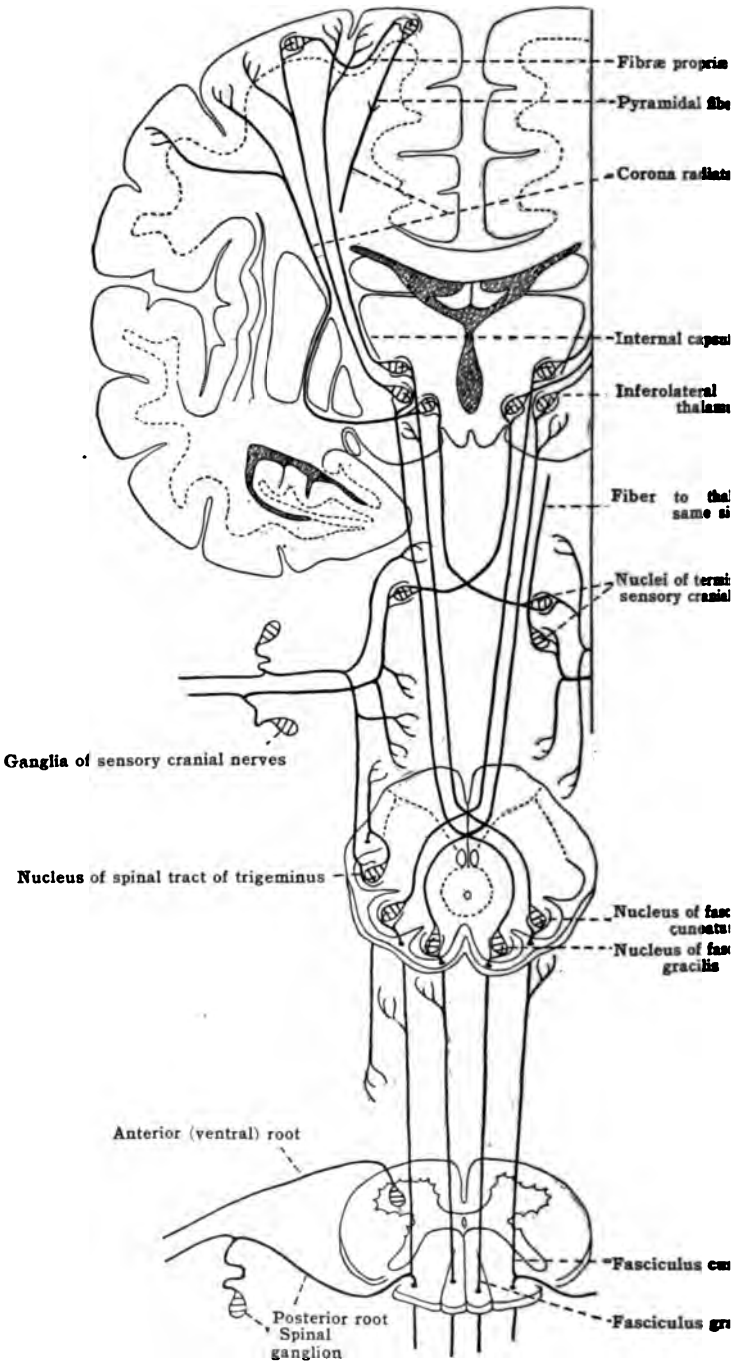
1. Giant pyramidal cells of precentral gyrus of somesthetic area.
   (*a*) Corona radiata, frontoparietal part.
   (*b*) Internal capsule, middle segments of frontoparietal portion.
   (*c*) Basis of the cerebral peduncle and the peduncle.
   (*d*) Pyramid of medulla oblongata.
   (e^1) Decussation of pyramids.
   (f^1) Lateral cerebrospinal fasciculus (crossed pyramidal tract).
   (e^2) Ventral cerebrospinal fasciculus (direct or uncrossed pyramidal tract).
   (f^2) Gradual decussation of latter in cervical and upper thoracic regions of spinal cord.
2. Cells of ventral horn of spinal cord of opposite side.
   (*a*) Ventral or efferent roots of spinal nerves.
   (*b*) Peripheral nerve-trunks directly to skeletal muscles or indirectly to smooth muscle or glands by way of sympathetic neurones.

II. Short Reflex Paths of Spinal Cord

1. Spinal ganglia.
   (*a*) Terminal corpuscles and peripheral process of T-fibers.
   (*b*) Dorsal root of spinal nerve.
   (*c*) Collaterals and terminal branches of bifurcation of dorsal root fibers within spinal cord.

(*d*) Directly to ventral horn cells of same level of spinal cord.
(*e*) Or, more commonly, to same through intermediation of Golgi cell of t
(*f*) Or to neurones of fasciculi proprii to ventral horn cells of other levels cord.

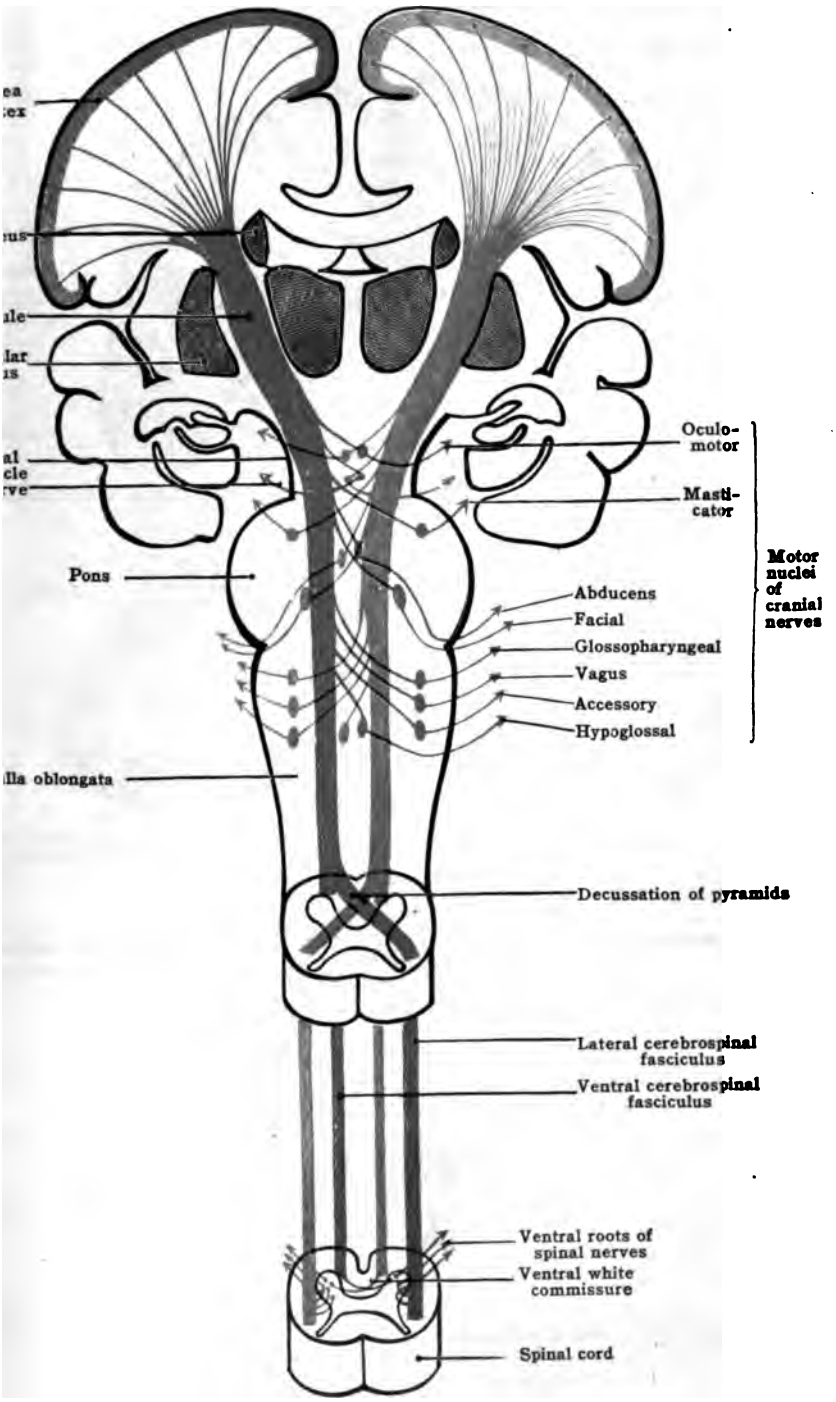
FIG. 741.—SCHEME OF PRINCIPAL SPINOCEREBRAL CONDUCTION PAT



2. Ventral horn cells of same (chiefly) and opposite side **and thence by way** roots and peripheral nerve trunks directly **to skeletal muscles.**
3. Dorsolateral group of ventral horn cells of same **(chiefly) and opposite** thence by ventral root fibers to cell-bodies in **sympathetic ganglia.**
4. Sympathetic axones to smooth muscle or glands.

ıL PATH FOR THE CRANIAL NERVES, EXCLUSIVE OF THOSE OF SPECIAL SENSE
ıding system of neurones.
ınglia of origin of sensory components of vagus, glossopharyngeus, glossopalatine and trigeminus.

G. 742.—SCHEME OF DESCENDING CEREBROSPINAL CONDUCTION-PATH.

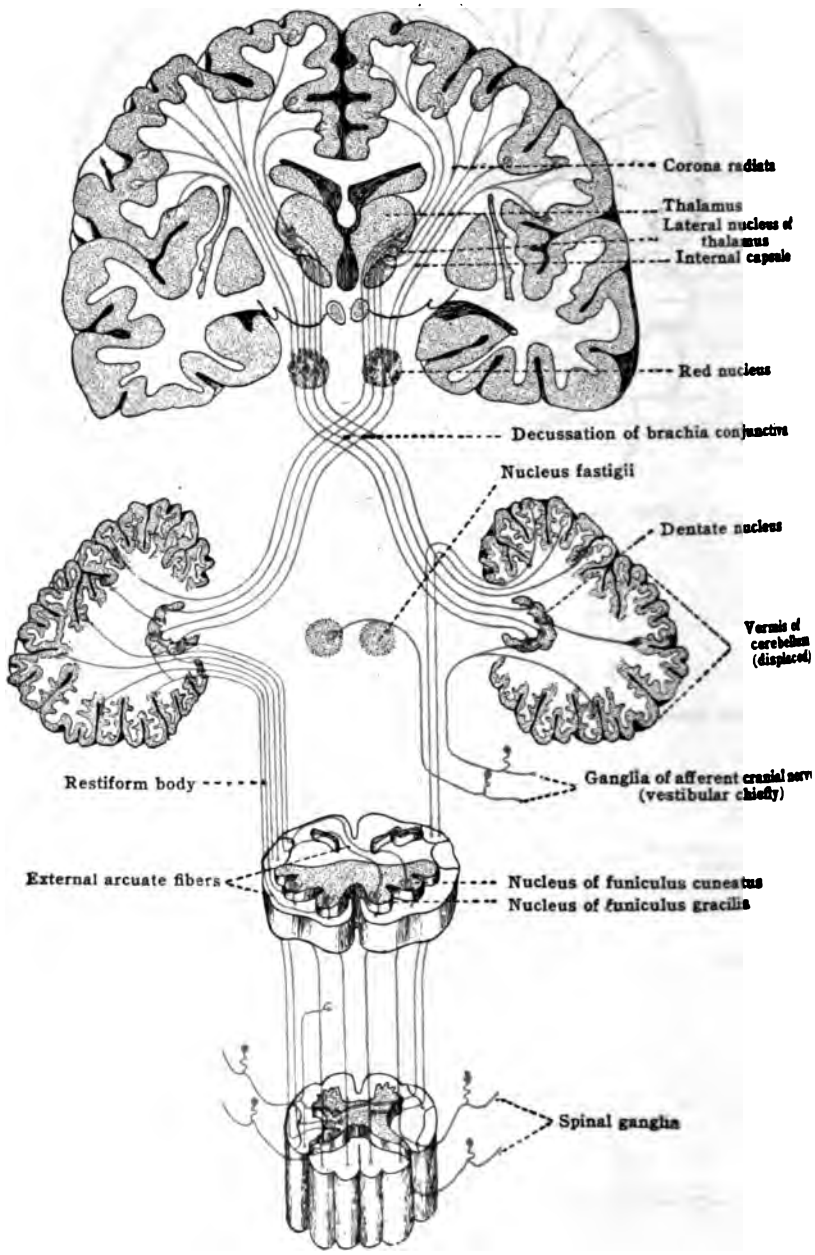


ı) Peripheral arborizations and afferent peripheral branches of T-fibers of same
ı) Central branches of T-fibers of same (sensory nerve roots).
uclei of termination of central branches (bifurcated and unbifurcated) in medulla oblongata.

(*a*) Reticular formation, internal arcuate fibers and medial lemniscus of the opp side. Trigeminal portion (trigeminal lemniscus) courses separated from m lemniscus in mesencephalon.

3. Inferior and lateral nuclei of thalamus.
   (*a*) Internal capsule, posterior segment of frontoparietal portion.
   (*b*) Corona radiata, frontoparietal part.
4. Cerebral cortex—chiefly lower third of posterior central gyrus.
   (*a*) Association and commissural fibers of cortex.

FIG. 743.—SCHEME OF PRINCIPAL ASCENDING CEREBELLAR CONDUCTION-PATHS.



B. Descending system of neurones.

1. Pyramidal cells of opercular region of somesthetic area.
   (*a*) Corona radiata, frontoparietal.
   (*b*) Internal capsule, genu chiefly.
   (*c*) Basis of cerebral peduncle and peduncle.
   (*d*) Decussation in brain-stem.
2. Nuclei of origin of motor cranial nerves and motor components of mixed cr nerves, of opposite side chiefly, and thence by way of these nerves to the re ive muscles supplied.

Notes: (1) Most of the descending cortical fibers to the nucleus of origin of the trochlear nerve and that portion of the nucleus of the oculomotor which supplies the internal rectus muscle apparently do not decussate but terminate in the nuclei of the same side.

(2) The efferent nucleus of the glossopalatine (salivatory nucleus) and the dorsal efferent nucleus of the vagus give rise to visceral efferent fibers, i.e., carry impulses destined for smooth muscle and glands by way of sympathetic neurones. The same is true for the superomedial part of the nucleus of the oculomotor.

(3) The nuclei of termination of the cranial nerves, especially those of the vestibular and trigeminus, send fibers also into the cerebellum.

IV. The Short Reflex Paths of the Cranial Nerves

These consist of the central branches of their afferent or sensory fibers, bearing impulses to the nuclei of origin of both their own motor components and to the nuclei of origin of other motor nerves. Fibers to the more distant nuclei pass to them by way of the medial longitudinal fasciculus. Instead of terminating in the motor nuclei directly, the sensory fibers are usually interrupted by a third or intermediate neurone interposed in the chain. The vagus and glossopharyngeal are connected by way of the solitary fasciculus and its nucleus with the structures below their level of entrance, the vagus with the ventral horn cells of the upper segments of the cervical cord, and through these with the muscles of respiration.

V. Conduction-Paths Involving the Cerebellum

A. Ascending cerebellar pathways.

1. Spinal ganglia.
   - (*a*) Terminal corpuscles, trunks and dorsal roots of spinal nerves.
   - (*b*) Collaterals and terminal branches of bifurcation of dorsal root fibers in spinal cord, chiefly those conveying impulses of *muscle-sense.*

2*x*. Dorsal nucleus (Clarke's column).
   - (*a*) Dorsal spinocerebellar fasciculus (direct cerebellar tract).
   - (*b*) Restiform body (inferior cerebellar peduncle)—
   - (*c*) Joined in medulla by external arcuate fibers (crossed and uncrossed fibers arising in nuclei of funiculus gracilis and cuneatus);
   - (*d*) Joined in medulla by fibers arising in nuclei of termination of afferent vagus, glossopharyngeal, vestibular, and trigeminal nerves;
   - (*e*) Joined by fibers both to and from (ascending and descending) the inferior olivary nucleus of the same and especially opposite sides (*cerebello-olivary fibers*).

2*y*. Nerve-cells in base of ventral horn of same and opposite side (lumbosacral region).
   - (*a*) Superficial anterolateral spinocerebellar fasciculus (Gowers' tract), ascending through spinal cord and reticular formation of medulla and pons.
   - (*b*) Anterior medullary velum and brachium conjunctivum to cerebellar cortex (vermis chiefly).

3. Cerebellar cortex, dentate nucleus, nucleus fastigii, nucleus emboliformis, and nucleus globosus.
   - (*a*) White substance (corpus medullare) of cerebellum, associating various regions of its cortex and its nuclei with each other.
   - (*b*) Brachium conjunctivum (superior cerebellar peduncle) arising chiefly from dentate nucleus.
   - (*c*) Decussation of brachium conjunctivum.

4. Red nucleus and lateral nucleus of thalamus. Most fibers of the brachium conjunctivum terminate in the red nucleus; many merely give off collaterals to it in passing to their termination in the thalamus. Most of the ascending fibers arising in the red nucleus also terminate in the thalamus; some ascend to the cerebral cortex direct.
   - (*a*) Internal capsule, middle third, and frontoparietal part of corona radiata.
   - (*b*) Somesthetic area of cerebral cortex and cortex of frontal lobe anterior to it.
   - (*c*) Inferior peduncle of thalamus to cortex of temporal lobe.

B. Descending cerebrocerebellar paths.

1. Pyramidal cells of somesthetic area send fibers through corona radiata, internal capsule, and cerebral peduncle to nuclei of pons and arcuate nucleus of same and opposite side.
2. Cells of cortex of posterior part of frontal lobe give fibers to form frontal pontile path through frontal parts of corona radiata and internal capsule and through medial part of cerebral peduncle to nuclei of pons of opposite side.
3. Cells of cortex of temporal lobe (superior and middle gyri) give fibers to form temporal pontile path which passes under the lenticular nucleus into anterior segment of occipital portion of internal capsule and lateral part of cerebral peduncle to nuclei of pons of opposite side. This path is joined in the internal capsule by a small occipitopontile path.
4. Cells of nuclei of pons send fibers by way of brachium pontis (middle cerebellar peduncle) to cortex of cerebellar hemisphere, of side opposite to that of the origin of the cerebral fibers making synapses with the cells of the pons.

C. Descending cerebellospinal paths.

1. Probably from cells of nucleus fastigius of same and opposite sides and probably from other nuclei of cerebellum arise fibers which terminate in the nuclei of termination of the vestibular nerve and reticular formation; these send fibers into the intermediate and anterior marginal fasciculi of spinal cord (fig. 661), and thence to the cells of the anterior horn.

2. The pathway arising in the red nucleus of the opposite side and descending in the rubrospinal tract of the lateral funiculus of the spinal cord (fig. 661). The rubrospinal tract decussates in the ventral portion of the tegmentum of the mesencephalon and is said to pass through the medulla oblongata in the medial longitudinal fasciculus. It must be noted here that in addition to the brachium conjunctivum some fibers arising in the cortex of the frontal lobe terminate in the red nucleus (corticorubral path).

VI. The Vestibular Conduction-Paths (Equilibration)

1. Vestibular ganglion gives origin to the peripheral utricular and three ampullar branches and to the combined and centrally directed vestibular nerve.
2. Lateral vestibular nucleus (Deiters'), medial nucleus, superior nucleus, and nucleus of descending or spinal root (nuclei of termination) give origin to fibers as follows:—
   (*a*) From lateral and superior nuclei to nucleus fastigii of opposite side and to cortex of vermis and to dentate nucleus (cerebellar connection).
   (*b*) From medial and superior nuclei to nuclei of origin of eye-muscle nerves of same and opposite sides, by way of medial longitudinal fasciculi.
   (*c*) From lateral nucleus and nucleus of descending root through reticular formation into lateral and ventral vestibulospinal tracts of spinal cord.
   (*d*) The nuclei receive fibers from the gray substance of the vermis. It is probable that all the nuclei of termination give off fibers bearing ascending impulses which ultimately reach the cerebral cortex, but the course pursued and neurones involved in such a chain are uncertain.

VII. The Auditory Conduction-Path (Cochlear Nerve)

1. Spiral ganglion of the cochlea gives origin to short peripheral fibers to organ of Corti, and to the centrally directed cochlear nerve.
2. Dorsal and ventral nuclei of the cochlear nerve (nuclei of termination).
   (*a*) Striæ medullares arise from dorsal nucleus and pass around outer side of restiform body (acoustic tubercle), then medianward under ependyma of floor of fourth ventricle to midline, then ventralward into tegmentum, where they decussate and join trapezoid body and lateral lemniscus of opposite side.
   (*b*) Fibers arising in ventral nucleus pass ventrally medianward and some terminate in the superior olivary nucleus of same side; others pass by way of trapezoid body and lateral lemniscus to terminate in superior olivary nucleus, nucleus of lateral lemniscus, medial geniculate body and nucleus of inferior quadrigeminate body of the opposite side.
3. Nuclei of superior olives of both sides and nucleus of lateral lemniscus send fibers to reticular formation and medial longitudinal fasciculus, associating auditory impulses with the nuclei of the motor cranial nerves.
4. Fibers from medial geniculate body and probably from nucleus of inferior quadrigeminate body pass into internal capsule and through temporal part of corona radiata to middle third of superior temporal gyrus and adjacent portions (auditory area).
5. It is probable that fibers from the auditory area of the cerebral cortex are also distributed to nuclei of the motor cranial nerves by way of the inferior quadrigeminate bodies.

VIII. Conduction Paths of the Visual Apparatus

A. Optic impulses.

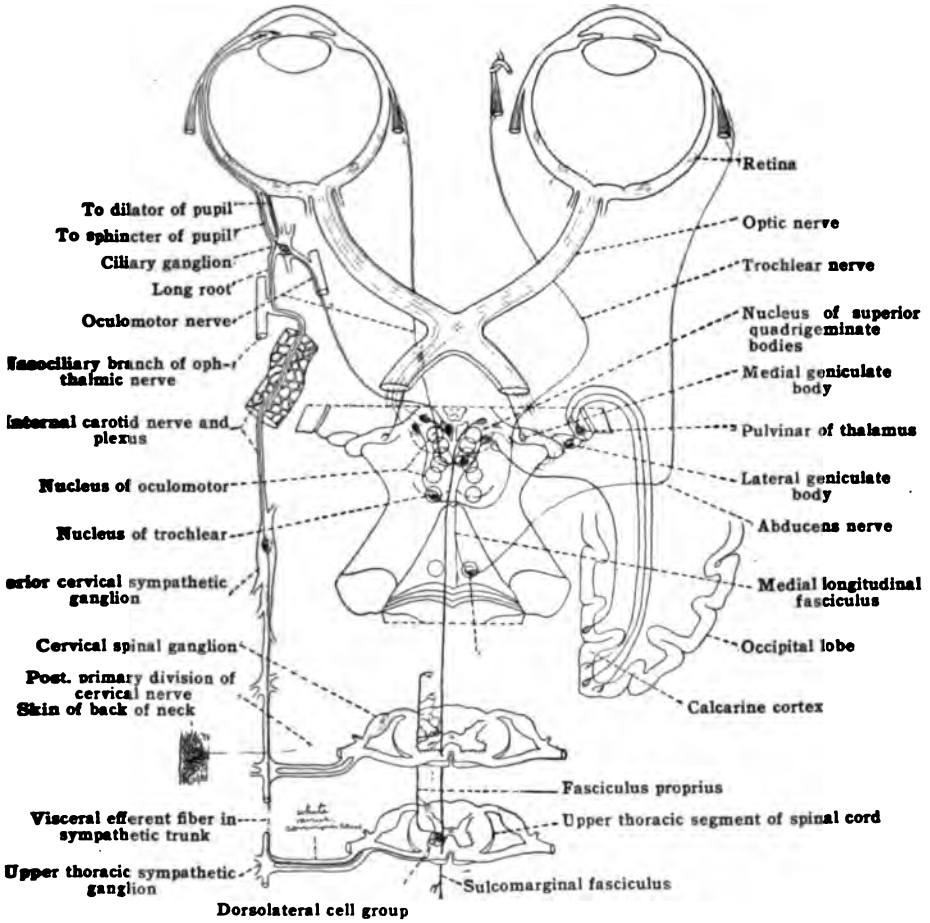
1 'Bipolar' cells of retina with short (peripheral) processes to layer of rods and cones (neuro-epithelium) and short centrally directed processes to ganglion-cell layer of retina (nucleus of termination).
2. Ganglion-cells of retina give origin to—
   (*a*) Optic stratum of retina.
   (*b*) Optic nerve.
   (*c*) Optic chiasma; fibers from nasal side of retina cross in chiasma to opposite side; fibers from lateral side of retina continue on same side in—
   (*d*) Optic tract to —
3. Pulvinar of thalamus, lateral geniculate body, and nucleus of superior quadrigeminate body.
   (*a*) Fibers from nucleus of superior quadrigeminate body pass ventrally, to nuclei of origin of oculomotor and trochlear nerves and to medial longitudinal fasciculus of same and opposite sides, and from it are distributed to nuclei of origin of abducens and facial nerves.
   (*b*) Fibers from lateral geniculate body and pulvinar pass through occipital portion of internal capsule and occipitothalamic radiation (optic radiation) to cortex of occipital lobe (visual area).
4. Cells of visual area of cortex send fibers through occipitothalamic radiation and occipital portion of internal capsule to nucleus of superior quadrigeminate body (occipitomesencephilic fasciculus), and thence, probably interrupted by cells of this nucleus, the impulses are carried to nuclei of eye-muscle nerves.
5. Cells of nucleus of superior quadrigeminate body and pulvinar send fibers by way of medial longitudinal fasciculus into lateral and ventral funiculi of spinal cord (see fig. 661), chiefly of the opposite side. Fibers from the quadrigeminate body cross midline chiefly in decussation of 'optic-acoustic reflex path' (fig. 703) and in fountain decussation.

6. The smaller cells of the superomedial group of the nucleus of the oculomotor nerve (nucleus of Edinger and Westphal) send axones, by way of the trunk of the nerve and the short root of the ciliary ganglion, which terminate about cells in—
7. The ciliary ganglion, whose cells send axones to enter the ocular bulb and terminate upon the smooth muscle fibers of the ciliary body and sphincter of the iris.

B. Spinopupillary ('ciliospinal') reflexes.

1. Peripheral processes of spinal ganglion cells terminating in the skin and central processes of same entering by way of dorsal roots of spinal nerves to bifurcate in spinal cord and give terminal twigs about—
2. Cells of the dorsolateral group of the ventral horn of the same and opposite sides of cervical and upper thoracic regions of spinal cord. These cells send (visceral efferent) axones by way of white rami communicantes of thoracic nerves and sympathetic trunk to terminate about cells in—

FIG. 744.—DIAGRAM OF PRINCIPAL PATHWAYS OF OPTIC APPARATUS.



3. The superior cervical sympathetic ganglion, which cells send axones chiefly by way of the carotid plexus and the sympathetic roots of the ciliary ganglion, through ciliary ganglion without synapses, into the ocular bulb to terminate in the ciliary body and radial (dilator) muscle fibers of the iris, producing dilation of the pupil.

C. Auditory-eye reflexes.

1. Cells of the nuclei of termination of the cochlear nerve and superior olive send fibers by way of the medial longitudinal fasciculus (some to this by way of the peduncle of the superior olive) to the nuclei of origin of the eye-moving nerves.
2. The same nuclei of the cochlear nerve send axones by way of the lateral lemniscus to terminate in the superior quadrigeminate body and thence may be sent impulses which are distributed to the nuclei of the eye-moving nerves.

IX. PRINCIPAL CONDUCTION-PATHS OF OLFACTORY APPARATUS

1. Bipolar cells of olfactory region of nasal epithelium send short (peripheral) processes to surface of the epithelium and centrally directed processes, the olfactory nerve, through lamina cribrosa of ethmoid bone into olfactory bulb (glomerular layer).

2. 'Mitral cells' of olfactory bulb give fibers which form—
   (*a*) The olfactory tract which divides into—
   (*b*) Medial olfactory stria through which fibers pass—(1) into parolfactory area (Broca's area); (2) into subcallosal gyrus; and (3) by way of anterior cerebral commissure to olfactory bulb and uncus of hippocampal gyrus of opposite side.
   (*c*) Intermediate olfactory stria to anterior perforated substance.
   (*d*) Lateral olfactory stria, which terminates to some extent in anterior perforated substance, but chiefly in uncus, hippocampal gyrus, and gyrus cinguli (olfactory area) of same side.
3. Cells of uncus and hippocampal gyrus give fibers which form—
   (*a*) The cingulum (in part), by which they are associated with the cortex of the gyrus cinguli and other areas of the cerebral cortex.
   (*b*) The hippocampal commissure (in part), by which they are correlated with the gray substance of the opposite side.
   (*c*) The fornix, which, interrupted in part in the nuclei of the corpus mammillare, conveys impulses—(1) to the anterior nucleus of thalamus of the same (chiefly, and opposite sides (mammillothalamic fasciculus), and (2) into the mesencephalon and substantia nigra (mammillomesencephalic fasciculus), and by way of this tract probably to the nuclei of the mesencephalon and medulla oblongata.
4. The parolfactory area, anterior perforated substance, anterior nucleus of thalamus and fornix give fibers which form the medullary stria of the thalamus and which terminate in the habenular nucleus.
5. Habenular nucleus sends fibers in fasciculus retroflexus to terminate in interpeduncular nucleus.
6. Interpeduncular nucleus sends fibers to nuclei of mesencephalon and probably to structures below it.

The Relations of the Brain to the Walls of the Cranial Cavity

The precise methods by which the exact positions of the most important fissures, sulci gyri, and areas can be ascertained and mapped out on the surface of the head in the living subject are fully described in Section XIV. Here, only a very general survey of the relations of the brain to the cranial bones is given and from a purely anatomical standpoint (fig. 745).

The parts of the brain which lie in closest relation with the walls of the cranial cavity are the olfactory bulb and tract, the basal and lateral surfaces of the cerebral hemispheres, the inferior surfaces of the lateral lobes of the cerebellum, the ventral surfaces of the medulla and pons, and the hypophysis.

Certain of these portions of the brain lie in relation with the basicranial axis, that is, with the basioccipital, the basisphenoid, and the ethmoid bones, while others are associated with the sides and vault of the cranial cavity. Considering the former portions first, the ventral surface of the medulla oblongata, which is formed by the pyramids, lies upon the upper surface of the basioccipital bone. More superiorly the ventral surface of the pons rests upon the basisphenoid, from which it is partly separated by the basilar artery and the pair of abducens nerves. In front of the dorsum sellæ the hypophysis (pituitary body) is lodged in the hypophyseal fossa. Still further forward the olfactory tracts lie in grooves on the upper surface of the presphenoid section of the sphenoid bone; and in front of the sphenoid the olfactory bulbs rest upon the cribriform plates of the ethmoid.

Posterior and lateral to the posterior part of the foramen magnum the lateral lobes of the cerebellum are in relation with the cranial wall, resting upon the lower parts of the supraoccipital and the posterior parts of the exoccipital portions of the occipital bone, while anteriorly each lobe is in relation with the inner surface of the mastoid process and the posterior surface of the petrous portion of the temporal bone. The area of the skull wall which is in close relationship with the cerebellar hemispheres may be indicated, on the external surface of the skull, by a line which commences at the inferior part of the external occipital protuberance and thence runs upward and lateralward. It crosses the superior nuchal line a little beyond its center, and, continuing in the same direction, crosses the inferior part of the lambdoid suture and reaches a point directly above the asterion (the meeting point of the occipital, temporal, and parietal bones); thence it descends, just in front of the occipitomastoid suture, to the tip of the mastoid process, and there turns medialward to its termination at the margin of the foramen magnum, immediately behind the posterior end of the occipital condyle.

The basal surface of each cerebral hemisphere may be said to consist of two parts, an anterior and a posterior, separated by the stem of the lateral cerebral fissure. The anterior part, formed by the orbital surface of the frontal lobe, rests upon the upper surfaces of the orbital plate of the frontal bone and the lesser wing of the sphenoid. It is, therefore, in close relation with the upper wall of the orbital cavity. The posterior part, behind the stem of the lateral fissure, begins with the anterior portion of the temporal lobe, including its pole. The pole itself projects against the orbital plate of the great wing of the sphenoid bone, and it is in relationship with the posterior part of the lateral wall of the orbit. The basal surface of the hemisphere, behind the pole of the temporal lobe is in contact with the upper surfaces of the great wing of the sphenoid and the petrous part of the temporal bone.

The convex surfaces of the cerebral hemispheres have the most extensive relationships with the cranial wall, and it is more especially to these surfaces that the surgeon turns his attention. The general area in which the convex surface of each cerebral hemisphere is in relation with the skull bones is readily indicated by a series of lines which correspond with the positions of its superciliary, inferolateral, and superomedial borders.

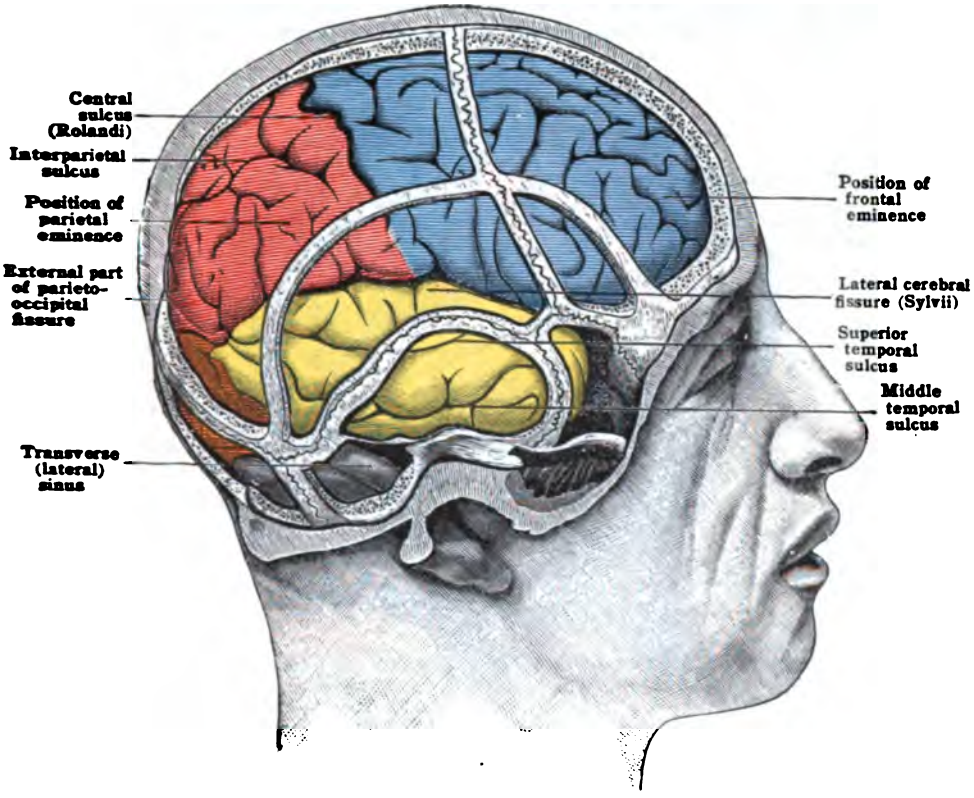
The line marking the superciliary margin of the hemisphere commences at the nasion (the midpoint of the frontonasal suture); it passes lateralward above the superciliary ridge, crosses

the temporal ridge, then, turning posteriorly in the temporal fossa, it reaches the parieto-sphenoidal suture, and continues backward along it to its posterior extremity.

The line marking out the inferolateral border commences at the posterior end of the parieto-sphenoidal suture, whence it passes downward, in front of the sphenosquamous suture, to the infratemporal crest (pterygoid ridge); there it turns posteriorly and, running parallel with and medial to the zygomatic arch, it crosses the root of the zygoma, and ascending slightly, it passes above the external auditory meatus. Continuing backward with an inclination upward it reaches a point immediately above the asterion; thence it descends, and, crossing the inferior part of the lambdoid suture and the superior nuchal line, it passes medialward to the inferior part of the external occipital protuberance.

The superomedial border of the hemisphere is defined by a line which runs from the nasion to the inion. This line should be drawn about 5 mm. lateral to the sagittal suture, because the medial area is occupied by the superior sagittal sinus, and it should be further away from the middle line on the right than on the left side, because the sinus tends to lie more to the right side.

FIG. 745.—DRAWING OF A CAST OF THE HEAD OF AN ADULT MALE.
(Prepared by Professor Cunningham to illustrate craniocerebral topography.)



The area of the cranial wall enclosed by the three lines which mark the positions of the superciliary, inferolateral, and the superomedial borders of the cerebral hemisphere is formed by the vertical plate of the frontal bone, the parietal bone, the great wing of the sphenoid, the squamous part of the temporal, and the upper section of the supraoccipital segment of the occipital bone. It covers the convex surfaces of the frontal, parietal, temporal, and occipital lobes of the cerebrum and the fissures and sulci which bound and mark them.

In every consideration of the topographical relations of the cerebral gyri to the walls of the cranial cavity it must be borne in mind that the conditions are not constant, and that, therefore, the relations are variable. The three main factors upon which this variability depends are age, sex, and the shape of the skull. As examples of the variations which occur it may be mentioned that the lateral cerebral fissure is relatively higher in the child than in the adult (compare figs. 745 and 746). The superomedial end of the central sulcus is further away from the coronal suture in the female and in the child than in the adult male, and in dolichocephalic than in brachycephalic heads. The angle formed between the line of the central fissure and the mid-sagittal plane, which averages about 68° in the adult, is more acute in dolichocephalic heads, and the external part of the parietooccipital fissure is further forward in the child, and possibly in the female, than it is in the adult male.

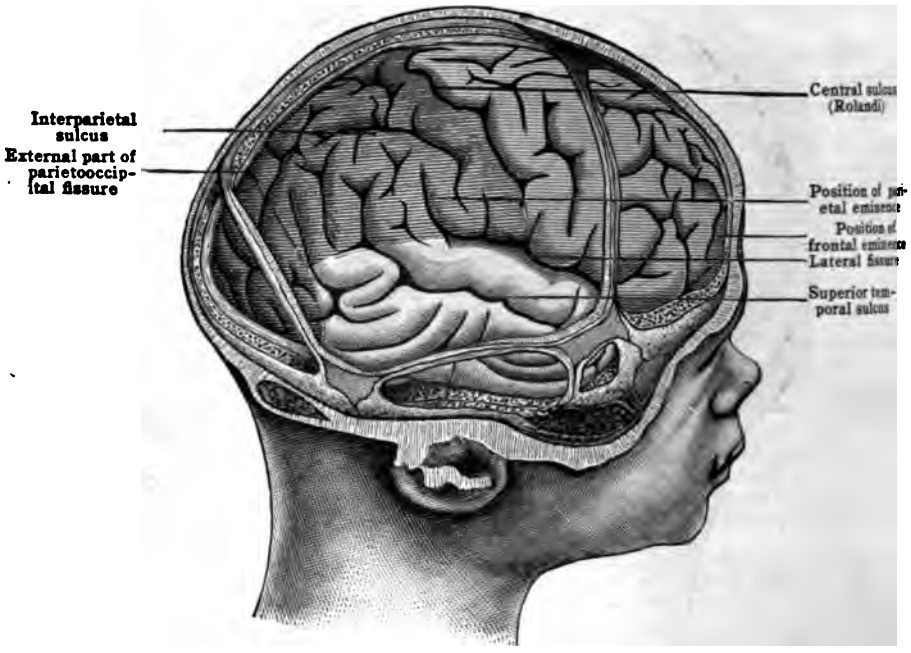
The position of the posterior horizontal limb of the lateral fissure varies even in the adult. Its posterior part is always under cover of the parietal bone, and it terminates either in front of or inferior to the parietal eminence, but the anterior part may be above, parallel with, or inferior

to the squamoparietal suture. In the adult the anterior part of the fissure runs upward and backward from the posterior end of the sphenoparietal suture along the anterior part of the squamoparietal suture to its highest point; thence it continues in the same direction beneath the parietal bone toward the lambda, terminating either in front of or below the parietal eminence. In the child, however, the fissure is considerably above the line of the squamoparietal suture (fig. 746), which it gradually approaches, attaining its adult position about the ninth year. This change of position, which occurs during the first nine years, is due partly to the ascent of the sutural line and partly to the descent of the fissure on the surface of the brain.

The frontal bone always covers the superior, middle, and inferior frontal gyri, except their posterior extremities, which are beneath the parietal bone (fig. 745). The ascending limb (ramus anterior ascendens) of the lateral fissure, which cuts into the posterior part of the inferior frontal gyrus, runs parallel with and under cover of the lower part of the coronal suture, or immediately in front of it, and the anterior horizontal limb is parallel with and beneath the upper margin of the great wing of the sphenoid.

The parietal bone is in relation with the convex surfaces of four lobes of the cerebrum. Speaking very generally, it may be said that the anterior third covers the posterior part of the

FIG. 746.—DRAWING OF A CAST OF THE HEAD OF A NEWLY BORN MALE INFANT.
(Prepared by Professor Cunningham to illustrate craniocerebral topography.)



frontal lobe, including the anterior central gyrus, and the posterior ends of the superior, middle, and inferior frontal gyri and precentral sulcus. The posterior two-thirds of the bone are superficial to the parietal lobe, the posterior part of the temporal lobe, the anterior part of the occipital lobe, the posterior part of the horizontal limb of the lateral fissure, the superior and inferior parts of the postcentral sulcus, the interparietal sulcus, the posterior sections of the superior and middle temporal sulci, and the external part of the parieto-occipital fissure. The central sulcus is beneath the parietal bone at the junction of its middle and anterior thirds (fig. 745).

In the adult, the upper end of the central sulcus is situated at about 55 per cent. of the whole length of the nasoinionic line posterior to the nasion. It is about 4 or 5 cm. from the coronal suture. The inferior end of the sulcus, which extends to near the posterior horizontal limb of the lateral fissure, lies beneath the point of intersection of the auriculobregmatic line with a line drawn from the stephanion (the point where the temporal ridge cuts the coronal suture) to the asterion. This point is about 46 per cent. of the horizontal arc measured from the glabella to the inion.

The superior end of the parieto-occipital fissure usually lies about 5 mm. in front of the lambda, and the course of the fissure may be indicated by a line drawn from 5 mm. in front of the lambda to a point immediately above the asterion, and, as the latter point corresponds with the preoccipital notch on the inferolateral border of the hemisphere, the line in question will indicate the adjacent margins of the parietal, temporal, and occipital lobes.

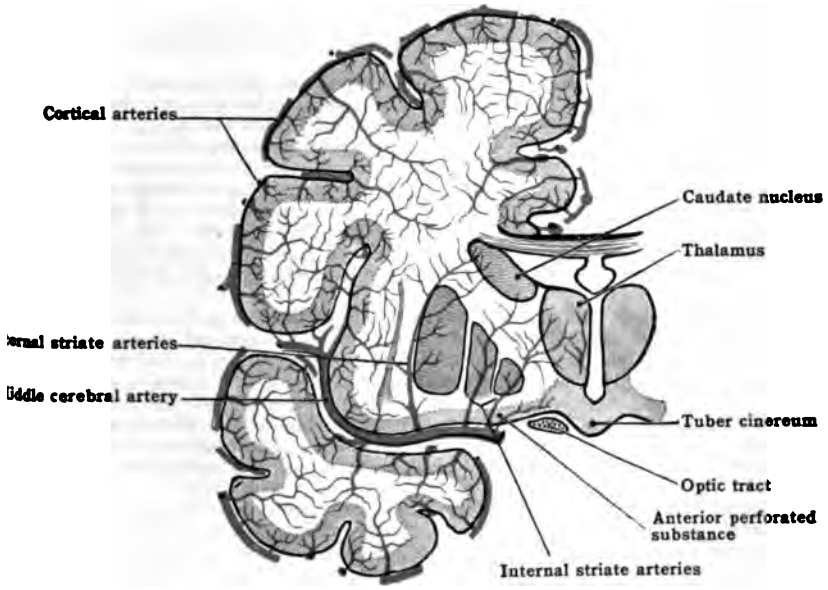
The occipital bone is in close relation with the cerebellum, as already pointed out, but it also covers the posterior part of the lateral surface of the occipital lobe of the cerebral hemisphere. The great wing of the sphenoid covers the outer surface of the pole of the temporal lobe, and the squamous part of the temporal bone covers the anterior parts of the superior, middle, and inferior temporal gyri and the sulci which separate them.

The Blood-Supply of the Encephalon

The double origin of the continuous arterial system of the brain given by the confluence of two vertebral arteries and the two internal carotid arteries, together with the description of the general distribution of the different cerebral, mesencephalic, and cerebellar arteries into which the system is divided, and the origin and course of the corresponding veins, are fully dealt with in Section VI. Here attention may be called briefly to the abundant and systematic terminal distribution of the terminal branches of the system and their intimate arrangement for the actual nourishment of the nervous tissues within.

The general plan of the blood supply for the entire encephalon may be summarized as follows:—(1) At their origin the different arteries are so connected, directly or indirectly, on the base of the encephalon, that the blood approaching the brain by way of the vertebral and internal carotid arteries is practically a common supply for all the arteries of the encephalon, so that a given part of it may possibly pass into any one of them. (2) In the pia mater of each primary division of the encephalon, the different arteries again become connected with each other directly in a superficial, freely anastomosing plexus, continuous throughout. (3) From this plexus of the surface, naturally composed in part of the trunks of the different arteries themselves, arise central branches which enter directly into the nervous substance and which break

Fig. 747.—Diagram Showing the Manner of Distribution of the Cortical and Central Branches of the Cerebral Arteries.



into twigs that are *terminal;* i.e., twigs that *do not* anastomose with the twigs of other central branches. (4) The arterial capillary system arising from the terminal twigs passes over into venous capillaries which converge to form corresponding venous twigs which in their turn pass to the surface and join in forming a peripheral, anastomosing venous plexus superimposed upon the similar arterial plexus. (5) From this venous plexus arise the different veins of the encephalon, which may or may not accompany the arteries for a short distance, and which finally empty into the sinuses in the cranial dura mater. These, likewise confluent, empty into the internal jugular veins. The choroid plexuses of the ventricles of the brain are modifications of the general anastomosing peripheral plexuses. The choroid plexuses of the lateral and third ventricles are derived largely from the branches of the choroid arteries, which arise separately from the internal carotid artery.

The blood supply of the cerebrum may best be taken as an illustration of the general plan of the blood-vascular system of the encephalon. The terminal or internal branches of the pial plexus, derived from the posterior, middle, and anterior cerebral arteries, are arranged in two groups, a **ganglionic** (nuclear) and a **cortical group.** The **ganglionic** branches themselves form four groups in each hemisphere:—

(1) The *anteromedial group* consists of central branches from the plexus of the domain of the anterior cerebral artery, which pass through the medial part of the anterior perforated substance and supply the head of the caudate nucleus, the septum pellucidum, the columns of the fornix, and the lamina terminalis.

(2) The *anterolateral group* consists of central branches from the domain of the middle cerebral artery. These pierce the anterior perforated substance in two subgroups—(*a*) the internal and (*b*) the external striate arteries (fig. 747.) The **internal striate arteries** pass through the segments of the globus pallidus of the lenticular nucleus and through the internal capsule, to both of which they give branches, and they terminate in the caudate nucleus and thalamus. The **external striate arteries** are larger and more numerous. They pass upward between the external capsule and the putamen, and then through or around the upper part of the putamen into the internal capsule, where they form two groups, the *lenticulothalamic*

and the *lenticulocaudate groups*. The former terminate in the thalamus and the latter in the caudate nucleus. On account of its larger size at its origin and its direct linear continuation with the internal carotid, emboli (*thrombi*) pass more frequently into the middle cerebral artery than into the anterior cerebral artery. One of the lenticulocaudate arteries which is larger and longer than the others and which is a direct branch from the middle cerebral artery has been called the **'artery of cerebral hemorrhage'** (Charcot), on account of the greater frequency with which it is ruptured.

(3) The *posteromedial* arteries are central branches of the posterior cerebral artery. They also enter the anterior perforated substance, but supply the floor of the third ventricle, the posterior part of the thalamus, and the hypothalamic region.

(4) The *posterolateral group* are also central branches of the posterior cerebral artery. They supply the posterior part of the internal capsule, the pulvinar of the thalamus, the geniculate bodies, the corpora quadrigemina and their brachia, the pineal body, and the cerebral peduncles.

The *cortical group* of the cerebral arteries arise from the anastomosing plexus in the pia mater of the cortical surfaces of the hemisphere. They pass into the cortical substance both from the summits of the gyri and from the walls of the sulci. They consist of short, medium, and long central branches, and pass at right angles into the gyri. The short branches terminate in the cortical substance; the medium branches supply the more adjacent white substance, and the longer branches pass more deeply into the general medullary center of the hemisphere.

All of both the ganglionic and the cortical arteries are terminal in the sense that they do not anastomose in the substance of the cerebrum.

The blood-vascular system of the other divisions of the encephalon is in accordance with the same general plan of that of the cerebrum. Slight individual modifications of the general plan are to be expected.

The **blood-vessels of the mesencephalon,** in addition to the supply derived from the posterolateral group of ganglionic arteries, include the vessels of the quadrigeminate bodies and those of the cerebral peduncles. The **arteries** of the quadrigeminate bodies are usually six in number, three for each side—the **superior, middle,** and **inferior quadrigeminate arteries.** The superior and middle are branches of the posterior cerebral and the inferior are branches of the superior cerebellar arteries. The superior supply the superior quadrigeminate bodies and the pineal body; the middle supply both the superior and inferior quadrigeminate bodies, and the inferior the inferior quadrigeminate bodies. They all anastomose in the pia on the surface of the stratum zonale, forming a fine-meshed plexus, and from this superficial plexus the central branches pass into the substance of the bodies. The **veins** terminate in the vein of Galen (v. cerebri magna.)

The **arteries of the cerebral peduncles** form two groups, medial and lateral. The **medial peduncular arteries** are branches of the basilar and the posterior cerebral arteries. They pass to the medial sides of the peduncles and supply the superior and medial part of the tegmentum. The vessels of this group which accompany the fibers of the oculomotor nerves are known as the radicular arteries; they supply the root-filaments and the nuclei of the nerves, which receive no other branches. The **lateral peduncular arteries** are branches of the posterior cerebral and superior cellebellar arteries. They supply the lateral portions of the peduncles and the lateral part of the tegmentum. The **veins** of the mid-brain terminate in the basilar veins and the vein of Galen.

The blood-vessels of the cerebellum.—**Six arteries** supply the cerebellum: two, the **posterior inferior cerebellar,** are derived from the vertebral arteries and the remaining four, two **anterior inferior** and two **superior cerebellar,** from the basilar artery. The course and general distribution of the arteries are described in Section VI, but here it must be noted that the branches of these six vessels form a rich network in the pia mater on the surfaces of the cerebellar lobes, and that extensions of the plexus pass with the folds of the pia mater into the sulci and fissures. From the superficial plexus central branches pass into the interior of the cerebellum and their collaterals from capillary plexuses in the white and gray substance. The extension of the surface plexus are of three lengths: – (1) a longer set, which pass through the cortex of the cerebellum and supply the white substance of the corpus medullare; (2) a set of shorter arterioles which pass through the molecular layer of the cortex and break up in its granular layer; (3) the shortest set pass into the cortex and immediately break up in its molecular layer. The meshes of the capillary plexuses in the gray substance are ovoidal and their axes run radially. The meshes of the plexuses in the white substance are parallel with the nerve-fibers. In addition to the vessels mentioned, a distinct central branch is distributed to each dentate nucleus. This springs either from the superior cerebellar or from the anterior inferior cerebellar artery of the corresponding side.

The **efferent veins** of the cerebellum do not accompany the arteries; they form a plexus in the pia mater which receives tributaries from the capillaries of the terminal branches of the central arteries in the interior, and they form three groups on each cerebellar surface, the vermian veins and the lateral veins. The **superior vermian vein** runs forward on the superior surface of the vermis and terminates in the vein of Galen. The **inferior vermain vein** runs posteriorly and ends in one of the transverse sinuses. The **superior lateral veins** open into the superior petrosal or transverse sinuses, and the **inferior lateral veins** into the inferior petrosal and transverse sinuses. The vein from the dentate nucleus usually joins the inferior lateral veins.

The blood-vessels of the pons.—The arteries to the pons are branches of the basilar artery, and of its anterior inferior and superior cerebellar branches. The plexus in the pia mater is comparatively unimportant, and the branches which enter the substance of the pons form two main groups, the central and the peripheral. The **central arteries** spring directly from the basilar. They pass backward along the raphe, giving branches to the adjacent parts, and they terminate in the nuclei of the pons and those in the floor of the fourth ventricle. The **peripheral arteries** are radicular and intermediate. The *radicular branches* spring from the peripheral plexus and from the anterior inferior cerebellar arteries; they accompany the roots of the

geminus, abducens, facial, vestibular, and cochlear nerves, supply their fibers and the adjacent rts, and they end in the grey nuclei with which the nerve-fibers are connected. The *inter-diate arteries* enter the surfaces of the pons irregularly and break up into capillaries in its bstance, just as the central arteries. The veins form a plexus on the surface. The dorsal d lateral part of this plexus is drained into the basilar vein on each side, and the inferior part connected by efferent channels with the inferior petrosal sinus and the cerebellar veins.

The blood-vessels of the medulla oblongata.—The arteries of the medulla are derived irectly from the vertebral arteries, from their anterior and posterior spinal and posterior inferior erebellar branches, and from the basilar artery. The branches of these vessels form a plexus in he pia mater from which, and from the arteries themselves, three main groups of vessels pass nto the medulla—the choroidal, the central, and the peripheral. The choroidal arteries are erived chiefly from the posterior inferior cerebellar arteries. They supply the choroid plexus of the fourth ventricle. The anterior central arteries rise from the anterior spinal artery, from the basilar artery, and from the peripheral plexus; they pass caudalward along the raphe, supplying the adjacent parts of the ventral funiculi and the olivary bodies and they break up into fine terminals in the gray substance of the floor of the fourth ventricle around the nuclei of the cranial nerves. The posterior central arteries spring from the posterior spinal arteries; they pass down the median septum of the inferior part of the medulla and supply the adjacent nervous substance. The peripheral arteries, like those of the spinal cord, are separable into radicular and intermediate groups. The *radicular arteries* pass from the anterior and posterior spinal branches and from the trunks of the vertebral arteries and accompany the fibers of the last six cranial nerves into the substance of the medulla. They supply the nerve-roots and adjacent white substance and they terminate in capillaries in the gray substance of the lateral part of the floor of the ventricle. The *intermediate peripheral arteries* spring from the arteries prveiously named and from the peripheral plexus, and they pass directly into the funiculi of the medulla, where they terminate in a capillary plexus which supplies the white substance and the gray nuclei; some of these arteries, more especially those derived from the posterior inferior cerebellar and the posterior spinal arteries, extend inward to the lateral part of the floor of the fourth ventricle. Twigs of all peripheral arteries anastomose with the common superficial plexus in the pia mater with which all central arteries are connected.

The veins which issue from the medulla form a peripheral plexus in the pia mater in which there are two main longitudinal channels, and anterior median and a posterior median vein. The former communicates posteriorly with the anterior median vein of the cord, and anteriorly with the veins of the pons and with the veins which accompany the hypoglossal nerves. The latter veins empty into the internal jugular veins. The posterior median vein is continuous caudally with the corresponding vein of the cord, and anteriorly, in the region of the calamus scriptorius, it divides into branches which join the radicular veins. The blood is carried away from the peripheral plexus mainly by the radicular veins, which pass along the roots of the last six cranial nerves. Those which accompany the hypoglossal nerves have already been referred to. The others end in the terminal parts of the transverse sinuses, the inferior petrosal sinuses, or the inferior part of the occipital sinuses.

The nerve supply of the blood vessels of the brain consists of a perivascular plexus of sympathetic nerve-fibers upon the walls of the vessels and medullated fibers which accompany the vessels and apparently terminate, for the most part, in the connective tissue about them. The former are thought to be vasomotor in function; the latter probably sensory fibers of the craniospinal type. Nerves were first described only for the larger vessels by Huber.

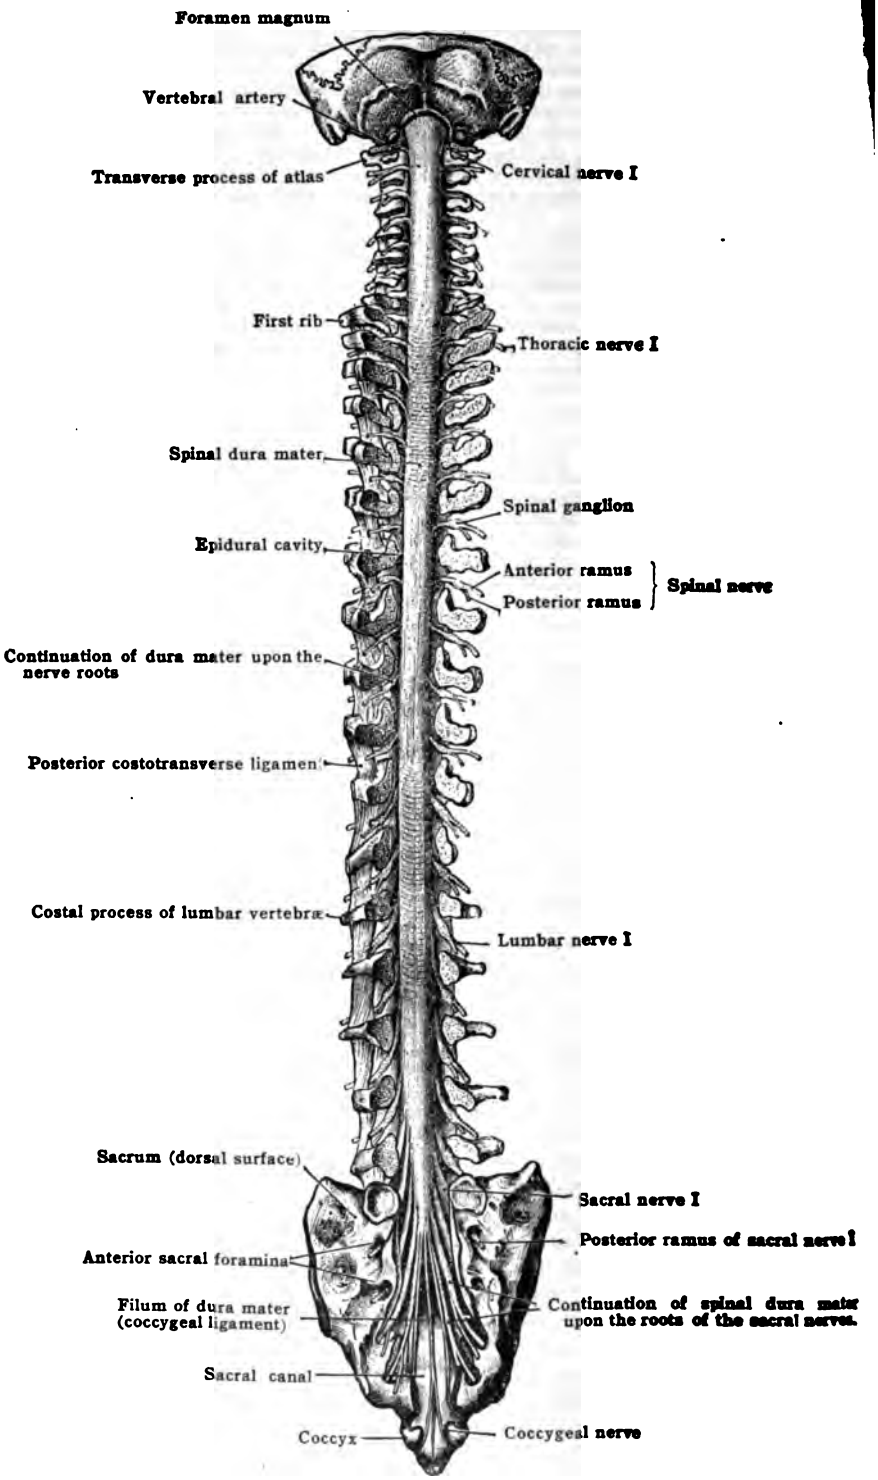
IV. THE MENINGES

Three membranes, collectively called the **meninges,** envelope the entire central nervous system, separate it from the walls of the bony cavities in which it lies, and aid in its protection and support. They consist of feltworks in which white fibrous connective tissue predominates, and through them pass the blood-vessels which supply the central nerve-axis and the nerves by which the axis is connected with the periphery. Though there are definite spaces or cavities between them, the membranes are not wholly separated from each other, and they are both continuous with and contribute to the walls of the blood-vessels and the sheaths (epineurium) of the nerves passing through them. Beginning with the outermost, they are—(1) the *dura mater*, the thickest, most dense and resistant of the membranes; (2) the *arachnoid*, the much less dense, web-like middle membrane; and (3) the *pia mater*, a thin, compact membrane, closely adapted to the surface of the central system, into which it sends numerous connective tissue processes. The pia is highly vascular, containing the rich superficial plexuses of blood-vessels from which the intrinsic blood supply of the central system is derived. The space between the dura mater and the arachnoid is known as the *subdural cavity*, and that between the arachnoid and the pia mater is the *subarachnoid cavity*.

The Dura Mater

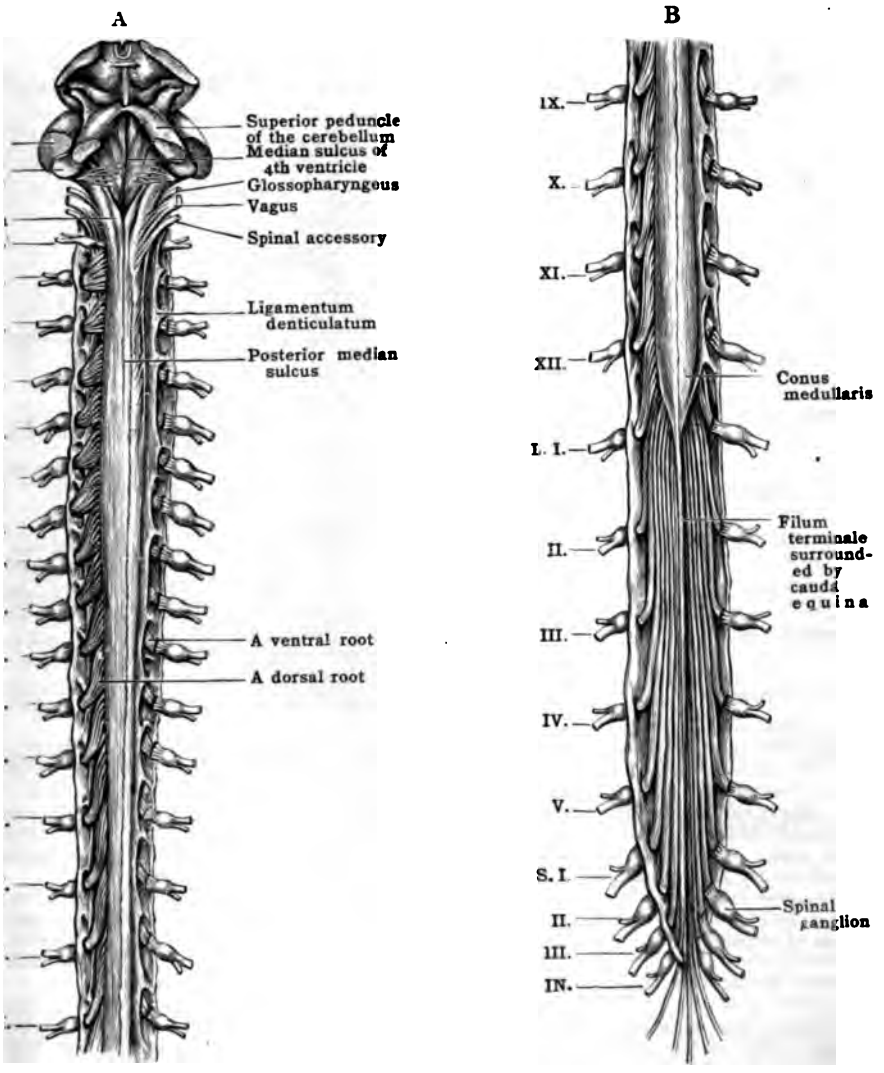
In the fresh condition the dura mater appears as a bluish-white, exceedingly resistant membrane, forming the outermost envelope of the entire central nervous

FIG. 748.—SHOWING THE SPINAL DURA MATER EXPOSED *in situ*. (Dorsal aspect.) (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



. Its external surface or that next to the bony wall is rough, while its al surface appears smooth, due to the fact that the subdural cavity partakes nature and has the lining of a lymph-space. The cranial dura mater s of two distinct, closely associated layers, the outermost of which serves internal periosteum of the cranial bones. The spinal dura mater is de- l as consisting of but one layer. The internal periosteum of the spinal though continuous at the foramen magnum with the outer layer of the

9.—Dorsal Aspect of the Medulla Oblongata and Spinal Cord with the Dura Mater Partially Removed. (Hirschfeld and Leveillé.)

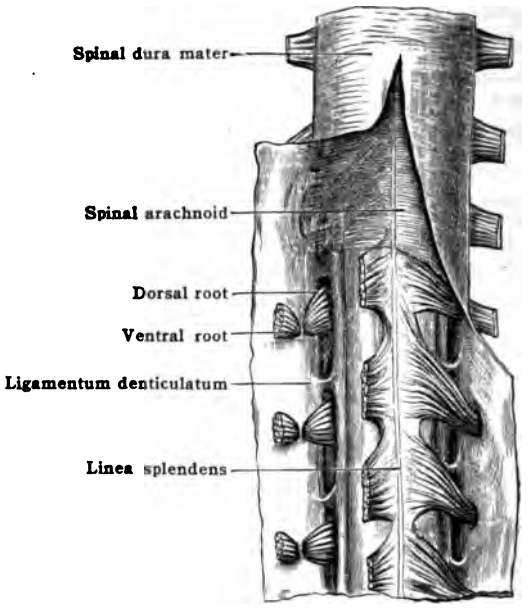


l dura mater, is not considered a part of the spinal dura mater, from the hat it is so widely separated from the layer actually investing the spinal by the epidural space. Thus, since the cranial and spinal portions of the nater differ, they are described separately.

e spinal dura mater is a fibrous tube with funnel-shaped caudal end which es and forms the outermost support of the spinal cord. It consists of but yer and this corresponds to the inner layer of the cranial dura mater. It at the foramen magnum and terminates in the spinal canal at about the f the second piece of the os sacrum. It is firmly attached to the periosteum surrounding bones only in certain localities:—

(1) The upper end of the tube blends intimately with the internal periosteum of th at the margin of the foramen magnum, and thus in this locality it becomes continuous outer layer of the cranial dura mater. Also in this locality it is attached firmly, th intimately, to the periosteum of the posterior surfaces of the second and third cervical This locality may be considered the upper fixation-point of the spinal dura mate extends laterally and contributes to the connective tissue investments of each pair nerves, and as such it passes into the intervertebral foramina and becomes continuous periosteum lining each. (3) Along its ventral aspect the spinal dura mater is att numerous processes to the posterior longitudinal ligament of the vertebral cana attachments are more or less delicate, loose, and irregular, and are easily torn or cut in the specimen. They are stronger and more numerous in the cervical and lumbar regio the thoracic. (4) In the space between the dura and the walls of the vertebral canal *cavity*) lies the rich *internal vertebral venous plexus*, and along the lateral aspect th occasionally connected with the periosteum through the tissue of the walls of the vess plexus, especially in case of the vessels which penetrate the dura. Along its dorsal a spinal dura mater is practically free from the wall of the vertebral canal. (5) At

FIG. 750.—VIEW OF MEMBRANES OF SPINAL CORD FROM VENTRAL ASPECT.



and funnel-shaped extremity, opposite the second sacral vertebra, the dura suddenly into a filament extending onto the coccyx and breaking up into a number of proce become continuous with the periosteum of the dorsal surface of the coccyx. Thi is the coccygeal ligament or filum of the dura mater, and its attachment may be the lower fixation-point of the spinal dura mater. (See figs. 748 and 655). The ext tube is maintained chiefly by means of the two fixation-points, for all the other at are sufficiently loose to permit of the movements of the vertebral column.

The *inner surface* of the spinal dura mater appears smooth, but upon closer exami found to be connected with the arachnoid by a few delicate subdural trabeculæ—occ strands of connective tissue bridging the subdural space (fig. 758). Along its late the inner surface is at intervals quite firmly attached to the pia mater by the dentat ligamenta denticulata, which are prolonged from the pia through the arachnoid.

Further, it is continuous at intervals with both the pia mater and arachnoid by connective-tissue sheaths of the nerve-roots which are prolonged from the pia and the dura mater in the passage of the nerve-roots through it. The dura is also pier spinal rami of the vertebral arteries, and the connective tissue of the outer walls of th blends with all three of the meninges. The filum terminale of the pia mater extend termination of the spinal cord into the point of the funnel-shaped end of the dura there blends with it in line with the coccygeal ligament of the outer surface.

The tube of the spinal dura mater varies in caliber with the variations in the dian spinal cord. However, the termination of its cavity occurs about seven segments termination of the spinal cord. This extension contains the long intradural nerve- ing the cauda equina, and the caliber of this part, before its sudden contraction, great as that found in any other region. As each pair of nerve-roots of the ca passes outward, they lie free for a variable distance in this tubular extension of the the latter blends with and contributes to the thickness of their sheaths.

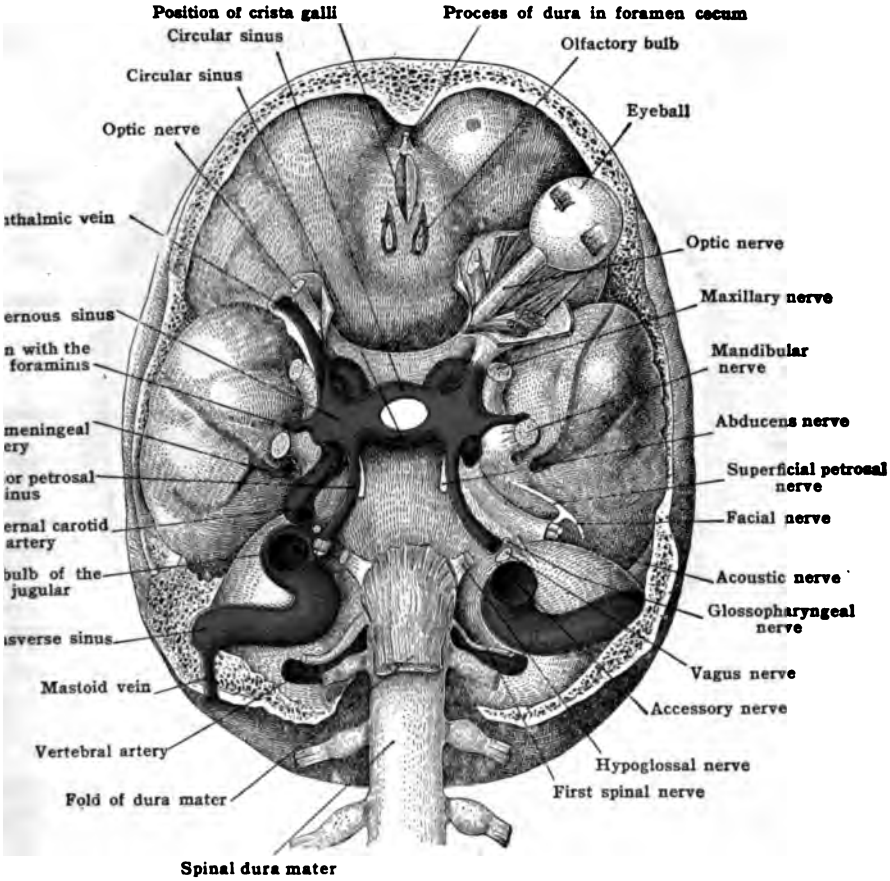
The subdural cavity, the space between the dura mater and the ara the thinnest of the meningeal spaces. Along the ventral aspect espe

rachnoid is quite closely applied to the inner surface of the dura mater. It is a small amount of cerebrospinal fluid (lymph) which prevents friction n the opposing surfaces, and is continuous with the fluid in the like space cranial meninges.

space is projected into the venous sinuses of the cranium in the region of the Pacchionian fig. 757), and its fluid is likewise in contact with the blood-vessels passing through it. obably continuous with the lymph-spaces of the nerve-roots passing through it, for fluids injected into it pass into the nerve-roots. The arachnoid is so thin and gauze- a ready interchange of fluids between the subdural and the subarachnoid spaces is possible le transfusion.

e cranial dura mater [dura mater encephali].—The dura mater investing the performs a double function—it serves as an internal periosteum for the

FIG. 751.—THE DURA MATER ENCEPHALI OF THE BASE OF THE CRANIUM.
(After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



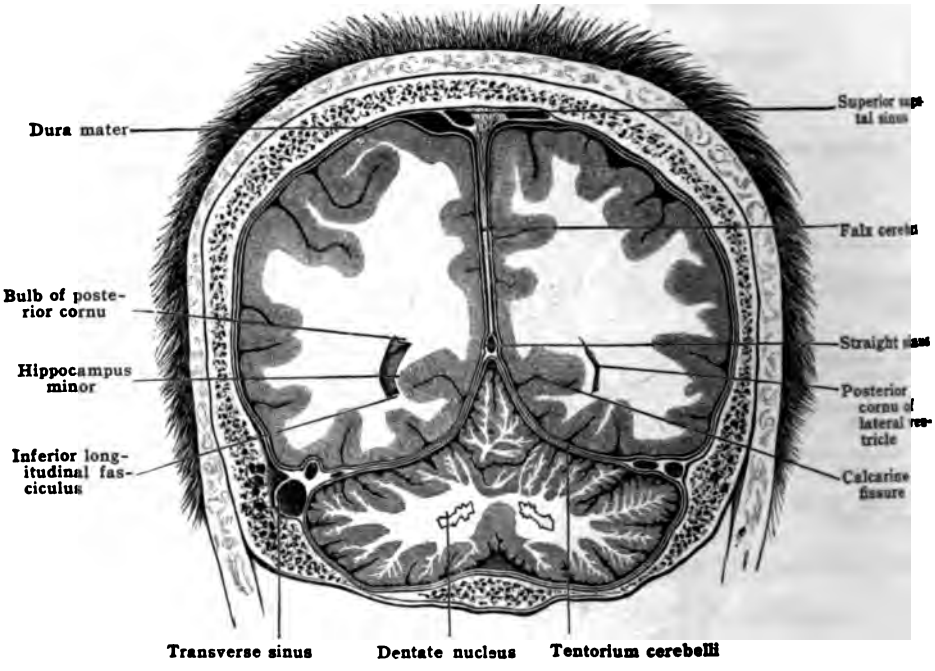
bones and gives support and protection to the brain. In conformity with ible function it consists of two layers, easily separable in the child, but adhering to each other in the adult, except in occasional localities, where xist small clefts lined with mesothelium. The large blood-sinuses and venunæ, corresponding to the internal vertebral venous plexus of the vertebral are placed between the two layers and the semilunar ganglia of the trigemo lie between them. The cranial dura begins with the adhesion of the dura mater to the periosteum at the foramen magnum, and it forms a sacvelope about the entire encephalon. Consisting of two layers, it is a much membrane than that of the spinal cord.

e *outer surface* of the cranial dura mater when torn away from the cranial appears very uneven, and when placed in water presents a flocculent ance.

This is due to the many fine bundles of connective tissue and the small blood-vessels which pass between the dura and the cranial bones and which are partially pulled out of their openings in the latter in the process of separation. The abundance of these connections, and, therefore the degree of adhesion to the bones, varies in different localities. The separation is much less difficult from the inner table of the bones of the vault of the cranium than from the bones of the base of the cavity. The adhesions to the vault of the cranium are most firm along the lines of the sutures. This is due to the fact that during the period before the sutures are closed the outer layer of the dura mater (internal periosteum) is directly continuous with the external periosteum, and, in consequence of this condition during development, the connective tissue connection is more abundant along these lines and some is caught in the closure of the sutures. Along the vault there are occasionally noticed small lymph-spaces between the bone and the dura mater. The stronger adherence to the base of the cranial cavity is due to the numerous foramina in the floor, through which all the larger cranial blood-vessels and the cranial nerves pass, and the dura mater is continuous with the connective tissue investments of these as well as with the periosteum lining the foramina. Also the floor of the cavity is more uneven than the vault, and the projections of the bones here tend to increase the firmness of attachment. The weight of the brain upon the floor probably contributes to the result.

FIG. 752.—CORONAL SECTION OF THE HEAD, PASSING THROUGH THE POSTERIOR CORNUA OF THE LATERAL VENTRICLES.

(From a mounted specimen in the Anatomical Department of Trinity College, Dublin.



The *inner surface* of the inner layer of the cranial dura mater forms the outer boundary of the subdural cavity. Except for the occasional delicate subdural trabeculæ and the passage of blood-vessels and nerve-roots, this surface appears smooth and glistening, being lined by a layer of mesothelium and containing a small amount of the cerebrospinal lymph.

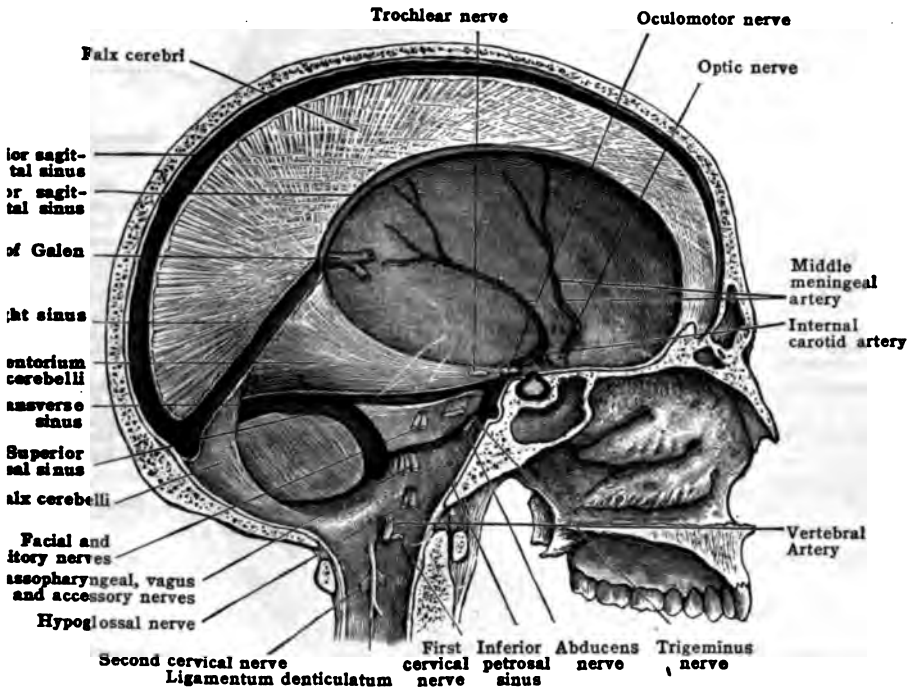
The subdural cavity of the base of the brain is prolonged a short distance outward along the roots of the various cranial nerves before it is obliterated by the blending of the dura mater with the sheaths of the nerves. This outward extension of the space is most marked about the optic and auditory nerves. In the optic especially, the dura mater remains separate from the nerve throughout its length, only fusing with its sheath upon the posterior surface of the ocular bulb (fig. 751).

In addition to its two layers, one of the most striking differences between the cranial dura mater and that of the spinal cord is that the inner layer of the former undergoes striking septa-like duplications or folds, forming exceedingly strong partitions which project between the larger subdivisions of the encephalon. These are four in number, two large and two small—the falx cerebri and the tentorium cerebelli; the falx cerebelli and the diaphragma sellæ. The larger enclose within their folds the great venous sinuses, into which most of the blood of the encephalon collects to pass outward by way of the internal jugular veins (figs. 753, 754).

The falx cerebri is the most striking of these partitions. It is a sickle-shaped which projects vertically from the vault into the longitudinal fissure between cerebral hemispheres. It begins attached to the crista galli in front, and es to terminate by blending with the superior surface of the transversely ed tentorium cerebelli. Its convex, superior border joins the outer layer of dura along the medial plane of the vault, and encloses the superior sagittal s. Its concave border is free and contains in its posterior two-thirds the ller inferior sagittal sinus.

he anterior and narrower end is often perforated and occasionally so much so as to appear coarse, fibrous reticulum. The posterior part of the concave border touches the upper ce of the corpus callosum, but the anterior part, which does not descend so low, is separated the corpus callosum by a part of the subarachnoid space. The base of the fold which s downward and blends with the upper surface of the tentorium cerebelli, contains the ght sinus running along the line of junction.

753.—THE CRANIUM WITH ENCEPHALON REMOVED TO SHOW THE FALX CEREBRI, THE NTORIUM CEREBELLI, AND THE PLACES WHERE THE CRANIAL NERVES PIERCE THE DURA ATER. (Sappey.)



The tentorium cerebelli is a large transverse, semilunar fold, concave forward scends from its central part which is elevated, and consequently it forms a shaped covering. Its superior surface is in relation with the tentorial sur- of the cerebral hemispheres, and its inferior surface conforms accurately to uperior surface of the cerebellum. The outer or convex border of the fold ached on each side to the posterior clinoid process, the superior border of the us portion of the temporal bone, the mastoid portion of the temporal bone, posterior inferior angle of the parietal bone, and the transverse ridges of ccipital bone. The transverse sinus lies in this border. From the internal ital protuberance to the mastoid portion of the temporal bone and along petrous part of the temporal bone it encloses the superior petrosal sinus.

he greater part of the inner or anterior border of the tentorium is free, and it forms the or and lateral boundaries of an arched cavity, the **tentorial notch** or foramen ovale of ioni, which encloses the mesencephalon, and through which ascend the cerebral peduncles he posterior cerebral arteries. The anterior extremities of the inner border cross the outer r, and they are attached to the anterior clinoid processes. A depressed angle is formed en the inner and outer borders of the tentorium in the middle fossa of the skull at the l portion of the posterior clinoid process, and in this angle the root of the oculomotor pierces the inner layer of the dura mater.

The nerves of the dura mater are partly derived from the sympathetic filaments wh accompany the arteries and partly from the cranial nerves. The nerves, other than sympat tic filaments, which supply the cranial dura mater are sensory fibers derived from the tri minus (chiefly) and vagus nerves, and possibly from the first cervical nerves. The branch from the trigeminus are derived from the three divisions of that nerve on either side, and it been stated that branches are given from the nasal branch of the ophthalmic division to t dura mater in the anterior fossa.

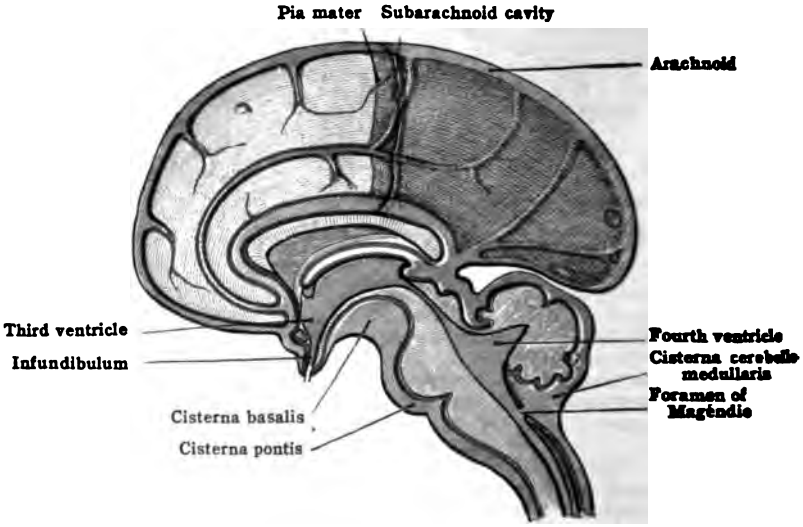
The meningeal branch of the opathalmic division of the trigeminus supplies the tentoriu that from the maxillary division accompanies the branches of the middle meningeal arte The meningeal branch of the mandibular division (nervus spinosus) passes into the skull throu the foramen spinosum and is distributed to the dura mater over the great wing of the sphen and to the mastoid cells. The *'recurrent branch of the hypoglossal nerve'* passes to the d mater of the posterior fossa of the cranium. This recurrent or meningeal branch of the hy glossal nerve really consists of fibers derived from the superior cervical ganglion of the sym thetic, and contains sensory fibers from the first and second cervical nerves. The meningeal branch of the vagus springs from the ganglion of the root of the nerve, and is distributed the posterior cranial fossa. The sympathetic filaments are distributed to the smooth mu in the walls of the blood-vessels.

The cranial **subdural cavity** is not of uniform thickness throughout, be thinner along the basal aspect of the encephalon. The lymph contained in i usually but little more than is sufficient to keep moist its bounding surfaces. is continuous with the lymph-spaces of the nerves and those of all the tis bathed, and it is continuous with the similar cavity of the vertebral canal. lymph is in free contact with the blood-vessels passing through it and w those in the tissues it bathes, and it is replenished by filtration through t walls. Though extensive, the subdural space is thin at best, for the dura mat quite closely applied to the second of the three meninges.

The Arachnoid

The arachnoid or 'serous' membrane is the middle of the three meninges o central nervous system. As in the case of the other two, an attempt is mad give this membrane a name descriptive of its texture. It is a gauzy reticulu almost web-like delicacy, which in reality pervades the space it occupies.

Fig. 756.—Diagram showing the Relations of the Pia Mater, the Arachnoid, and Subarachnoid Cavity to the Brain.

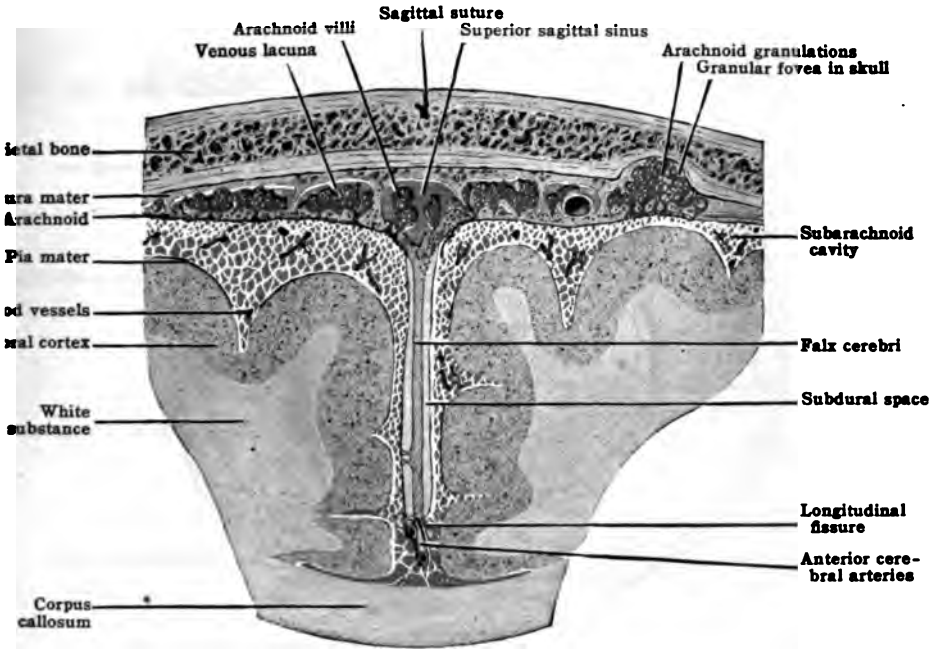


Its *outer surface*, or that closely related to the dura mater and bounding the subdural alone shows a sufficiently organized structure to merit the name of membrane. This s is covered by a layer of mesothelium which is identical with that lining the inner surface dura mater and is continuous with it by way of the cells covering the blood-vessels, the roots, the ligamenta denticulata of the spinal cord, and the occasional delicate tra passing between the dura mater and the arachnoid. Immediately under the mesoth the connective-tissue fibers of the arachnoid are woven into a very thin, more or less co web. This, however, quickly grades into a loose, spongy reticulum which pervades th subarachnoid cavity throughout, and the strands of which are directly continuous in

compact tissue of the pia mater. Thus an *inner surface* can hardly be claimed. This sponge-like arachnoid tissue holds the cerebrospinal fluid of the subarachnoid cavity, meshes of the sponge constituting a reticular web of intercommunicating spaces lined by thelial cells covering the strands of the web. In addition, the cavity is traversed by the al and cranial nerves, by the blood-vessels passing to and from the pia, and, in the vertebral l distinctively, it is traversed by the ligamenta denticulata and the filum terminale. ugh these the arachnoid is further continuous with the pia mater. The cranial subarachnoid ty is larger, and the strands of the web are relatively more abundant than in that of the bral canal.

The cranial arachnoid is directly continuous into that of the spinal cord, and he two localities does not differ as much as does the dura mater. Within the nium, the arachnoid does not closely follow the surface of the encephalon. It olded in between the cerebellum and cerebral hemispheres, following the con- r of the tentorium cerebelli, but it does not fold into the fissures and sulci ept the anterior part of the longitudinal fissure and slightly into the lateral lvian) fissure. Otherwise it fills in the inequalities of surface of the encephalon,

757.—Coronal Section Transverse to the Great Longitudinal Fissure, Showing the Meninges. (Spalteholz.)



outer surface forming a sheet enveloping the whole and bridging over the sulci the deeper grooves between the gross divisions. Upon the summits of the gyri it nore closely applied to the pia mater, and there its reticulum becomes more se. The sulci, occupied by its reticulum, form a continuous system of channels d more abundantly by the cerebrospinal fluid.

The arachnoid folds in between the cerebellum and medulla oblongata, and the base of the brain it ensheathes the olfactory bulbs and tracts, and its outer face forms a continuous sheet stretching from one temporal lobe to the other bridging over the interpeduncular fossa and the inequalities of surface in the ion of the optic chiasma and the stems of the lateral fissures. Obviously, refore, the subarachnoid cavity between its outer surface and the pia mater is considerable depth in certain localities. These localities comprise the *subchnoid cisternæ*. These occur where the cavity at the base of the brain is espely large, and make possible a 'water-bed' which serves to protect the brain from rious contiguity with the bones.

The following cisterns are distinguished (fig. 756):—

1) **The cisterna basalis** lies at the base of the cerebrum and is divided by the optic chiasma two parts —(*a*) the *cisterna chiasmatis* and (*b*) the *cisterna interpeduncularis*.

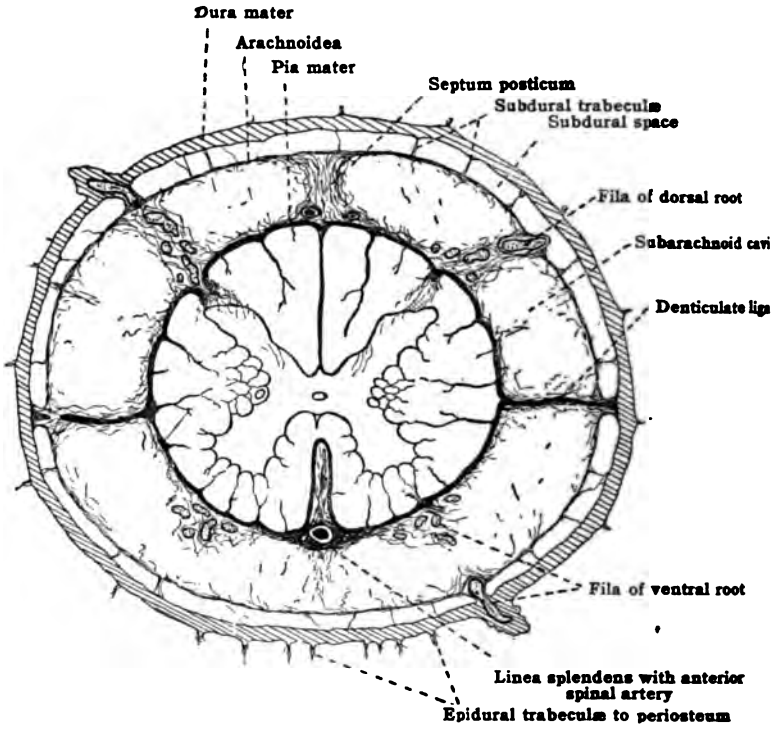
(2) **The cisterna pontis** is situated about the pons, especially in its basilar sulcus and transverse fissures of either border, and is continuous anteriorly with the cisterna basalis posteriorly with the subarachnoid cavity about the medulla.

(3) **The cisterna superior** lies in the angle between the splenium of the corpus callosum the superior surfaces of the cerebellum and the mesencephalon, and is connected ventr around the cerebral peduncles, with the cisterna basalis.

(4) **The cisterna cerebellòmedullaris** (cisterna magna) is the cavity between the infe surface of the cerebellum and the dorsal surface of the medulla oblongata. It is continu below into the spinal subarachnoid space. The fluid in this cavity is directly continuous w that in the fourth ventricle by way of the foramen of Magendie (median aperture), and t lateral apertures of the fourth ventricle.

Pacchionian bodies [granulationes arachnoideales] (fig. 757).—In certain situ tions, more particularly along the margins of the longitudinal fissure, particularly in the frontal region, and to a much less extent upon the superior surface the vermis of the cerebellum. the subarachnoid tissue elaborates numerous sm

FIG. 758.—DIAGRAM OF TRANSVERSE SECTION OF UPPER THORACIC REGION OF THE SPI CORD SHOWING THE RELATIONS OF THE SPINAL MENINGES AND THEIR CAVITIES



ovoid or villus-like projections, the Pacchionian bodies. Each arach villus consists of a retiform network of subarachnoid connective tissue v meshes are filled with cerebrospinal fluid. The Pacchionian bodies on the v of the brain project through the inner layer of the dura mater, both into the rior sagittal sinus and into the venous spaces or parasinoidal sinuses which the sides of that sinus, and, as they become larger, they press against the layer of the dura and produce ovoid depressions in the inner plate o cranium. Within the sinuses they are covered by the endothelium lining sinuses.

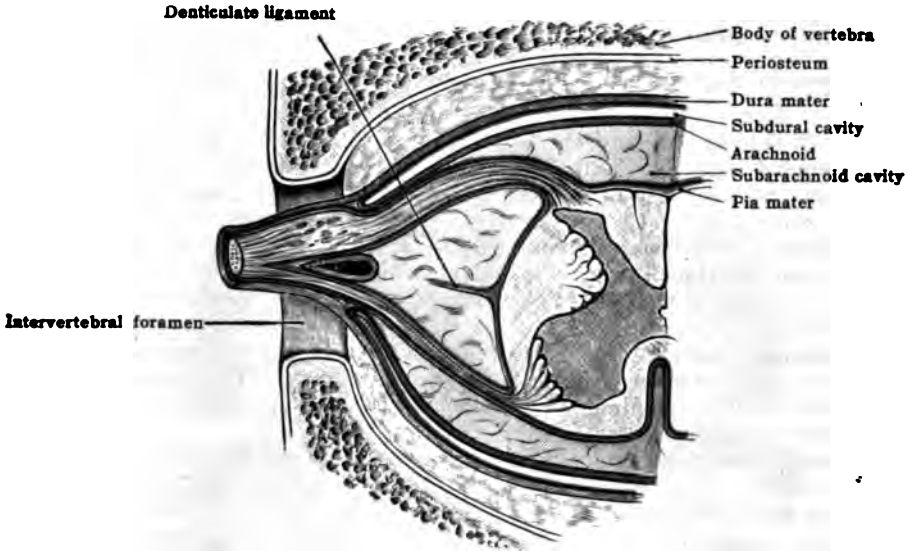
They probably facilitate the passage of lymph from the subarachnoid cavity into th sinuses, and thus may aid in relieving pressure within. On the other hand, through th cerebrospinal fluid is replenished at need from the blood plasma. They are not pre birth, but they appear at the tenth year and increase in number and size with advancing They are less marked in the female than in the male.

The spinal arachnoid (figs. 758, 759) is a loose, reticular sac which is capacious about the lumbar enlargement of the spinal cord and about the equina. Like that of the encephalon, the portion next to the dura mater

[illegible]mbles a membrane, being a loosely organized feltwork, covered on the side of [illegible] subdural cavity by a layer of mesothelium common to that cavity. Through- [illegible] its length the spinal subarachnoid cavity is relatively wide, and, as in the [illegible]nium, contains a fine, spongy, web-like reticulum, numerous threads of which [illegible] continuous with the pia mater. This spongy tissue is the inner modification [illegible]he arachnoid, and its meshes are occupied by the cerebrospinal fluid. It is [illegible] so abundant as in the cranial subarachnoid cavity.

[illegible]n addition to the delicate threads, the arachnoid is more firmly attached to the pia mater [illegible] three imperfect partitions. The most continuous of these is arranged along the dorsal [illegible]-line and is known as the **septum posticum** of Schwalbe (subarachnoid septum). This may [illegible]described as a linear accumulation of the spongy tissue which pervades the subarachnoid [illegible]ce. It is most incomplete in the upper cervical region, where it becomes merely a line of [illegible]ds connecting with the pia. It is most complete as a septum in the lower cervical and in [illegible] thoracic region, but at best it maintains a spongy character. The other two partitions are [illegible]med by the **denticulate ligaments**, which extend laterally from either side of the spinal cord, [illegible]necting the pia and dura mater and involving the arachnoid in passing through it. Within [illegible] subarachnoid cavity these form more or less complete septa, though outside the arachnoid [illegible]y are attached to the dura only at the intervals of their pointed dentations. They belong [illegible] the pia matter and will be described with it. The arachnoid is further continuous with [illegible] pia by way of the connective tissue sheaths of the roots of the spinal nerves and the blood- [illegible]sels passing through the subarachnoid cavity.

FIG. 759.—DIAGRAM SHOWING RELATIONS OF MENINGES TO SPINAL NERVE-ROOTS.



Vessels and nerves.—The arachnoid has no special blood-supply and probably no special nerves other than those supplying the walls of the blood-vessels passing through it.

The cerebrospinal fluid.—The subarachnoid cavity is the great lymph-space of the central nervous system. That of the spinal region is directly continuous into that of the cranium, and the fluid contained communicates freely with that in the ventricles of the brain and the central canal of the medulla and spinal cord by way of the foramen of Magendie or medial aperture into the fourth ventricle. In addition, there are the lateral apertures into the fourth ventricle and there is possibly an interchange of fluid between the lateral ventricle and the subarachnoid cavity of the base of the brain by diffusion through the thin floor of the choroid fissure. The arachnoid throughout is not a membrane sufficiently compact to seriously oppose diffusion between the fluid contained in its cavity and that contained in the subdural cavity, and the mesothelium covering it probably even facilitates such activities. The cerebrospinal fluid occupying the cavities is a transparent fluid of a slight yellow tinge, characteristic of the lymph in other lymph-spaces of the body. It is not very great in amount, probably never exceeding 200 c.c. in normal conditions. It is greatest in amount in old age, when the cavities are larger, due to atrophy and shrinkage of the nervous tissues. It collects from the lymph spaces in the meninges, and from exudation through the walls of the vascular choroid plexuses and sinuses of the system it bathes. Its amount may be temporarily increased by a period of increased blood-pressure in the cranial vessels. Pressure due to its abundance may be relieved by diffusion through the membranes containing it, and especially through the villi of the Pacchionian bodies into the venous sinuses and lacunæ, and thence into the venous system through the internal jugular veins.

The Pia Mater

The **pia mater,** the third of the meninges, is a thin membrane which envelops and closely adheres to the entire central nervous system and sends numerous processes into its substance. It likewise contributes the most proximal and compact portion of the sheaths of the nerve-roots in their passage through the meningeal spaces. It is very vascular in that the superficial plexuses of blood-vessels of both the brain and spinal cord ramify in it as they give off the central branches into the nervous substance. The structure and arrangement of the membrane vary somewhat in the cranial and spinal regions.

The spinal pia mater consists of two layers, an inner and an outer. It is thicker and more compact than that of the encephalon, due to the extra development of its outer layer, which is in the form of a strong, fibrous layer with the fibers arranged for the most part longitudinally.

Its inner layer is a thin feltwork of fibers which is closely adherent to the surface of the spinal cord throughout, sending numerous connective-tissue processes into it which contributes to the support of the nervous tissues. The larger of these processes carry with them the numerous intrinsic blood-vessels from the superficial plexus. The two layers are closely connected with each other, and are distinguished by the difference in the arrangement of their fibers. The spinal pia mater also appears less vascular than the cranial from the fact that the blood-vessels composing the plexus lying in it are obviously much smaller than those of the encephalon.

The membrane dips into the anterior median fissure and also bridges it over by forming an extra thickening along it. This thickening appears as a band along the mid-line of the ventral surface of the cord, the **linea splendens** (fig. 750). It carries, or ensheathes, the anterior spinal artery, the largest of the arterial trunks of the superficial plexus (figs. 665, 758).

The pia mater contributes the innermost and most compact portion of the epineurium of each of the nerve-roots, and thus, upon the roots, it is prolonged laterally into the intervertebral foramina, where the dura mater blends with it in producing the increased thickness of the epineurium.

From each side of the cord the pia mater gives off a leaf-like fold, the **denticulate ligament** (figs. 749, 750, 758), which spreads laterally toward the dura mater midway between the lines of attachment of the dorsal and ventral nerve-roots. The outer edge of this fold is dentate or scalloped into about twenty-one pointed processes, which extend through the arachnoid and are attached to the inner surface of the dura mater. The dentations are usually attached between the levels of passage of the roots of the spinal nerves, the uppermost one a little cephalad to the first cervical nerve and the region where the vertebral artery perforates the dura mater; the most caudal one between the last thoracic and first lumbar nerves, or, between the last two thoracic nerves. The ligaments, aided slightly by the septum posticum, serve to hold the spinal cord more or less suspended in the subarachnoid cavity.

Below, at the sudden, conical termination of the spinal cord in the lumbar portion of the vertebral canal, the pia mater is spun out into a thin, tubular filament, the **filum terminale,** which continues caudalward into the sac formed by the dura mater about the cauda equina, and at the end fuses with the dura mater in line with the filum of the spinal dura mater (coccygeal ligament) of the outside (figs. 655, 748).

The cranial pia mater is closely applied to the external surface of the brain, dipping into all the fissures, furrows, and sulci. It is connected with the arachnoid by numerous filaments of the spongy subarachnoid tissue and by the blood-vessels traversing the subarachnoid cavity. It is also pierced by the cranial nerves, and furnishes them their sheaths, which become continuous with the arachnoid and dura mater.

Its *outer surface* bounds the subarachnoid cavity. It is with difficulty separable into two layers of mixed white fibrous and elastic connective tissue, with slightly pigmented connective-tissue cells enmeshed between them. Its *inner surface* sends a large number of fibrous processes into the nervous substance, which blend with the neuroglia and aid in the support of the nervous elements. The larger of these processes accompany the central arterial and venous branches of the rich superficial plexuses of blood-vessels contained in the pia on the surface of the brain. Pieces of the pia when pulled off and placed in water present a flocculent appearance as to their inner surfaces, due to these processes having been pulled out.

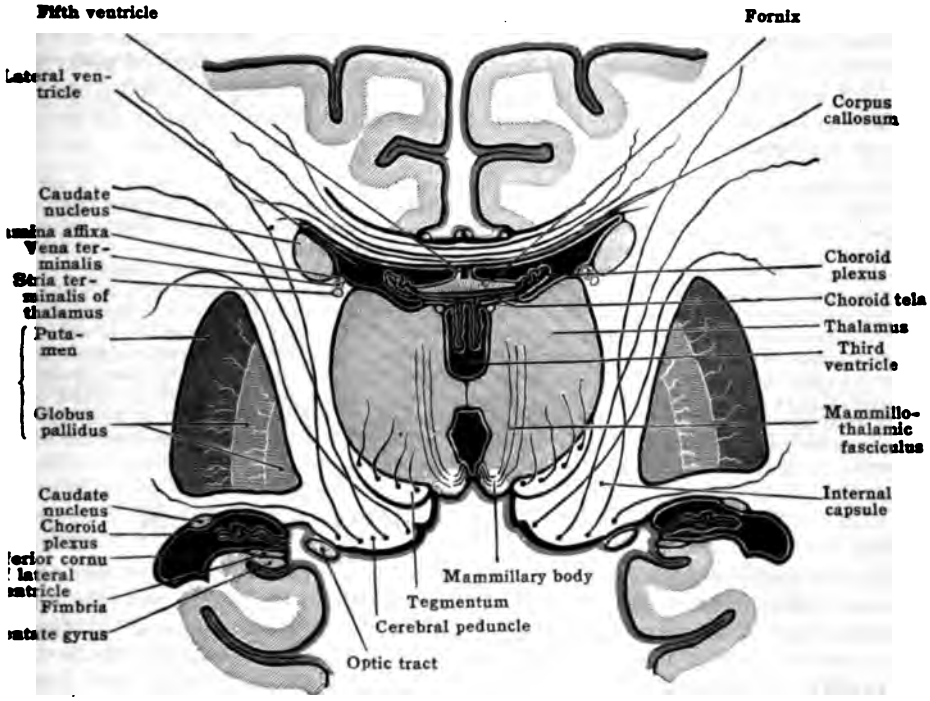
The cranial pia mater sends strong, vascular duplications into two of the great transverse fissures of the encephalon; viz., the *transverse cerebellar fissure,* between the cerebellum and the medulla oblongata, and the *transverse cerebral fissure,* between the cerebellum, mesencephalon, and thalamencephalon below, and the

hanging cerebral hemispheres. These duplications are spread over the cavi- of the fourth and third ventricles, and are known as the *choroid telæ* of these tricles respectively.

The tela chorioidea of the fourth ventricle is that duplication which extends the transverse cerebellar fissure, between the inferior surface of the cerebellum rmis chiefly) and the dorsal surface of the medulla (fourth ventricle). The two ers of this fold of the pia remain separate and a portion of the cisterna posterior he subarachnoid cavity lies between them.

The inferior of the layers is the tela chorioidea proper (fig. 680.) It is triangular in shape, with base cephalad at the nodule of the vermis and its apex below at the level of the tuber vermis. superior layer of the fold is the pia mater of the inferior vermis. The tela chorioidea proper trengthened by the epithelioid roof (ependyma) of the fourth ventricle and is continuous with pia mater of the medulla oblongata and spinal cord. In roofing over the calamus scriptorius onstitutes the obex. A little above the calamus scriptorius it is pierced by the foramen of gendie and the two lateral apertures into the fourth ventricle occur in its superolateral ions.

. 760.—Diagram of Coronal Section of Cerebrum through Middle of Thalamencephalon Showing Relations of Pia Mater Encephali and Choroid Plexuses of Third and Lateral Ventricles.



In front of the foramen of Magendie the vessels of the choroid tela, which are ived from the posterior inferior cerebellar arteries, form two longitudinal, ulated strands which invaginate the epithelioid roof of the ventricle, one on ıer side of the mid-line, and project into its cavity. These form the **choroid xus of the fourth ventricle.** At the base of the triangular tela the two choroid **xuses** join each other and then turn transversely lateralward into the lateral re- **ses** of the ventricle, where they pass behind the restiform bodies and form the *nucopiæ.*'

The choroid tela of the third ventricle, or **velum interpositum,** is a triangular olication of the pia mater which extends between the fornix above and the thal- i and third ventricle below, and in front fuses with the brain substance at the erventricular foramina (figs. 727, 760).

In the transverse cerebral fissure the layers of pia forming this tela are separate, the upper ıg the pia of the under surface of the corpus callosum and continuous with that of the ten- al surfaces of the occipital lobes; the lower being continuous into the pia enfolding the eal body and covering the mesencephalon, anterior medullary velum, and cerebellum. The

layers forming the portion of the duplication which roofs over the third ventricle are loosely adherent to each other and form the tela chorioidea proper of that ventricle. The upper surface of this portion is in relation with the fornix and its lower surface, covered by the ependyma lining of the ventricle, lies laterally over the superior surfaces of both thalami, and medially forms the roof of the third ventricle between them. The epithelioid ependyma is continuous with that covering the thalami and lining the ventricles. Between the two layers of this portion, and embedded in a small amount of the spongy subarachnoid tissue retained between them, are the two veins of Galen (internal cerebral). Posteriorly these veins unite in the region of the pineal body to form the single great cerebral vein (*vena cerebri magna*) which empties into the straight sinus. Anteriorly the veins of Galen receive the veins of the septum pellucidum from each lamina of the septum pellucidum above, and also the terminal vein (vein of corpus striatum), lying in the stria terminalis of the thalamus, empties into them from each side.

The choroid tela of the third ventricle or velum interpositum extends laterally between the fornix and fimbria above and the stria terminalis of the thalamus below into each lateral ventricle. The blood-vessels of the border projecting into the lateral ventricle are amplified into a plexus which appears as a strip of reddish, lobulated, villus-like processes known as the **choroid plexus of the lateral ventricle.** The plexus, being in the border of the tela, begins at the interventricular foramen, extends through the body or central portion of the lateral ventricle, and downward into its inferior cornu. It is most developed at the junction of the body with the inferior cornu, and is there known as the **glomus chorioideum.**

From the inferior surface of the choroid tela of the third ventricle, hanging down on either side of the midline into the cavity of the ventricle, are two other longitudinal, lobulated strands of blood-vessls which are the **choroid plexuses of the third ventricle.** At the anterior end of the third ventricle these two plexuses join with each other and also with the plexus of the lateral ventricle of each side through the interventricular foramina.

The choroid plexuses of both the ventricles are covered by a layer of ependyma, *epithelial choroid lamina*, which is but a reflection of the ependyma lining the cavities throughout and represents the remains of the germinal layer of the embryonic brain-vesicles. The blood-vessels of the choroid plexus of the lateral ventricle receive blood by the choroid artery (a direct branch of the internal carotid), which enters the plexus through the choroid fissure immediately medial to the uncus, and also by the choroidal branches of the posterior cerebral artery, which supply the plexus of the body of the ventricle. The choroid plexuses of the third ventricle receive blood chiefly by branches from the superior cerebellar arteries. The greater part of the blood of both plexuses passes out by way of the tortuous choroid veins, which, at the interventricular foramina, empty into the venæ terminales (veins of the corpus striatum), which, in their turn, go to form the greater part of the veins of Galen. Thence the blood passes by way of the vena cerebri magna into the straight sinus. It is probable that the cerebrospinal fluid of the third and lateral ventricles is derived chiefly by diffusion through the walls of the vessels of the choroid plexuses.

THE PERIPHERAL NERVOUS SYSTEM

The intimate connection and consequent control exercised by the central nervous system over all the tissues and organs of the body is attained through the peripheral part of the nervous system. This part or system, abundantly attached to the central system, consists of numerous bundles of nerve-fibers which divide and ramify throughout the body, anastomosing with each other and forming various plexuses, large and small. The terminal rami divide and subdivide until the divisions attain the individual nerve-fibers of which they are composed, and finally the nerve-fibers themselves divide and terminate in relations with their allotted peripheral elements. It is by means of these that stimuli arising in the peripheral tissues are conveyed to the central system, and that impulses in response are borne from the central system to the peripheral organs. For purposes of description, as well as upon the basis of certain differences in structure, arrangement, and distribution, the peripheral nervous system is separated into two main divisions: (1) **the craniospinal** and (2) **the sympathetic system.**

Both of these divisions include numerous ganglia or peripheral groups of nerve-cells from which arise a considerable proportion of the fibers forming their nerve-trunks, but neither of the divisions may be considered wholly apart from the central system nor are they independent or separate from each other. The sensory or afferent fibers of the craniospinal nerves pass by way of the afferent nerve-roots into the central system and contribute appreciably to its bulk, and the motor or efferent fibers of these nerves have their cells of origin (nuclei) situated within the confines of the central system. The sympathetic system is intimately asso-

ciated with the craniospinal, and consequently with the central system—(1) by means of fibers which enter and terminate in the craniospinal ganglia and the spinal cord and brain to supply the blood-vessels there; (2) by efferent fibers of central origin which course in the nerve-trunks and terminate in the ganglia of the sympathetic system; (3) also, the sympathetic trunks usually contain numerous afferent craniospinal fibers which thus course to their peripheral termination, usually in the so-called 'splanchnic area,' or domain of the sympathetic, in company with the sympathetic fibers. Likewise the peripheral branches of the craniospinal nerves usually carry for varying distances numerous sympathetic fibers which are on their way to terminate upon their allotted peripheral tissue-elements.

The following differences between the craniospinal and sympathetic systems of nerves may be cited: (1) The craniospinal nerves are anatomically continuous with the brain and spinal cord; probably no fibers arising in the sympathetic ganglia actually enter the central system other than for the innervation of its blood-vessels. (2) The ganglia of the craniospinal nerves all lie quite near the central axis, in line on either side of it, and at more or less regular intervals; the sympathetic ganglia are scattered throughout the body tissues, are far more numerous and more variable in size, and many of these ganglia are not symmetrical for the two sides of the body. (3) The craniospinal nerves are paired throughout, and the nerves of each pair are symmetrical as to their origin and also, with certain exceptions (notably the vagus), in their course and distribution; most of the larger and more proximal of the sympathetic nerve-trunks and plexuses are symmetrical for the two sides of the body; many of them are not, and many of the smaller and most of the more peripheral nerves and ganglia, large and small, are not paired at all. (4) Even in their finer twigs, the craniospinal nerves of the two sides probably do not join with each other across the midline of the body; the sympathetic nerves do so abundantly, especially within the body-cavity. (5) The craniospinal nerves are distributed to the ordinary sensory surfaces of the body and the organs of special sense and to the skeletal, (striated or 'voluntary') muscles of the body; the sympathetic fibers are devoted chiefly to the supply of the so-called involuntary muscles of the body, including the smooth muscle in the walls of the viscera and in the walls of the blood and lymph vascular-systems, and also to (striated) cardiac muscle, while others serve as secretory fibers to the glands. (6) Craniospinal nerve-fibers are characterized in general by well-developed medullary sheaths, making the nerves appear as white strands; most of the sympathetic fibers are non-medullated, some are completely and some partially medullated, but none possess as thick medullary sheaths as those of the craniospinal nerves. Thus sympathetic nerves appear as gray strands n the periphery.

The craniospinal nerves.—There are forty-six pairs of craniospinal nerves, of which thirty-one pairs are attached to the spinal cord (spinal nerves) and fifteen pairs to the encephalon (cranial nerves). The spinal nerves are the more primitive and retain the typical character, i. e., each is attached to the spinal cord by two roots, a dorsal or sensory ganglionated root, and a ventral, which is motor and not ganglionated. Most of the cranial nerves have only one root, which in some cases corresponds to a dorsal root and therefore has a ganglion, and in other cases corresponds, physiologically at least, to a ventral root of a spinal nerve. Among other individual differences, the fibers of the first cranial nerve, for example, do not collect to form a distinct nerve-trunk and its fibers are not medullated.

I. THE CRANIAL NERVES

Customarily, the cranial nerves are described as comprising twelve pairs and each is referred to by number. However, present knowledge of their origin, central connections and peripheral distribution suggests that those enumerated as the fifth, seventh, and eighth pairs under the old nomenclature are better each separated into its two component nerves, each of which merits a separate description and a separate name. None of the cranial nerves corresponds closely to a typical spinal nerve with its motor and sensory root. The so-called motor portion of the fifth is no more its motor root than is the seventh nerve. The sensory portion of the seventh is not wholly sensory and rather resembles the ninth pair in distribution, and it has long been commonly referred to as a separate nerve. The two parts of the eighth nerve, both sensory, are known to be wholly different in functional character and are so named. Further, the names of the nerves, descriptive of their function, are pedagogically much more efficient than the use of numbers in referring to them.

Separating the three pairs mentioned, each into its two nerves, gives fifteen pairs instead of twelve. Their names and functional nature are given in the fol-

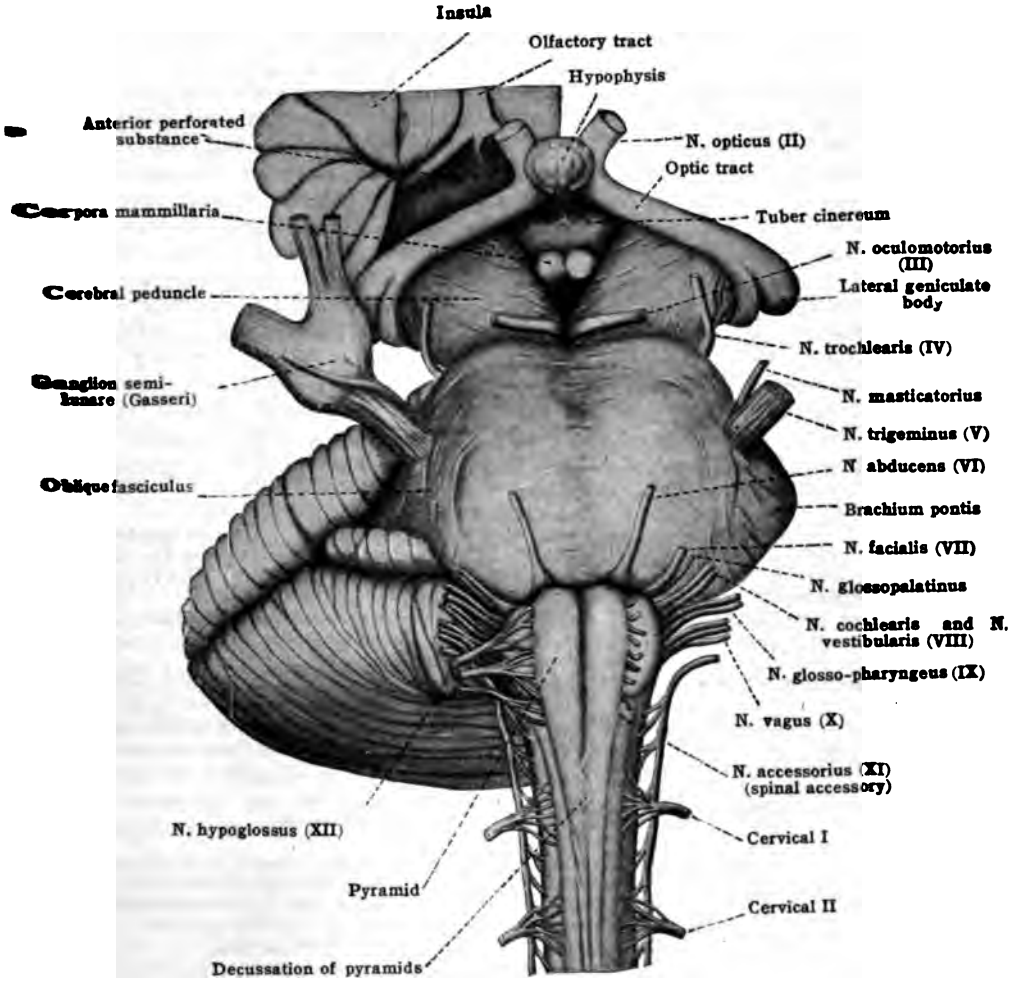
lowing table. The Roman numerals given in parentheses correspond to the n numbers given when twelve pairs only are considered. It is also customar enumerate the cranial nerves from in front backward and caudalward, and custom is followed here, but again it would be pedagogically better to take t in the reverse order. Then each in its turn could be directly considered a continuous series with the spinal nerves below and the similarities to and pro sive modifications from the spinal type could be better realized. It will be rem bered that *somatic efferent* or *motor* fibers are those which terminate directly t the fibers of skeletal muscle while *visceral efferent* or motor fibers transfer t impulses to sympathetic neurones, and the axones of the latter terminate t gland cells and upon the fibers of cardiac and smooth muscle.

NAME	NATURE	GENERAL DISTRIBUTION
Olfactory (I)	Sensory	Olfactory region, nasal epitheliu
Optic (II)	Sensory	Retina.
Oculomotor (III)	Motor { Somatic	Eye-moving muscles.
	Motor { Visceral	Ciliary body, iris.
Trochlear (IV)	Motor-somatic	Eye-moving muscles.
Abducens (VI)	Motor-somatic	Eye-moving muscles.
Trigeminus (V)	Sensory	Face, mouth, and scalp.
Masticator (*minor part or motor root of trigeminus*)	Motor-somatic	Muscles of mastication.
Facial (VII)	Motor { Somatic	Facial muscles.
	Motor { Visceral (?)	Salivary glands, vessels (?).
Glossopalatine. (*Intermediate part of facial.*)	Sensory { Somatic / visceral }	Tongue, palate.
	Motor-visceral	Salivary glands.
Cochlear (*auditory*) (VIII)	Sensory	Internal ear (cochlea)
Vestibular (*equilibrator*) (VIII).	Sensory	Semicircular canals, utriculus culus.
Glossopharyngeal (IX)	Sensory { Somatic / Visceral }	Tongue, palate, pharynx.
	Motor { Somatic	Pharynx.
	Motor { Visceral	Glands and vessels.
Vagus (X)	Sensory { Visceral / Somatic }	Alimentary canal, lung, heart
	Motor { Somatic	Larynx, pharynx.
	Motor { Visceral	Alimentary canal, heart, laryn chea, lung.
Hypoglossal (XII)	Motor-somatic	Tongue-moving muscles.
Spinal accessory (XI)	Motor { Somatic	Neck and shoulder-muscles.
	Motor { Visceral	Pharynx, larynx, heart.

The cranial nerves, like the spinal nerves, are developed from cells of the t tive neural tube and, beginning with the trigeminus downward, all the se nerves are developed from the cells corresponding to those of the ganglion which give origin to the spinal ganglia and the sensory components or dorsal of the spinal nerves. Otherwise between the cranial nerves and the spinal r there are many important differences. Each spinal nerve has a dorsal or se root, which springs from the cells of a spinal ganglion; a ventral or motor whose fibers are processes of the nerve-cells which are situated in the walls central system, and at their attachment to the surface of the cord the two roo some distance apart. Only one of the (usually recognized) twelve pairs of c nerves corresponds at all closely with typical spinal nerves. This one trigeminus which possesses a sensory ganglionated root and near its attac is accompanied by a small motor nerve, the masticator, which serves in small part as a corresponding motor root of the trigeminus. But even in th where the similarity between the cranial and spinal nerves is greatest, the still points of anatomical difference, which if not essential are very obvio the so-called motor root joins not the whole but only with one branch of th sory portion. The two are only slightly separated from each other at attachment to the surface of the brain. All the other cranial nerves diff still more marked manner from typical spinal nerves. The olfactory nerv afferent nerve whose cells of origin (olfactory ganglion) are scattered i mucous membrane of the nose, an organ of special sense, and its fibers a collected together into a nerve-trunk, but pass, as a number of small bu through the lamina cribrosa of the ethmoid bone directly into the olfactory The optic nerve is also a nerve of special sense. Its fibers form a very di

[redacted]dle, similar in appearance to an ordinary nerve, from which, however, it [redacted]ers essentially, both with regard to structure and development; for, unlike an [redacted]nary nerve, its connective tissue consists to a large extent of neuroglia instead [redacted]rdinary connective tissue, and its component nerve-fibers are of much smaller [redacted]ber than those of an ordinary nerve. It represents the location of the original [redacted]ic stalk, a diverticulum from the neural tube, and it associates the retina (optic [redacted]), a bit of modified cortex, with the encephalon. The optic nerve, therefore, [redacted]responds more closely with an association tract of the central system than with [redacted] ordinary nerve.

FIG. 761.—SURFACE ATTACHMENT OF THE CRANIAL NERVES.
(After Allen Thomson modified.)



The oculomotor, trochlear, abducens and hypoglossal nerves are practically purely motor nerves, and thus correspond only with the ventral roots of spinal nerves. The spinal accessory is purely motor. Its fibers arise from the cells of the anterir horn of the spinal cord and from a nucleus of the medulla which represents a displaced portion of that horn, but they do not leave the surface of the spinal cord and brain in the usual situation of ventral roots. On the contrary, they emerge in a series of rootlets from the lateral funiculus of the cord on the dorsal side of the ligamentum denticulatum, and from the upward prolongation of this funiculus.

The cochlear and vestibular are nerves of special sense, and in some respects both correspond closely with the dorsal root of a typical spinal nerve, and the gan-

glia of both represent spinal ganglia, but their distribution is limited to the membranous labyrinth.

The vagus and glossopharyngeal nerves contain both motor and sensory fibers, but they differ from typical spinal nerves in that the motor fibers, in company with the sensory, issue from the posterolateral sulcus of the medulla, and they are intimately intermingled, from their origin, with the sensory fibers, which latter arise from ganglia interposed in the trunks of the nerves and otherwise correspond with the fibers of the dorsal root of a typical spinal nerve.

Superficial attachments and origins.—It is customary to speak of the area where the nerve-fibers leave or enter the brain substance as the superficial attachments of the cranial nerves, and the groups of cells from which the fibers spring, and about which they terminate, as their nuclei of origin and termination, respectively.

THE OLFACTORY NERVES

The **olfactory nerve-fibers** (fig. 762) are the central processes of the bipolar olfactory nerve cell-bodies situated in the olfactory region of the nasal mucous membrane. In man, the olfactory region comprises the epithelium upon the superior third of the nasal septum and that upon practically the whole of the superior nasal concha. The area is relatively small as compared with that of other mammals and, as in other mammals, is characterized by an increased thickness of the epithelium and a yellowish brown color when fresh. The peripheral processes of the olfactory cell-bodies (the olfactory ganglion) are short and extend only to the surface of the olfactory epithelium. As the central processes pass upward from their cells of origin they form subepithelial plexuses in the mucous membrane, and from the upper parts of these plexuses, immediately below the lamina cribrosa of the ethmoid, about twenty filaments issue on each side. These filaments comprise the **olfactory nerve.** They are non-medullated. They pass upward, through the foramina in the lamina cribrosa, into the anterior fossa of the cranium in two rows, and after piercing the dura mater, the arachnoid, and the pia mater, they enter the inferior surface of the olfactory bulb.

They contribute to the superficial stratum of nerve-fibers on the inferior surface of the olfactory bulb, ending in the *glomeruli* formed by the terminal ramifications of the olfactory nerve-fibers in synapsis with the similar ramifications of the main dendrites of the large mitral cells which lie in the deeper part of the gray substance of the olfactory bulb.

The olfactory nerve-fibers are gray fibers, since they do not possess medullary sheaths, and they are bound together into bundles by connective-tissue sheaths derived from the pia mater, from the subarachnoid tissue, and from the dura mater.

Central connections—The olfactory impulses are transmitted by way of the peripheral processes of the olfactory neurones through the cell-bodies and the olfactory nerve-fibers and through the glomeruli to the mitral cells. Thence they are carried by the central processes (axones) of the mitral cells, which pass backward along each olfactory tract and its three olfactory striæ. (See Rhinencephalon, p. 901.)

THE TERMINAL NERVE (*Nervus Terminalis*)

In lower vertebrates and recently in those mammals whose sense of smell is relatively much more developed than in man, three nerves have been found in relation with the olfactory apparatus:—(1) The olfactory nerve proper whose fibers, as noted above, are the central processes of the nerve cell-bodies situated in the epithelium of the olfactory region of the nasal mucosa, and which terminate in the olfactory bulb; (2) the vomeronasal nerve, whose fibers are the central processes of nerve cell-bodies situated in the epithelium of the vomeronasal (Jacobson's) organ and which pass caudalward in the submucosa and upward to join the filaments of the olfactory nerve proper and which, in the dog, cat, rabbit, rat, etc., terminate in the accessory olfactory bulb—a small protuberance possessed by these animals on the posteromedial aspect of the olfactory bulb proper; (3) the terminal nerve, a small plexiform nerve, which unlike the other two is ganglionated.

In man, the vomeronasal (Jacobson's) organ is rudimentary after birth and, therefore, the vomeronasal nerve is not present, the only fibers for the vomeronasal region being those of general sensibility from the trigeminus and sympathetic fibers common to the epithelium of the entire nasal fossa.

The terminal nerve has been recently described as present in the human fetus and in the adult of other animals. It is mentioned here because of the expressed belief that it is an added cranial nerve and that it is present in the human adult. From the observations recorded for human and rabbit fetuses and the adult dog, ox, horse, squirrel and cat, the following description may be given: It is variably plexiform throughout its course. Peripheral twigs have been described for it as distributed to the mucosa of the nasal septum, some to the mucosa joining the olfactory

region while other and larger twigs extend further forward and are distributed to mucosa of the vomeronasal organ, accompanying and sharing in the distribution of the vomeronasal nerve when this is present. It is not certain that many of the fibers of these twigs are not fibers of the trigeminus and vomeronasal nerves. Its central connections are in the form of two or three small roots which pass through the cribriform plate of the ethmoid bone in company with and medial to the vomeronasal nerve and then, still plexiform, extend caudalward over the inferomedial aspect of the olfactory bulb and upon the olfactory peduncle or stalk (olfactory tract) beyond, a root often extending to near the lamina terminalis and optic chiasma. The roots disappear in the medial and inferomedial aspect of the frontal portion of the brain at different localities caudal to the olfactory bulb and usually near the olfactory peduncle, but often one may disappear in the region corresponding to the anterior perforated substance of the adult human brain.

Numerous small groups of ganglion-cells are found interposed along both the peripheral and intracranial course of the terminal nerve. A group, larger in size than the others and situated in the intracranial course of the nerve, is called the *ganglion terminale.* The fibers of the nerve are non-medullated. Both the ganglion-cells and the fibers of the nerve are described as having more the appearances characteristic of sympathetic neurones than of craniospinal. On the other hand, our conceptions of sympathetic neurones do not permit of their terminating within the central system except for the innervation of its blood-vessels. It may result that, instead of being an independent nerve as now claimed, the nervus terminalis is a part of the forward extension of the cephalic sympathetic, the larger ganglia and plexuses of which latter are well known, and that its neurones receive and convey impulses to the gland-cells of the nasal mucosa and to the muscle of the blood-vessels of the mucosa and those supplying blood to the inferomedial part of the frontal end of the cerebrum (Brookover, Larsell).

THE OPTIC NERVES

The fibers of the optic nerve are the central processes of the ganglion-cells of the retina. Within the ocular bulb they converge to the optic papilla, where they are accumulated into a rounded bundle, the **optic nerve.** The nerve thus formed pierces the choroid and the sclerotic coats, and, at the back of the bulb, enters the orbital fat, in which it passes backward and medialward to the optic foramen. After traversing the foramen it enters the middle fossa of the cranium, and joins with its fellow from the opposite side, forming the optic chiasma. It may, therefore, for descriptive purposes, be divided into four portions—the intraocular, the intraorbital, the intraosseous, and the intracranial (fig. 842). The total length of the nerve varies from forty-five to fifty millimeters.

The intraocular part is rather less than one millimeter in length. It passes backward from the optic papilla through the choroid and through the sclerotic coats of the bulb. As it passes through the latter coat of the bulb in many separate bundles, the area of the sclera it traverses has a cribriform appearance when the nerve is removed, and consequently is known as the *lamina cribrosa scleræ.*

The intraorbital part of the nerve emerges from the sclerotic about three millimeters below and to the medial side of the posterior pole of the bulbus, and it is about thirty millimeters long. It passes backward and medialward, surrounded by the posterior part of the fascia bulbi (Tenon's capsule) and by the orbital fat, to the optic foramen.

As it runs backward in the orbit it is in relation above with the nasociliary (nasal) nerve and the ophthalmic artery which pass obliquely from behind and laterally, forward and medialward across the junction of its posterior and middle thirds, and also in relation with the superior ophthalmic vein, the superior rectus muscle, and the upper branch of the oculomotor nerve. Below it are the inferior rectus muscle, and the inferior division of the oculomotor nerve. To its lateral side, near the posterior part of the orbit, are the ophthalmic artery, the ciliary ganglion, the abducens nerve, and the external rectus muscle. The anterior two-thirds of this portion of the optic nerve are surrounded by the ciliary arteries and the ciliary nerves and it is penetrated on its medial and lower aspect by the central artery of the retina. As it enters the optic foramen to become continuous with the intraosseous part, it is in close relation with the ligaments of Lockwood and Zinn (annulus tendineus communis) and with the four recti muscles which arise from them.

The intraosseous portion is from six to seven millimeters long. It lies between the roots of the small wing of the sphenoid and the body of that bone, and it is in relation below and laterally with the ophthalmic artery.

The intracranial portion (fig. 761), which is from ten to twelve millimeters long, runs backward and medialward, beneath the posterior end of the olfactory tract, and above the ophthalmic artery, the medial border of the internal carotid

glia of both represent spinal ganglia, but their distribution is limited to the membranous labyrinth.

The vagus and glossopharyngeal nerves contain both motor and sensory fibers, but they differ from typical spinal nerves in that the motor fibers, in company with the sensory, issue from the posterolateral sulcus of the medulla, and they are intimately intermingled, from their origin, with the sensory fibers, which latter arise from ganglia interposed in the trunks of the nerves and otherwise correspond with the fibers of the dorsal root of a typical spinal nerve.

Superficial attachments and origins.—It is customary to speak of the areas where the nerve-fibers leave or enter the brain substance as the superficial attachments of the cranial nerves, and the groups of cells from which the fibers spring, and about which they terminate, as their nuclei of origin and termination, respectively.

THE OLFACTORY NERVES

The **olfactory nerve-fibers** (fig. 762) are the central processes of the bipolar olfactory nerve cell-bodies situated in the olfactory region of the nasal mucous membrane. In man, the olfactory region comprises the epithelium upon the superior third of the nasal septum and that upon practically the whole of the superior nasal concha. The area is relatively small as compared with that of other mammals and, as in other mammals, is characterized by an increased thickness of the epithelium and a yellowish brown color when fresh. The peripheral processes of the olfactory cell-bodies (the olfactory ganglion) are short and extend only to the surface of the olfactory epithelium. As the central processes pass upward from their cells of origin they form subepithelial plexuses in the mucous membrane, and from the upper parts of these plexuses, immediately below the lamina cribrosa of the ethmoid, about twenty filaments issue on each side. These filaments comprise the **olfactory nerve.** They are non-medullated. They pass upward, through the foramina in the lamina cribrosa, into the anterior fossa of the cranium in two rows, and after piercing the dura mater, the arachnoid, and the pia mater, they enter the inferior surface of the olfactory bulb.

They contribute to the superficial stratum of nerve-fibers on the inferior surface of the olfactory bulb, ending in the *glomeruli* formed by the terminal ramifications of the olfactory nerve-fibers in synapsis with the similar ramifications of the main dendrites of the large mitral cells which lie in the deeper part of the gray substance of the olfactory bulb.

The olfactory nerve-fibers are gray fibers, since they do not possess medullary sheaths, and they are bound together into bundles by connective-tissue sheaths derived from the pia mater, from the subarachnoid tissue, and from the dura mater.

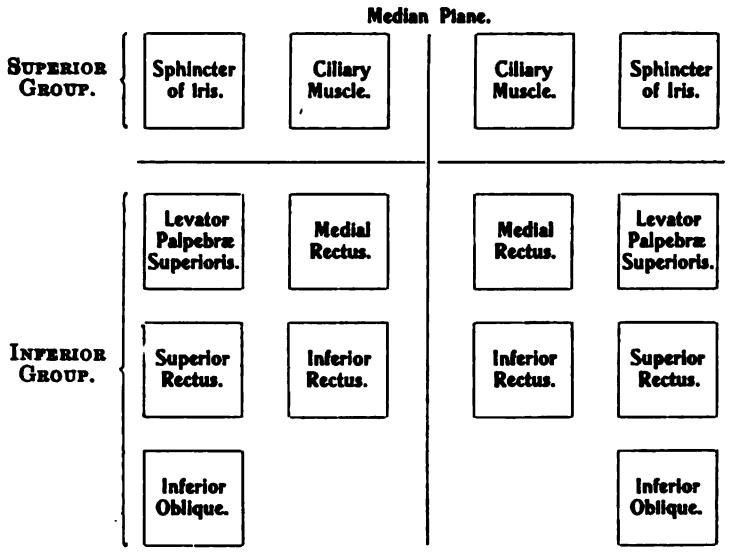
Central connections—The olfactory impulses are transmitted by way of the peripheral processes of the olfactory neurones through the cell-bodies and the olfactory nerve-fibers and through the glomeruli to the mitral cells. Thence they are carried by the central processes (axones) of the mitral cells, which pass backward along each olfactory tract and its three olfactory striæ. (See Rhinencephalon, p. 901.)

THE TERMINAL NERVE (*Nervus Terminalis*)

In lower vertebrates and recently in those mammals whose sense of smell is relatively much more developed than in man, three nerves have been found in relation with the olfactory apparatus:—(1) The olfactory nerve proper whose fibers, as noted above, are the central processes of the nerve cell-bodies situated in the epithelium of the olfactory region of the nasal mucosa, and which terminate in the olfactory bulb; (2) the vomeronasal nerve, whose fibers are the central processes of nerve cell-bodies situated in the epithelium of the vomeronasal (Jacobson's) organ and which pass caudalward in the submucosa and upward to join the filaments of the olfactory nerve proper and which, in the dog, cat, rabbit, rat, etc., terminate in the accessory olfactory bulb—a small protuberance possessed by these animals on the posteromedial aspect of the olfactory bulb proper; (3) the terminal nerve, a small plexiform nerve, which unlike the other two is ganglionated.

In man, the vomeronasal (Jacobson's) organ is rudimentary after birth and, therefore, the vomeronasal nerve is not present, the only fibers for the vomeronasal region being those of general sensibility from the trigeminus and sympathetic fibers common to the epithelium of the entire nasal fossa.

The terminal nerve has been recently described as present in the human fetus and in the adult of other animals. It is mentioned here because of the expressed belief that it is an added cranial nerve and that it is present in the human adult. From the observations recorded for human and rabbit fetuses and the adult dog, ox, horse, squirrel and cat, the following description may be given: It is variably plexiform throughout its course. Peripheral twigs have been described for it as distributed to the mucosa of the nasal septum, some to the mucosa joining the olfactory



As they leave their nucleus of origin in the midbrain, the fibers of the oculomotor nerve form a series of fasciculi, which curve ventrally around and through the red nucleus and the medial part of the substantia nigra, to the oculomotor sulcus on the medial surface of the cerebral peduncle (fig. 761), where they emerge in from six to fifteen root-filaments which pierce the pia mater and collect into the trunk of the nerve. Immediately after its formation along the oculomotor sulcus, the trunk of the nerve passes between the posterior cerebral and the superior cerebellar arteries, and, running downward, forward, and laterally in the posterior part of the cisterna basalis, it crosses the anterior part of the attached border of the tentorium cerebelli at the side of the dorsum sellæ, and, piercing the arachnoid and the inner layer of the dura mater, it courses through the outer wall of the cavernous sinus about midway between the anterior and posterior clinoid processes. Immediately after its entry into the wall of the sinus it lies at a higher level than the trochlear nerve, but the latter soon crosses on its lateral side and gets above it, and directly afterward the oculomotor nerve divides into a smaller superior and a larger inferior branch (fig. 764). Before its division **communications** join it from the cavernous plexus of the sympathetic about the internal carotid artery, and from the ophthalmic division of the trigeminus. Both branches proceed forward, and the nasal branch of the trigeminus, which has passed upward, on the lateral side of the inferior branch of the oculomotor, lies between them. At the anterior end of the cavernous sinus the two branches pass through the superior orbital (sphenoidal) fissure, between the heads of the lateral rectus muscle, and enter the orbital cavity. In the orbit, the **superior branch** lies between the superior rectus and the optic nerve; it supplies the superior rectus and then turns round the medial border of that muscle and terminates in the levator palpebræ superioris. The **inferior branch** runs forward, beneath the optic nerve, and divides into three branches which supply the inferior and medial recti and the inferior oblique.

The branch to the inferior oblique muscle is connected with the ciliary ganglion by a short thick visceral efferent offset, the **short root of the ciliary ganglion,** by synapses of the fibers of which with the sympathetic neurones of this ganglion the oculomotor nerve sends impulses to the ciliary muscle and the sphincter muscle of the iris. The inferior branch also gives some small twigs to the inferior rectus. The branches of the oculomotor nerve which supply the recti muscles enter the muscles on their ocular surfaces, but the branch to the inferior oblique muscle enters the posterior border of that muscle.

Some of the fibers which spring from the medial portion of the oculomotor nucleus do not pass into the nerve of the same side, but into that of the opposite side, and it is believed that they are distributed to the opposite medial rectus muscle. Other fibers which arise from the nucleus descend in the medial longitudinal fasciculus and either terminate about the cells of the nucleus of the facial or join the facial nerve, in which they pass to the upper part of the orbicularis palpebrarum. The eye is opened by the oculomotor and closed by the facial nerve.

artery and the diaphragma sellæ to the chiasma. From the chiasma to the central connections of the nerve, the path is known as the optic tract.

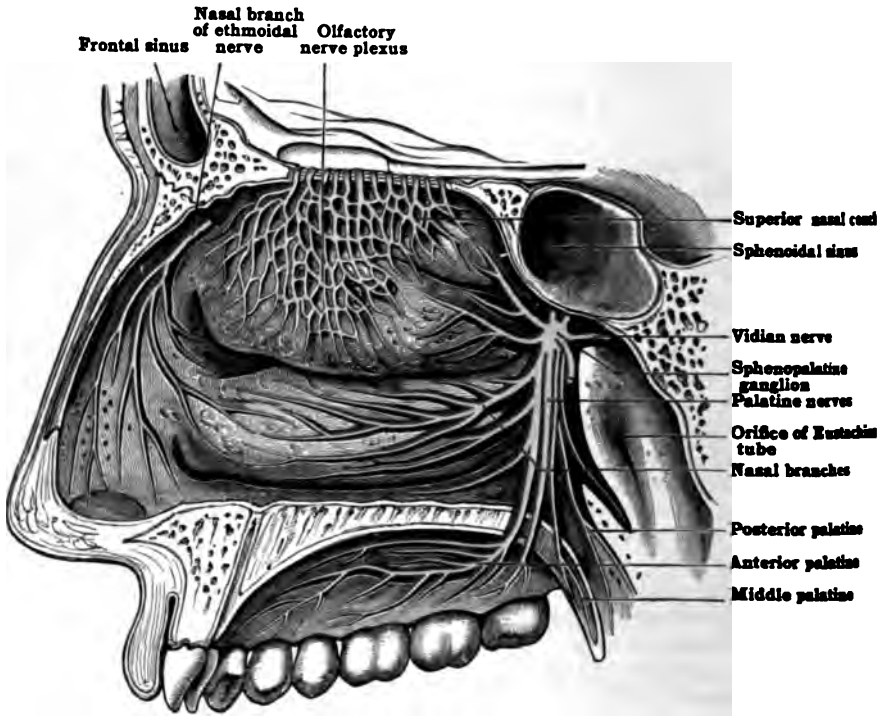
Central connections.—The central connections of the fibers of the optic nerve have been considered with the optic chiasma and the optic tract (see p. 886).

The sheaths of the optic nerve.—The optic nerve receives a sheath from each of the membranes of the brain, and prolongations of the subdural and subarachnoid cavities also pass outward along it to the posterior part of the sclera.

THE OCULOMOTOR NERVES

The oculomotor or third cranial nerve is a motor nerve. Each supplies seven muscles connected with the eye, two of which, the sphincter of the iris and ciliary muscle, are smooth muscle and within the eyeball. The remaining five

FIG. 762.—NERVES OF THE NASAL CAVITY.



(skeletal muscle) are in the orbital cavity, and four of them—the superior, inferior, and medial recti and the inferior oblique—are inserted into the eyeball, while the fifth, the levator palpebræ superioris, is inserted into the upper eyelid.

The fibers of the oculomotor nerve spring from their nucleus of origin situated in the substance of the floor of the cerebral aqueduct in the region of the superior quadrigeminal body (fig. 703). The cells of this nucleus are divided into two main groups, a superior and inferior (fig. 704). The superior group gives rise to visceral motor (autonomic) fibers and includes two nuclei, a medial and a lateral. The latter, besides being lateral, is also somewhat dorsal to the former. The inferior group (somatic motor) has been divided into five secondary nuclei, according to the eye-muscles the cells of each group innervate. Three of the five, lateral to the others and somewhat dorsally, and of the remaining two, which are placed medially, one encroaches upon the midline (*nucleus medialis*) and is continuous with the corresponding group of the opposite side and is common to the oculomotor nerves of both sides.

It has been found, by the study of diseased conditions and by experiments with animals, that the sources of innervation of the eye-muscles supplied by the nerve correspond to the several divisions of both the superior and inferior group of cells into a medial and lateral series. The relative position of the divisions of each group and the muscles they are thought to innervate are shown in the following diagram devised by Starr:

orbit and the levator palpebræ superioris. At the medial border of the roof it turns forward to its termination, and enters the orbital or superior surface of the superior oblique muscle to which its fibers are distributed.

The central connections of the nucleus of the trochlear nerve are similar to those of the oculomotor save that its cells probably do not send fibers which connect with the facial nerve. The trochlear is peculiar in that—(1) it is the smallest of the cranial nerves; (2) it is the only nerve having its superficial attachment upon the dorsal aspect of the encephalon; (3) it is the only cranial nerve whose fibers undergo a total decussation, and (4) in that it terminates in a muscle of the side of the body opposite that in which it has its origin. Gaskell has suggested that this latter condition has probably been brought about, phylogenetically, by the transference of the muscles which have carried their nerves with them. It should be remembered that most of the fibers arising from the medial group of the cells of the nucleus of the oculomotor cross the opposite side. This is thought to be especially true for those supplying the medial rectus muscle. It is claimed that the trochlear and the abducens also carry some somatic sensory fibers, but the proof of this is not so well established as for the oculomotor.

THE ABDUCENS

The abducens (or sixth) nerve on each side arises from the cells of a nucleus which lies in the gray substance of the floor of the fourth ventricle in the region of the inferior part of the pons (fig. 693). The nucleus is situated close to the middle line, ventral to the acoustic medullary striæ and beneath the colliculus facialis and it is in direct linear series with the nuclei of the oculomotor, trochlear and hypoglossal nerves. It is the third of the eye-moving nerves. The fibers which pass from the nucleus into the nerve run inferiorly and ventralward through the reticular formation, the trapezium, and the pyramidal fasciculi, and they emerge from the ventral surface of the medulla in the sulcus at the inferior border of the pons and the upper end of the pyramid of the medulla (fig. 761). From this superficial attachment the nerve runs upward and forward in the subarachnoid space between the pons and the basisphenoid and at the side of the basilar artery. A little below the level of the upper border of the petrous portion of the temporal bone it pierces the dura mater, passes beneath the petrosphenoidal ligament, at the side of the dorsum sellæ, and enters the dura of the medial wall of the cavernous sinus, in which it runs forward along the lateral side of the internal carotid artery. At the anterior end of the sinus it passes through the superior orbital (sphenoidal) fissure between the heads of the rectus lateralis, below the inferior branch of the oculomotor nerve, and above the ophthalmic vein. In the orbit it runs forward on the inner or ocular surface of the rectus lateralis, and finally it pierces this muscle and terminates upon its fibers.

While it is in the cavernous sinus it receives communications from the carotid plexus of the sympathetic and from the ophthalmic nerve.

All the fibers arising in the nucleus of the abducens do not pass into the nerve. Some of them ascend in the medial longitudinal fasciculus of the same and opposite sides, and terminate about cells of the medial group of the nucleus of the oculomotor nerve, by which the impulses are conveyed to the opposite medial rectus muscle. Thus impulses reaching the abducens nucleus can throw into simultaneous action the lateral rectus of the same side and the medial rectus of the opposite side, and thus turn both eyes in the same direction.

Central connections.—The nucleus of the abducens receives impulses from the anterior central gyrus of the opposite side by the pyramidal fibers, and it is associated with the sensory nuclei of other nerves by way of the medial longitudinal fasciculus, and that of the trigeminus especially through the reticular formation.

THE TRIGEMINUS

The trigeminus is the largest of the cranial nerves with the exception of the optic. It is usually described as the fifth cranial nerve and as possessing both a sensory and a motor root. For reasons already given, the 'motor root' is here described separately and given the separate name, *masticator nerve*. The fibers of the trigeminus proper, which are all sensory, spring from cells of the semilunar (Gasserian) gang on, which corresponds with the ganglion of the dorsal root of a spinal nerve, and they enter the brain-stem through the side of the anterior half of the pons (fig. 761).

The semilunar (Gasserian) ganglion (fig. 764) is a semilunar mass which lies in Meckel's cave, a cleft between the layers of the dura matter above a depression in the medial part of the upper surface of the petrous portion of the temporal bone. The concavity of the ganglion is turned forward, and from it three large nerves

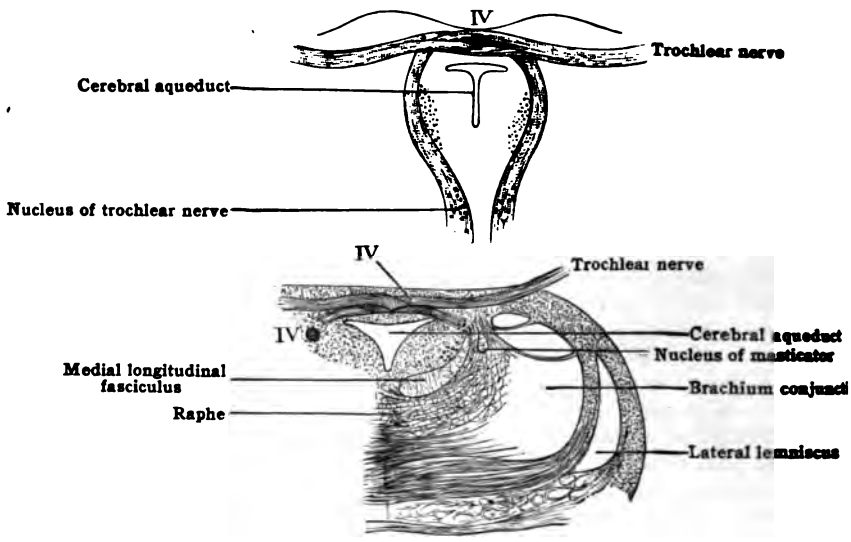
Against the common contention that the oculomotor is a purely motor nerve is the claim that it contains some somatic afferent (sensory) fibers carrying impulses of muscul from the muscles the nerve supplies. A few branched nerve cell-bodies have bee (Kopsch) scattered among its fibers in serial sections of its root. All the eye-moving receive sensory fibers from the ophthalmic branch of the trigeminus.

Central connections.—The nucleus of the oculomotor is associated with the middle po the anterior central gyrus, the posterior end of the middle frontal gyrus and with the about the visual area of the occipital lobe of the same and opposite sides by the py fibers. It is associated with the superior colliculus, and probably the cerebellum by th in the superior cerebellar peduncles, and with the sensory nuclei of the other cranial n the medial longitudinal fasciculus. To produce the coördinated activities of the eye-muscles, it must be associated with the nuclei of the trochlear and abducens.

THE TROCHLEAR NERVES

The fibers of each trochlear or fourth nerve (or patheticus) spring fr cells of a nucleus which lies in the gray substance of the floor of the cerebra duct in line with the oculomotor nucleus, but in the region of the inferior geminate bodies. As the fibers pass from their origins they run ventra laterally in the substance of the tegmentum for a short distance, then the

FIG. 763.—DIAGRAM OF SECTIONS THROUGH THE ORIGIN OF THE TROCHLEAR NERVE. (i (The upper figure is an oblique section, the lower is a coronal section.)



medianward and dorsalward, and, in passing through the anterior end of t rior medullary velum, they decussate totally with the fibers of the trochle of the opposite side (figs. 700, 761, 763). After the decussation the fiber from the surface of the superior medullary velum, at the side of the frenu usually in two small bundles, which pierce the pia mater and join togethe the slender trunk of the nerve. This trunk curves forward and ventra the base of the brain around the sides of the superior peduncle of the ce and cerebral peduncle of the side opposite to that in which the nerve or running parallel with and between the superior cerebellar and posterior arteries. As it reaches the base of the brain behind the optic tract t enters the cisterna basalis, in which it runs forward, immediately be piercing the free border of the tentorium cerebelli, to the superior bord petrous portion of the temporal bone, where it pierces the arachnoid and mater and enters the posterior end of the lateral (outer) wall of the c sinus. In the wall of the cavernous sinus it receives communications cavernous plexus of the sympathetic and, by a small filament, from the op division of the trigeminus. It gradually ascends, as it passes forwar lateral wall of the sinus, and, beyond the middle of the sinus, it crosses th side of the trunk of the oculomotor nerve and gains a higher position (At the anterior end of the sinus the nerve enters the orbit above the later and immediately turns medialward between the periosteum of the roc

orbit and the levator palpebræ superioris. At the medial border of the roof it turns forward to its termination, and enters the orbital or superior surface of the superior oblique muscle to which its fibers are distributed.

The central connections of the nucleus of the trochlear nerve are similar to those of the oculomotor save that its cells probably do not send fibers which connect with the facial nerve. The trochlear is peculiar in that—(1) it is the smallest of the cranial nerves; (2) it is the only nerve having its superficial attachment upon the dorsal aspect of the encephalon; (3) it is the only cranial nerve whose fibers undergo a total decussation, and (4) in that it terminates in a muscle of the side of the body opposite that in which it has its origin. Gaskell has suggested that this latter condition has probably been brought about, phylogenetically, by the transference of the muscles which have carried their nerves with them. It should be remembered that most of the fibers arising from the medial group of the cells of the nucleus of the oculomotor cross the opposite side. This is thought to be especially true for those supplying the medial rectus muscle. It is claimed that the trochlear and the abducens also carry some somatic sensory fibers, but the proof of this is not so well established as for the oculomotor.

THE ABDUCENS

The abducens (or sixth) nerve on each side arises from the cells of a nucleus which lies in the gray substance of the floor of the fourth ventricle in the region of the inferior part of the pons (fig. 693). The nucleus is situated close to the middle line, ventral to the acoustic medullary striæ and beneath the colliculus facialis and it is in direct linear series with the nuclei of the oculomotor, trochlear and hypoglossal nerves. It is the third of the eye-moving nerves. The fibers which pass from the nucleus into the nerve run inferiorly and ventralward through the reticular formation, the trapezium, and the pyramidal fasciculi, and they emerge from the ventral surface of the medulla in the sulcus at the inferior border of the pons and the upper end of the pyramid of the medulla (fig. 761). From this superficial attachment the nerve runs upward and forward in the subarachnoid space between the pons and the basisphenoid and at the side of the basilar artery. A little below the level of the upper border of the petrous portion of the temporal bone it pierces the dura mater, passes beneath the petrosphenoidal ligament, at the side of the dorsum sellæ, and enters the dura of the medial wall of the cavernous sinus, in which it runs forward along the lateral side of the internal carotid artery. At the anterior end of the sinus it passes through the superior orbital (sphenoidal) fissure between the heads of the rectus lateralis, below the inferior branch of the oculomotor nerve, and above the ophthalmic vein. In the orbit it runs forward on the inner or ocular surface of the rectus lateralis, and finally it pierces this muscle and terminates upon its fibers.

While it is in the cavernous sinus it receives communications from the carotid plexus of the sympathetic and from the ophthalmic nerve.

All the fibers arising in the nucleus of the abducens do not pass into the nerve. Some of them ascend in the medial longitudinal fasciculus of the same and opposite sides, and terminate about cells of the medial group of the nucleus of the oculomotor nerve, by which the impulses are conveyed to the opposite medial rectus muscle. Thus impulses reaching the abducens nucleus can throw into simultaneous action the lateral rectus of the same side and the medial rectus of the opposite side, and thus turn both eyes in the same direction.

Central connections.—The nucleus of the abducens receives impulses from the anterior central gyrus of the opposite side by the pyramidal fibers, and it is associated with the sensory nuclei of other nerves by way of the medial longitudinal fasciculus, and that of the trigeminus especially through the reticular formation.

THE TRIGEMINUS

The trigeminus is the largest of the cranial nerves with the exception of the optic. It is usually described as the fifth cranial nerve and as possessing both a sensory and a motor root. For reasons already given, the 'motor root' is here described separately and given the separate name, *masticator nerve*. The fibers of the trigeminus proper, which are all sensory, spring from cells of the semilunar (Gasserian) gang on, which corresponds with the ganglion of the dorsal root of a spinal nerve, and they enter the brain-stem through the side of the anterior half of the pons (fig. 761).

The **semilunar** (Gasserian) **ganglion** (fig. 764) is a semilunar mass which lies in Meckel's cave, a cleft between the layers of the dura matter above a depression in the medial part of the upper surface of the petrous portion of the temporal bone. The concavity of the ganglion is turned forward, and from it three large nerves

the *ophthalmic*, the *maxillary* and the *mandibular*, are given off. From the convexity, which is directed backward, springs the root of the nerve. The medial end of the ganglion is in close relation with the cavernous sinus and the internal carotid artery at the foramen lacerum, and the lateral end lies to the medial side of the foramen ovale. The surfaces of the ganglion are striated, due to bundles of fibers traversing them. The upper surface is separated by the inner layer of the dura mater from the temporal lobe of the brain, and the lower rests upon the masticator nerve and the outer layer of dura mater upon the petrous portion of the temporal bone.

The fibers of the trigeminus root as they leave the semilunar (Gasserian) ganglion, form from thirty to forty fasciculi which are bound together into a flat band, from 6 to 7 mm. broad, which passes backward over the upper border of the petrous portion of the temporal bone and below the superior petrosal sinus into the posterior fossa of the cranium. In the posterior fossa it runs backward, medialward, and downward, and passes into the pons through its continuation into the middle peduncle of the cerebellum. In the tegmentum of the pons region, the fibers bifurcate into ascending and descending branches which terminate about the cells of the nucleus of termination of the trigeminus. This nucleus, large at the level of the entrance of the root, has tapering superior and inferior extremities. The inferior extremity of the nucleus, which is much the longer, descends as low as the upper portion of the spinal cord and the fibers of the root terminating about the cells of this extremity are known as the spinal tract of the trigeminus.

Central connections.—The nuclei of termination of the trigeminus send impulses to the somesthetic area of the cortex of the opposite side by the fibers of the medial leminscus (trigeminal lemniscus) and, for reflex actions, to the motor nuclei of other cranial nerves and to ventral horn cells of the cervical spinal cord by the medial longitudinal fasciculus and by fasciculi propri in the reticular formation of the same, and opposite sides.

THE BRANCHES OF THE TRIGEMINUS

The main branches of the trigeminus, given off by the front side of the semilunar ganglion, are three in number (ophthalmic, maxillary, and mandibular), each of which is referred to as a nerve and each of which is purely sensory, though the third branch, or mandibular nerve, is joined by the fibers of the masticator nerve which is motor.

(1) The Ophthalmic Nerve or First Division

The ophthalmic nerve, the first division of the trigeminus, is the smallest of the three branches which arise from the semilunar (Gasserian) ganglion. It springs from the medial part of the front of the ganglion and passes forward, in the lateral wall of the cavernous sinus, where it lies below the trochlear nerve and lateral to the abducens nerve and the internal carotid artery (fig. 764). A short distance behind the superior orbital (sphenoidal) fissure the nerve divides into three terminal branches—the frontal, lacrimal, and nasociliary (nasal) nerves. They pierce the dura mater, which closes the fissure, and pass forward into the orbit. Before its division the ophthalmic nerve receives filaments from the cavernous plexus of the sympathetic and it gives off, soon after its origin, a **tentorial (recurrent meningeal) branch** which runs backward, in close association with the trochlear nerve, and ramifies between the layers of the tentorium cerebelli. Further forward three branches spring from the ophthalmic nerve which contribute sensory fibers to the oculomotor, trochlear, and abducens nerves.

The terminal branches.—(*a*) The **frontal nerve** is the largest terminal branch. It pierces the dura mater and passes into the orbit through the superior orbital (sphenoidal) fissure, above the rectus lateralis and a little below and to the lateral side of the trochlear nerve. In the orbit it runs forward, between the levator palpebræ superioris and the periosteum, and breaks up into three branches, the supraorbital, frontal proper, and supratrochlear.

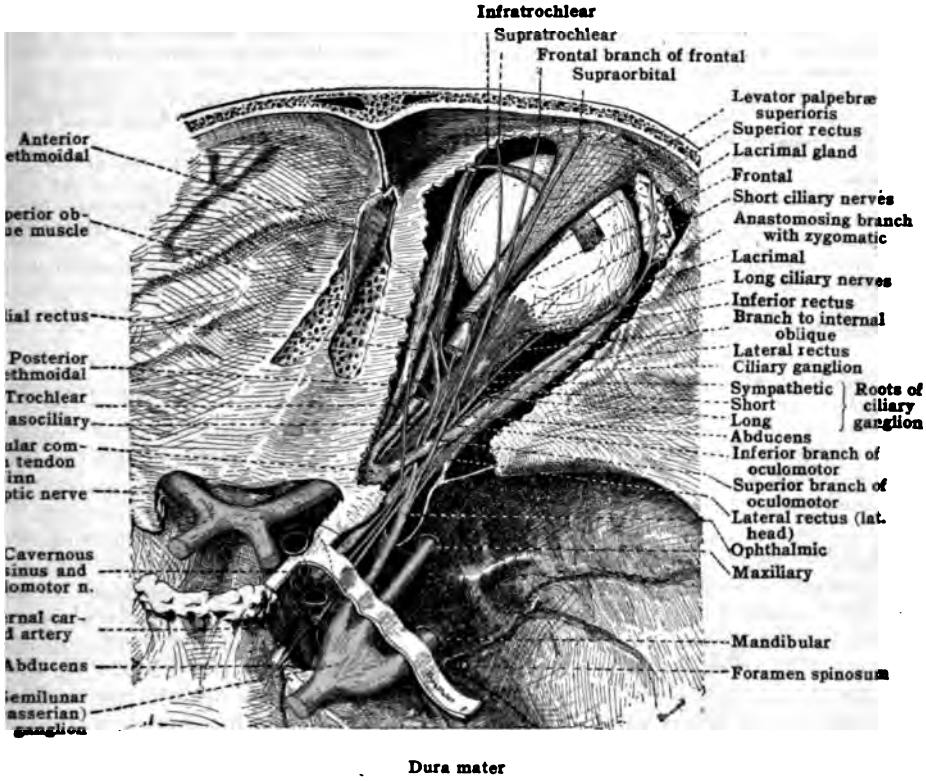
The **supraorbital nerve**, the largest of the three branches, leaves the orbit at the supraorbital notch (fig. 764). As it passes through the notch it gives off a small branch which enters the bone and supplies the diploë and the mucous membrane of the frontal sinus. Its terminal branches give twigs to the pericranium and to the skin of the scalp, the upper eyelid, the frontal region, and the parietal region almost as far as the lambdoid suture (fig. 770). One branch running at the upper margin of the orbital cavity unites with a branch of the facial nerve.

The **frontal branch**, given off at a variable point, lies medial to the supraorbital, passes through the frontal foramen, and is distributed to the skin of the forehead and upper eyelid (*fig. 764*).

The supratrochlear branch runs forward and medialward toward the upper and medial le of the orbit, where it passes above the pulley of the superior oblique muscle, pierces the ebral fascia, and ascends to the lower and middle part of the forehead, accompanied by frontal artery (fig. 764) Before it leaves the orbit it sends a branch downward behind or ont of the pulley of the obliquus superior which joins with the infratrochlear nerve, and as aves the orbit it gives off filaments to supply the skin and conjunctiva of the medial third ie upper eyelid. Its terminal branches pierce the orbicularis and frontalis muscles, and, as pass to the skin of the forehead, they communicate with branches of the facial nerve.

(*b*) **The lacrimal nerve** [n. lacrimalis] is the smallest of the three branches of the thalmic division. It passes through the superior orbital (sphenoidal) fissure ral to and slightly below the frontal nerve, and is directed forward and lateral- d, along the upper border of the rectus lateralis to the lacrimal gland (fig. 764).

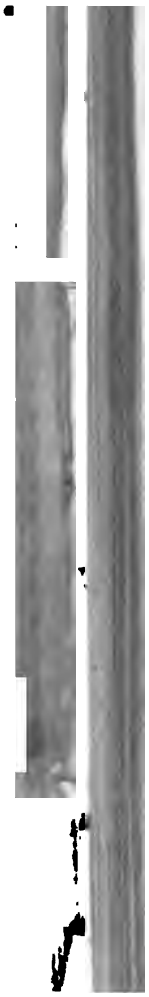
FIG. 764.—NERVES OF THE ORBIT FROM ABOVE AND BEHIND. (Schematic.)



the lateral wall of the orbit it receives a small branch from the zygomatic ve (the orbital branch of the maxillary nerve). This branch brings to the imal nerve secretory fibers for the lacrimal gland. A small twig passes beyond gland, pierces the palpebral fascia, supplies filaments to the conjunctiva, and ien distributed to the integument at the lateral angle of the eye and to the skin r the zygomatic process of the frontal bone.

(*c*) **The nasociliary (nasal) nerve** enters the orbit between the two heads of the us lateralis and between the superior and inferior branches of the oculomotor ve. In the orbit it lies at first lateral to the optic nerve, but, as it runs ob- ely forward and medialward to the medial wall of the orbital cavity, it crosses ve the optic nerve and between it and the rectus superior, and near the border he rectus medialis it divides into its terminal branches, the chief of which are *infratrochlear* and *anterior ethmoidal* nerves (fig. 764). In addition to those ived from the cavernous plexus before the division of the ophthalmic nerve, nasociliary nerve itself receives numerous sympathetic (secretory and vaso- or) fibers.

ts several branches are: (i) The **long root of the ciliary ganglion** which is given off at the rior orbital (sphenoidal) fissure. It is a slender filament which runs forward on the lateral of the optic nerve to the superior and posterior part of the ciliary ganglion (fig. 764).



the supratrochlear nerve. The **inferior palpebral branch** is distributed to the conjunctiva and skin of the medial part of both eyelids, the caruncle, and the skin upper part of the side of the nose.

(v) The **anterior ethmoidal** (distal part of the nasal) **nerve**, passing forward and ward between the obliquus superior and the rectus medialis, leaves the orbit through th rior ethmoidal foramen, accompanied by the anterior ethmoidal vessels, and enters i anterior fossa of the cranium (fig. 764). It then crosses the lamina cribrosa of the et lying outside the dura mater, which separates it from the olfactory bulb, and descends i nasal fossa through the ethmoidal fissure, a slit-like aperture at the side of the crista ga the submucosa of the nasal fossa it terminates by dividing into two sets of *anterior nasal br* the internal nasal branches and the external nasal branch (fig. 762).

The **internal nasal branches** divide into the **medial nasal branches** (the septal bran the nasal nerve), which run downward and forward on the upper and front part of the s and the **lateral nasal branches** (the external terminal branch of the **nasal** nerve), wh twigs to the anterior extremities of the superior and middle nasal conchæ (turbinated and to the mucous membrane of the lateral wall of the nose (fig. 762).

The **external nasal branch** (the anterior terminal branch of the nasal nerve) runs do in a groove on the inner surface of the nasal bone. It pierces the wall of the nose betw nasal bone and the upper lateral cartilage, and supplies the integument of the lower the dorsum of the nose as far as the tip.

(2) The Maxillary Nerve or Second Division of the Trigemi

The maxillary nerve is entirely sensory in function and it is intermed size between the ophthalmic and mandibular nerves. It springs from the of the anterior border of the semilunar (Gasserian) **ganglion** and runs forv the lower and outer part of the lateral wall of the **cavernous sinus** (fig Leaving the middle fossa of the cranium, by passing through the foramen dum, it enters the pterygopalatine (sphenomaxillary) fossa (figs. 762, 764) it is joined by twigs with the sphenopalatine ganglion; then, changing its it passes forward, as the **infraorbital nerve,** through the inferior orbital (s maxillary) fissure into the infraorbital sulcus in the floor of the orbit; con forward it traverses the infraorbital canal accompanied by the **infraorbital** and appears in the face, beneath the levator labii superioris (quadratus) anc the levator anguli oris (caninus) muscles where it divides into four sets of t branches which anastomose more or less freely with branches of the facia to form the **infraorbital plexus.**

Branches.—The branches of the maxillary nerve are—(*a*) branches gi in the middle fossa of the cranium; (*b*) branches given off in the pterygop (sphenomaxillary) fossa; (*c*) branches given off in the infraorbital sulc canal; and (*d*) terminal branches.

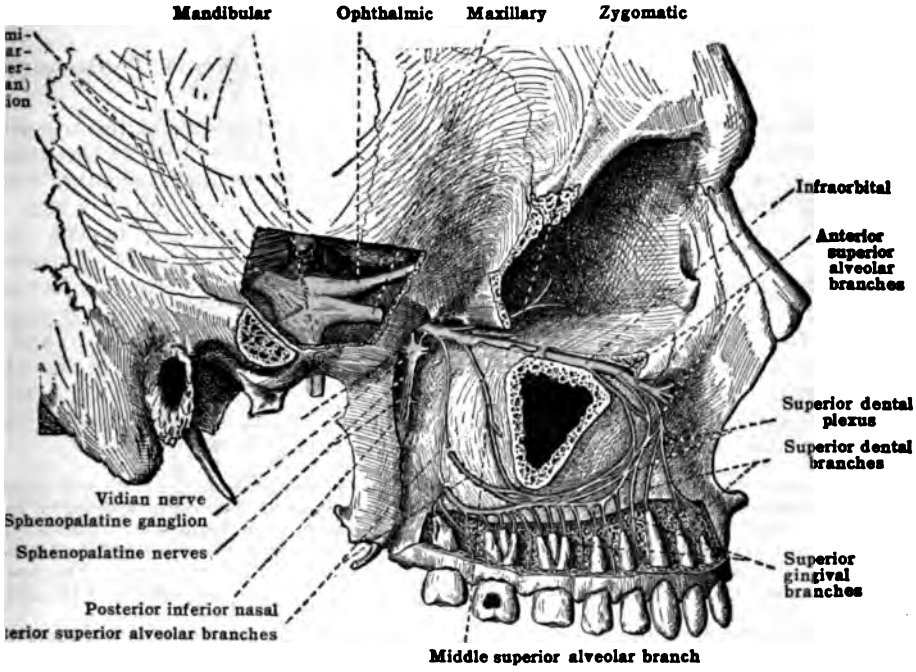
(*a*) The **middle (recurrent) meningeal branch**, given off in the midd

he zygomaticofacial (malar) branch runs forward, passes through a zygomatico-orbital **ien,** then through the zygomaticofacial (malar) foramen, pierces the orbicularis palpe- **m,** communicates with the zygomatic (malar) branch of the facial nerve, and supplies **kin** of the prominence of the cheek. The **zygomaticotemporal (temporal) branch** runs **rd** in a groove in the lateral wall of the orbit, passes through a zygomatico-orbital foramen, through the zygomaticotemporal (sphenomalar) foramen, and enters the temporal fossa. **ns** around the anterior border of the temporal muscle, pierces the deep layer of the tem- **fascia,** and runs backward for a short distance in the fat between the superficial and deep **lla,** then, turning lateralward, it pierces the superficial lamellæ about an inch above the **na,** anastomoses with the temporal branch of the facial nerve, and supplies the skin of the **ior** part of the temporal region.

he infraorbital nerve, that large part of the maxillary nerve lying distal to the spheno- **ine ganglion,** enters the orbit through the inferior orbital (sphenomaxillary) fissure, **npanied** by the infraorbital artery, and with it passes through the infraorbital canal **765**)) to the face, where it divides into four sets of terminal branches, some of which, by **omoses** with the branches of the facial nerve, form the **infraorbital plexus.**

hree sets of superior alveolar nerves arise from the maxillary and the infraorbital nerves, **ly,** the posterior superior alveolar branches, the middle superior alveolar branch, and the **ior superior alveolar branches.**

FIG. 765.—LATERAL VIEW OF THE MAXILLARY NERVE.



he posterior superior alveolar (dental) nerves are usually two in number, but sometimes **by a single trunk.** They pass downward and lateralward through the pterygomaxillary **e into** the zygomatic fossa, where they give branches to the mucous membrane of the gums **he** posterior part of the mouth; then they enter the posterior alveolar (dental) canals and **with** the other alveolar branches to form the **superior dental plexus,** through which they **branches** to the roots and pulp cavities of the molar teeth and to the mucous membrane **a maxillary sinus** (fig. 765).

c) The branches given off in the infraorbital sulcus and canal are the middle anterior superior alveolar (dental) nerves.

) The middle superior alveolar (dental) nerve leaves the infraorbital nerve in the pos- **· part** of the infraorbital sulcus, and, passing downward and forward in a canal in the max- **t** divides into terminal branches that anastomose with the other alveolar branches to form *uperior dental plexus.* Through the plexus it supplies the bicuspid teeth and gives branches **e** mucous membrane of the maxillary sinus and also to the gums (fig. 765).

i) The anterior superior alveolar (dental) nerve is the largest of the superior alveolar **es.** It is given off by the infraorbital nerve in the anterior part of the infraorbital canal, **passes** downward in a bony canal in the anterior wall of the maxilla. After uniting with **ther** alveolar nerves to form the superior dental plexus, it supplies the canines and the **ors** and gives branches to the mucous membrane of the maxillary sinus and the gums (fig.

It also gives off a **nasal branch** which enters the nasal fossa through a small foramen, and

The inferior palpebral branches, usually two, pass upward and supply sensory fibe the skin and conjunctiva of the lower eyelid (fig. 770).

The external nasal branches pass medialward under cover of the levator labii s (quadratus), and supply the skin of the posterior part of the lateral aspect of the nose.

The internal nasal branches pass downward and medialward under the lateral wa nose, and then turn upward to supply the skin of the vestibule of the nose.

The superior labial branches, three or four in number, as a rule are larger than the p and nasal branches. They pass downward to supply the skin and mucous membra upper lip and the neighboring part of the cheek.

(3) The Mandibular Nerve or Third Division of the Trigemi

The **mandibular division** is the largest of the three divisions of the tri (figs. 766 and 770). As a nerve, it is usually described as formed by the u two distinct nerves, namely, the entire masticator nerve and the large of sensory fibers derived from the semilunar (Gasserian) ganglion whi peripherally as the third division of the trigeminus. These two nerves separate until they pass through the foramen ovale and then unite imm outside the skull to form a large trunk which almost directly after its fo divides into a small *anterior* and a larger *posterior portion.* The trunk is s between the pterygoideus externus, laterally, and the otic ganglion a tensor veli palatini medially. In front of it is the posterior border of th goideus internus, and behind it, the middle meningeal artery. Two b arise from the trunk of the nerve before its division, namely, the spinou rent) nerve and the nerve to the pterygoideus internus.

The spinous (recurrent) nerve, after receiving a vasomotor filament from the otic enters the cranium through the foramen spinosum, accompanying the middle meninge and divides into an anterior and a posterior branch. The anterior branch communi the meningeal branch of the maxillary division of the trigeminus, furnishes filamen dura mater, and ends in the osseous substance of the great wing of the sphenoid. The branch traverses the petrosquamous suture and ends in the lining membrane of th cells.

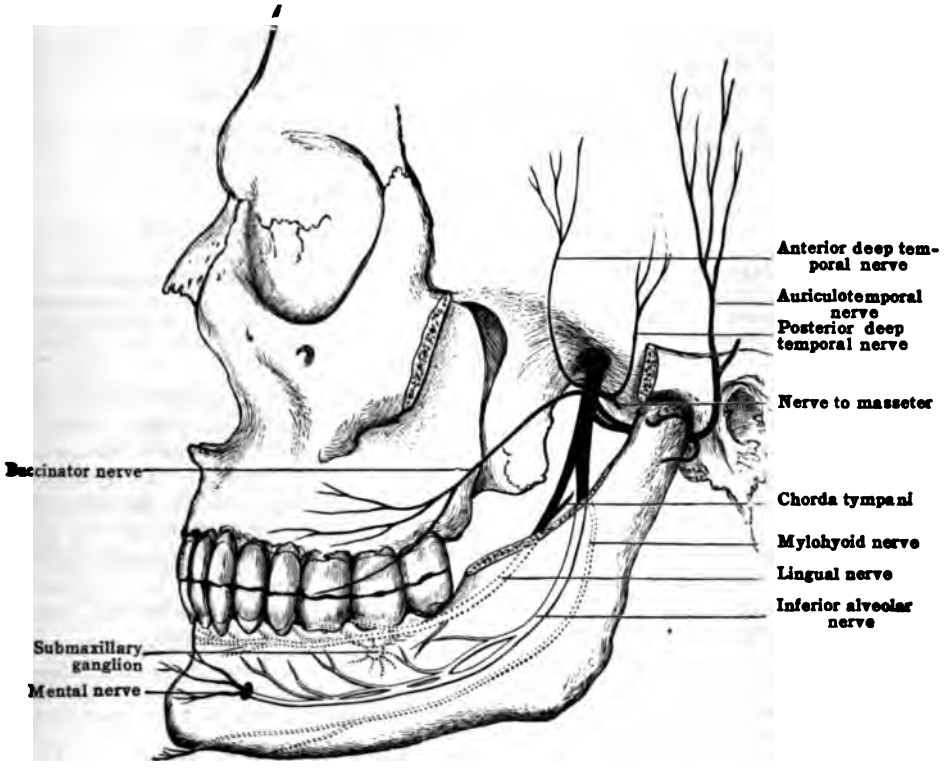
The fibers going to form the *nerve to the internal pterygoid muscle* are almost wh fibers and therefore comprise a branch of the masticator nerve and are described as s the description of the masticator (fig. 767).

The **anterior portion** of the mandibular nerve is smaller than the post is chiefly composed of motor fibers which form branches of the masticat and supply the muscles of mastication, the temporalis, masseter, an

The posterior portion of the mandibular nerve divides into three large branches. **o** of these, the lingual and the auriculotemporal nerves, are exclusively sensory; **third**, the inferior alveolar (dental) nerve, contains a strand of motor fibers, **mylohyoid** nerve, which comprise a branch of the masticator nerve.

The lingual nerve is the most anterior branch of the mandibular nerve (figs. **5, 773**). It lies in front and to the medial side of the inferior alveolar (dental) **ve** and descends at first on the medial side of the pterygoideus externus, then **ween** the pterygoideus internus and the ramus of the mandible to the posterior **rt** of the mylohyoid ridge, where it passes off the anterior border of the ptery**deus** internus; at this point it is situated a short distance behind the last

g. 766.—DISTRIBUTION OF THE MANDIBULAR DIVISION OF THE TRIGEMINUS COMBINED WITH BRANCHES OF THE MASTICATOR NERVE. (Henle.)



olar tooth and is covered in front by the mucous membrane of the posterior **rt** of the mouth cavity. After leaving the pterygoideus internus it crosses the **ers** of the superior constrictor, which are attached to the mandible, and turns **rward** toward the tip of the tongue, crossing the lateral surfaces of the stylo**ssus**, hyoglossus, and genioglossus. In its course across the hyoglossus it **s first** above, then to the lateral side of, and finally below Wharton's duct, and **it** ascends on the genioglossus it lies on the medial side of the duct.

Communications and branches.—While it is on the medial side of the pterygoideus externus **e lingual** nerve is joined, at an acute angle, by the chorda tympani (figs. 766, 773), a branch **the** glossopalatine nerve, and as it lies between the ramus of the mandible and the pterygoid**s internus** it is connected by a branch with the inferior alveolar (dental) nerve, and gives off **e or two** small branches, the **rami isthmi faucium**, which are ditributed as sensory fibers to **e tonsil** and the mucous membrane of the posterior part of the mouth (fig. 773).

While it is above the duct it gives a branch, which contains many sensory and visceral **erent** chorda tympani fibers, to the submaxillary ganglion (see pp. 981, 997), and it receives **anches**, chiefly sympathetic, from that ganglion. A little further forward it is connected by **e or two** branches, which run along the anterior border of the hyoglossus, with the hypo**ssal** nerve (fig. 773). It then gives off the **sublingual nerve**, which runs forward to supply the **blingual** gland and the neighboring mucous membrane. Its terminal (**lingual**) branches are **rived** chiefly from the glossopalatine nerve. They pierce the muscular substance of the **ngue** and are distributed to the mucous membrane of its anterior two-thirds. They interlace **th** similar branches of the other side and with branches of the glossopharyngeal nerve.

The **inferior alveolar (dental) nerve** is the largest branch of the posterior portion of the mandibular nerve. It commences on the medial side of the external pterygoid muscle and descends to the interval between the sphenomandibular ligament and the ramus of the mandible, where it receives one or two communicating branches from the lingual nerve. Opposite the middle of the medial surface of the ramus it enters the mandibular (inferior dental) canal, accompanied by the inferior alveolar (dental) artery, which lies in front of the nerve, and it runs downward and forward through the ramus and the body of the mandible (fig. 766). At the mental foramen it divides into two parts, one of which, the *mental nerve,* passes out through the mental foramen, the other, commonly called the *incisive branch,* continues forward in the canal, and supplies, through the inferior dental plexus, the inferior canine and incisor teeth and the corresponding regions of the gums.

Branches.—The branches of the inferior alveolar (dental) nerve are branches forming the inferior dental plexus, and the mental nerve. A bundle of motor fibers, the *mylohyoid nerve,* a branch of the masticator nerve, is given off just before the inferior alveolar nerve enters the mandibular canal.

The **inferior dental plexus** is formed by a series of branches which communicate with one another within the bone, giving rise to a fine network. From this plexus two sets of branches are given off: the **inferior dental branches,** corresponding in number to the roots of the teeth, enter the minute foramina of the apices of the roots and end in the pulp; the second set, the **inferior gingival branches,** supply the gums.

The **mental nerve** is a nerve of considerable size which emerges through the mental foramen (fig. 766). It communicates, near its exit from the bone, with branches of the facial nerve, and then divides into three branches. The smallest branch, turning downward, divides into several twigs, the *mental branches,* which supply the integument of the chin. The other two, *inferior labial branches,* pass upward, diverging as they ascend, and divide into a number of twigs. The stoutest twigs ramify to the mucous membrane which lines the lower lip. Other twigs are distributed to the integument and fascia of the lip and chin.

The **auriculotemporal nerve** usually arises from the posterior portion of the mandibular nerve by two roots which embrace the middle meningeal artery and unite behind it to form the trunk of the nerve. The trunk passes backward on the medial aspect of the pterygoideus externus, and between the sphenomandibular ligament and the mandibular orticulation, lying in close relation with the capsule of the joint. Behind the joint it enters the upper part of the parotid gland, through which it turns upward and lateralward. It emerges from the upper end of the gland, crosses the root of the zygoma close to the posterior border of the superficial temporal artery, and divides into auricular and temporal terminal branches at the level of the tragus of the pinna (fig. 766).

Communications.—(*a*) Each of the two roots of the nerve receives a communication from the otic ganglion containing fibers derived from the glossopharyngeal nerve. These fibers have passed from the glossopharyngeal through the tympanic plexus and the small superficial petrosal nerve and through the otic ganglion.

(*b*) Sensory filaments pass from the auriculotemporal nerve to the temporofacial branch of the facial nerve.

(*c*) Filaments of connection with the sympathetic plexus on the internal maxillary artery.

(*d*) A communication to the inferior alveolar (dental) nerve.

Branches of the auriculotemporal nerve.—(*a*) An **articular branch** to the mandibular joint, given off as the nerve lies on the medial side of the capsule.

(*b*) **Branches to the external auditory meatus.** Two branches, as a rule, are given off in the parotid gland. They enter the meatus by passing between the cartilage and the bone and supply the upper part of the meatus and the membrana tympani by a fine branch, and occasionally the lower branch gives twigs to the skin of the lobule of the pinna.

(*c*) **Parotid branches** are distributed to the substance of the parotid gland. Sensory or trigeminal fibers for the gland spring either directly from the nerve or from the communicating branches previously given by it to the glossopalatine nerve. The parotid branches also contain fibers derived from the glossopharyngeal nerve which pass successively through its tympanic branch, the tympanic plexus, the small superficial petrosal nerve, the otic ganglion, and the communicating twigs from the otic ganglion to the roots of the auriculotemporal nerve. The parotid branches are later again mentioned as concerned chiefly with the *ganglialed cephalic plexus.*

(*d*) The **anterior auricular branches,** usually two in number, are distributed to the skin of the tragus and the upper and outer part of the auricle.

(*e*) The **superficial temporal branches** supply the integument of the greater part of the temporal region, and anastomose with the temporal branch of the facial nerve.

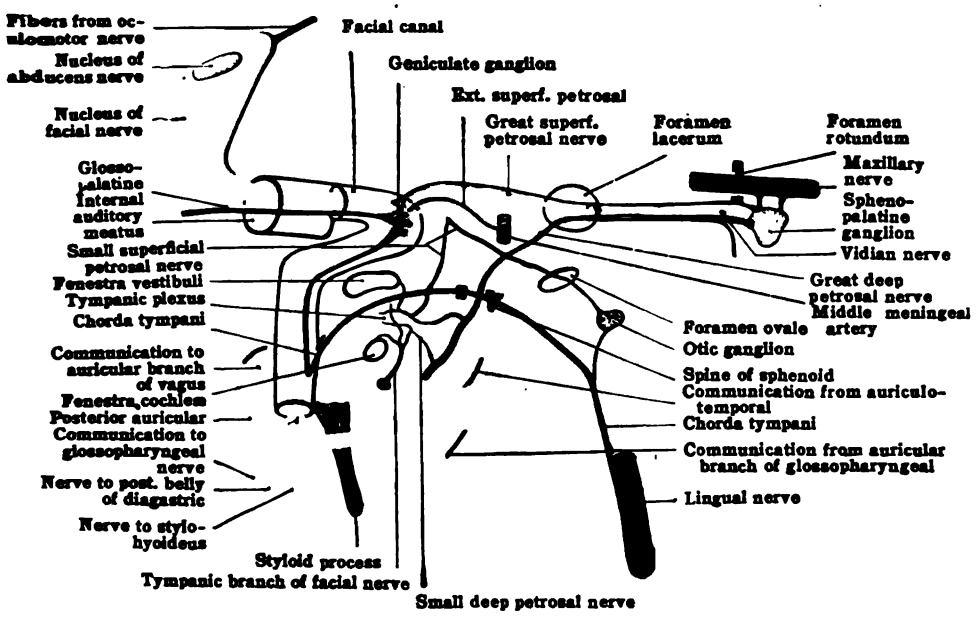
THE MASTICATOR NERVE (Fig. 767)

The masticator nerve (*motor root or portio minor of trigeminus*). The fibers of the masticator nerve spring from two nuclei, a slender upper or mesencephalic

the posterior wall to the stylomastoid foramen. As soon as it emerges from the stylomastoid foramen it turns forward around the lateral side of the base of the styloid process, and plunges into the substance of the parotid gland, where it divides into its cervicofacial and temporofacial terminal divisions. Before its terminal divisions, the nerve gives off three, and sometimes four, small branches: one, the nerve to the stapedius muscle, before it leaves the skull, the others after it leaves the skull.

The nerve to the stapedius is given off from the facial nerve as it descends in the posterior wall of the tympanum behind the pyramidal eminence. It is stated that filaments are also given off from the facial to the internal auditory artery (probably visceral motor from the glossopalatine) while the nerve is passing through the internal auditory meatus.

FIG. 768.—DIAGRAM OF THE FACIAL (YELLOW) AND GLOSSOPALATINE NERVE (BLUE).



After it leaves the skull the facial nerve (fig. 770) gives off two or three collateral branches and its two terminal divisions, the temporofacial and cervicofacial. The collateral branches are the posterior auricular nerve, a branch to the posterior belly of the digastric, and sometimes a lingual branch.

(1) The **posterior auricular nerve** is the first branch of the extracranial portion of the facial nerve. It passes between the parotid gland and the anterior border of the sternomastoid muscle and runs upward in the deep interval between the external auditory meatus and the mastoid process. In this situation it communicates with the auricular branch of the vagus. It supplies the auricularis posterior, sends a slender twig upward to the auricularis superior, and ends in a long slender branch, **the occipital branch,** which passes backward to supply the occipitalis muscle. It also receives filaments from the small occipital and great auricular nerves, and supplies the intrinsic muscles of the auricle (pinna).

(2) **The nerve to the posterior belly of the digastric** arises from the facial nerve close to the stylomastoid foramen and enters the muscle near its center, or sometimes near its origin. It usually gives off two branches: the **nerve to the stylohyoid,** which sometimes arises directly from the facial nerve and passes to the upper part of the muscle that it supplies, and the **anastomotic branch,** which joins the glossopharyngeal nerve below its petrous ganglion.

(3) **The lingual branch,** first described by Cruveilhier, is not commonly present. It arises a little below the nerve to the stylohyoideus and runs downward and medialward to the base of the tongue. In its course it passes to the medial sides of the styloglossus and stylopharyngeus, and runs downward along the anterior border of the latter muscle to the wall of the pharynx. It pierces the superior constrictor, insinuates itself between the tonsil and the anterior palatine arch, and it is stated that it gives filaments to the base of the tongue and to the styloglossus and glossopalatinus (palatoglossus) muscles.

The terminal divisions.—In the substance of the parotid gland the two terminal divisions of the facial nerve lie superficial to the external carotid artery and to the posterior facial (temporomaxillary) vein. The way in which these

The **deep temporal nerves,** usually two in number, posterior and anterior, pass betw bone and the upper border of the external pterygoid muscle, and turn upward around the temporal crest of the sphenoid bone to end in the deep surface of the temporalis (fig The posterior of the two often arises in common with the masseteric nerve. The a is frequently associated with the buccinator (long buccal) nerve till the latter has passed b the two heads of the pterygoideus externus. There is frequently a third branch, the a which passes lateralward above the pterygoideus externus, and turns upward close to th to enter the deep surface of that muscle. A small strand of masticator fibers accompa buccinator nerve to enter and end in the anterior part of the temporal muscle.

The **masseteric nerve,** which frequently arises in common with the posterior deep te nerve, passes between the bone and the pterygoideus externus, and accompanies the ma artery through the notch of the mandible to be distributed to the masseter (fig. 76 is easily traced through the deeper fibers nearly to the anterior border of the masset it emerges above the pterygoideus externus it gives off a twig to the mandibular artic

The **nerve to the external pterygoid,** after a course of about 3 mm., divides into twig enter the deep surface of the two heads of the muscle. It is usually adherent at its o the buccinator nerve.

The **mylohyoid branch,** carried in the posterior portion of the mandibular nerve, i off immediately before the inferior alveolar (dental) nerve enters the mandibular (infer tal) canal. It pierces the lower and back part of the sphenomandibular ligament a downward and forward in the mylohyoid groove between the mandible on the lateral s the internal pterygoid muscle and the lateral surface of the submaxillary gland on the me In the anterior part of the digastric triangle it is continued forward between the ante of the submaxillary gland and the mylohyoideus, and it breaks up into branches whic the mylohyoideus and the anterior belly of the digastric (fig. 766).

THE FACIAL NERVE

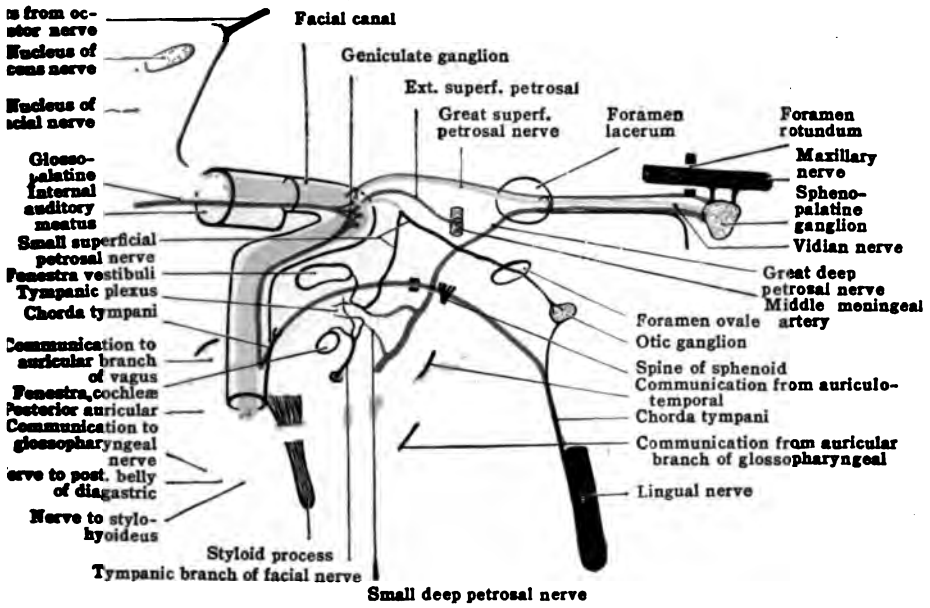
The facial (or seventh) nerve is purely motor. It is accompanied distance by a bundle usually called its *sensory root* or the *intermediat* This latter, however, on the basis of its origin, distribution, and mixed in sensory character, is described separately below as the *glossopalatin* It is smaller than the facial, is fused to the trunk of the facial, and the g giving rise to its sensory fibers is situated upon the external genu of th (figs. 768, 771).

The fibers of the facial nerve (fig. 768) spring from a nucleus of cells s laterally in the reticular formation at the level of the lower part of th dorsal to the superior olive, and between the root fibers of the abducens ne the laterally placed spinal tract of the trigeminus. From this nucleus th of the nerve passs medially and dorsalward to the floor of the fourth ventri just under the floor, they turn anteriorly, passing dorsal to the nucleu abducens (fig. 694). At the anterior end of this nucleus they turn sharp tralward and lateralward, and at this point it is claimed that fibers descer the near-by medial longitudinal fasciculus from the nucleus of the ocul nerve of the same side become intermingled with the fibers of the facial ne pass outward with them. This, however, is uncertain. Continuing vent through the reticular formation the fibers of the facial emerge from the bra at the inferior border of the pons, lateral to the superficial attachment abducens. At the point of its emergence, the facial nerve pierces the pia from which it receives a sheath, and then proceeds forward and late in the posterior fossa of the cranium to the internal auditory meatus, v enters in company with the glossopalatine nerve and with the cochl vestibular nerves. As it lies in the meatus it is situated above and in the latter nerves, from which it is separated by the glossopalatine, a surrounded, together with these three nerves, by sheaths of both the ar and the dura mater and by prolongations of the subarachnoid and s spaces. While it is still in the meatus it blends with the glossopalatine a the combined trunk is formed. At the outer end of the meatus the trunk the arachnoid and the dura mater and enters the facial canal (aqueduct c pius), in which it runs forward and slightly lateralward to the hiatus l where it makes an angular bend, the external genu [geniculum], arou anterior boundary of the vestibule of the inner ear; this bend is enlarged adhesion of the geniculate ganglion (of the glossopalatine) upon its border (fig. 769). From the geniculum the facial nerve runs backwar facial canal along the lateral wall of the vestibule and the medial wall of t panum, above the fenestra vestibuli (ovalis), to the junction of the me posterior walls of the tympanic cavity; then, bending downward, it des

posterior wall to the stylomastoid foramen. As soon as it emerges from stylomastoid foramen it turns forward around the lateral side of the base of the oid process, and plunges into the substance of the parotid gland, where it des into its cervicofacial and temporofacial terminal divisions. Before its inal divisions, the nerve gives off three, and sometimes four, small branch- one, the nerve to the stapedius muscle, before it leaves the skull, the others r it leaves the skull.

The nerve to the stapedius is given off from the facial nerve as it descends in the posterior of the tympanum behind the pyramidal eminence. It is stated that filaments are also n off from the facial to the internal auditory artery (probably visceral motor from the glosso- tine) while the nerve is passing through the internal auditory meatus.

IG. 768.—DIAGRAM OF THE FACIAL (YELLOW) AND GLOSSOPALATINE NERVE (BLUE).



After it leaves the skull the facial nerve (fig. 770) gives off two or three col- ral branches and its two terminal divisions, the temporofacial and cervico- al. The collateral branches are the posterior auricular nerve, a branch to the terior belly of the digastric, and sometimes a lingual branch.

1) **The posterior auricular nerve** is the first branch of the extracranial portion of the facial e. It passes between the parotid gland and the anterior border of the sternomastoid le and runs upward in the deep interval between the external auditory meatus and the toid process. In this situation it communicates with the auricular branch of the vagus. pplies the auricularis posterior, sends a slender twig upward to the auricularis superior, ends in a long slender branch, **the occipital branch,** which passes backward to supply the pitalis muscle. It also receives filaments from the small occipital and great auricular nerves, supplies the intrinsic muscles of the auricle (pinna).

2) **The nerve to the posterior belly of the digastric** arises from the facial nerve close to stylomastoid foramen and enters the muscle near its center, or sometimes near its origin. ually gives off two branches: the **nerve to the stylohyoid,** which sometimes arises directly the facial nerve and passes to the upper part of the muscle that it supplies, and the **anas- otic branch,** which joins the glossopharyngeal nerve below its petrous ganglion.

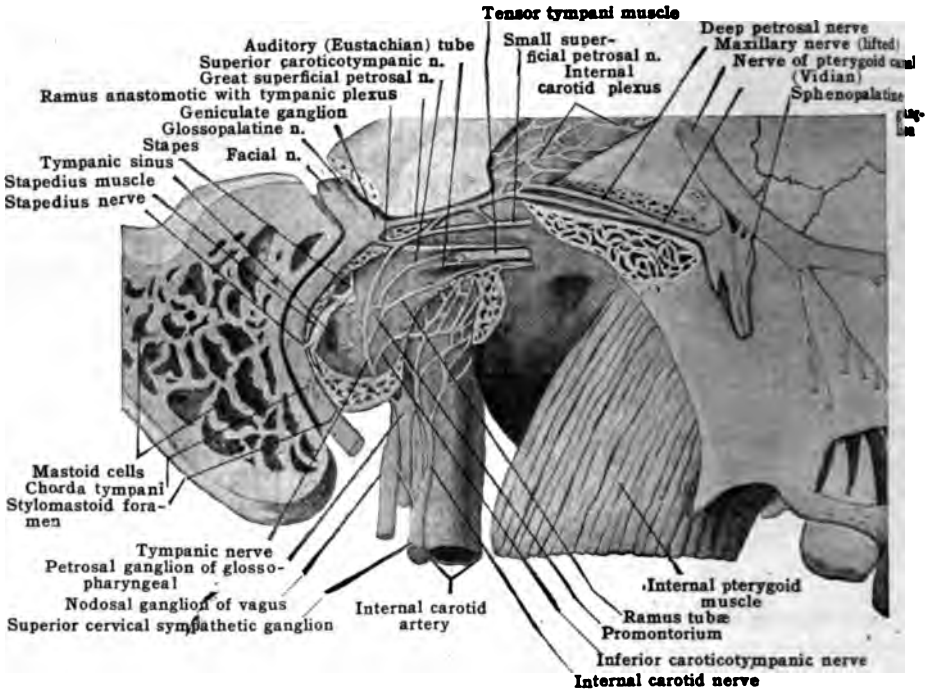
3) **The lingual branch,** first described by Cruveilhier, is not commonly present. It arises le below the nerve to the stylohyoideus and runs downward and medialward to the base he tongue. In its course it passes to the medial sides of the styloglossus and stylopharyn- s, and runs downward along the anterior border of the latter muscle to the wall of the ynx. It pierces the superior constrictor, insinuates itself between the tonsil and the rior palatine arch, and it is stated that it gives filaments to the base of the tongue and to styloglossus and glossopalatinus (palatoglossus) muscles.

The terminal divisions.—In the substance of the parotid gland the two inal divisions of the facial nerve lie superficial to the external carotid artery to the posterior facial (temporomaxillary) vein. The way in which these

terminal divisions give off their branches varies much in different subjects and often on the opposite sides of the same subject. One of the more common forms is here described.

The **temporofacial** or upper division runs upward and forward, and, after receiving communicating twigs from the auriculotemporal nerve, gives off temporal and zygomatic (malar) branches. The **cervicofacial** or lower division runs downward and forward, receives branches from the great auricular nerve, and gives off—(1) *buccal branches*, comprising what have been called infraorbital and buccal branches; (2) the *marginal mandibular* (supramandibular) branch; and (3) the *ramus colli* (inframandibular branch). These branches from the two terminal divisions anastomose freely to form the **parotid plexus** (pes anserinus).

FIG. 769.—THE RIGHT FACIAL NERVE, WITHIN THE SKULL, AND THE RELATIONS OF THE GLOSSOPALATINE AND GLOSSOPHARYNGEAL NERVES WITH THE TYMPANIC AND INTERNAL CAROTID PLEXUSES. (From Sobotta's Atlas, modified.)



The **temporal branches** passing upward communicate freely with each other and with the zygomatic branches. They also communicate with the zygomaticotemporal branch of the zygomatic nerve (the orbital branch of the maxillary nerve) and with the supraorbital nerve. They supply the frontalis, orbicularis oculi, corrugator supercilii, and auricularis anterior and superior (fig. 770).

The **zygomatic (malar) branches** passing upward and forward, communicate with the buccal branches of the facial nerve; with the zygomaticofacial branch of the zygomatic nerve (the orbital branch of the maxillary nerve); with the supraorbital and lacrimal branches of the ophthalmic nerve, and with the palpebral twigs of the maxillary. They supply both eyelids, the orbicularis oculi, and the zygomaticus (fig. 770).

The **buccal (infraorbital and buccal) branches** arise sometimes from the lower terminal division and sometimes from both the upper and the lower terminal divisions. The buccal branches, passing forward upon the masseter and underneath the zygomaticus and quadratus labii superioris, interlace with the zygomatic and marginal mandibular (supramandibular) branches of the facial nerve, with the buccinator (long buccal) branch of the trigeminus, and with the terminal branches of the maxillary nerve, forming with the last-named nerve the infraorbital plexus. They supply the zygomaticus, risorius, quadratus labii superioris, caninus, buccinator, incisivi, orbicularis oris, triangularis, quadratus labii inferioris, and the muscles of the nose (fig. 770).

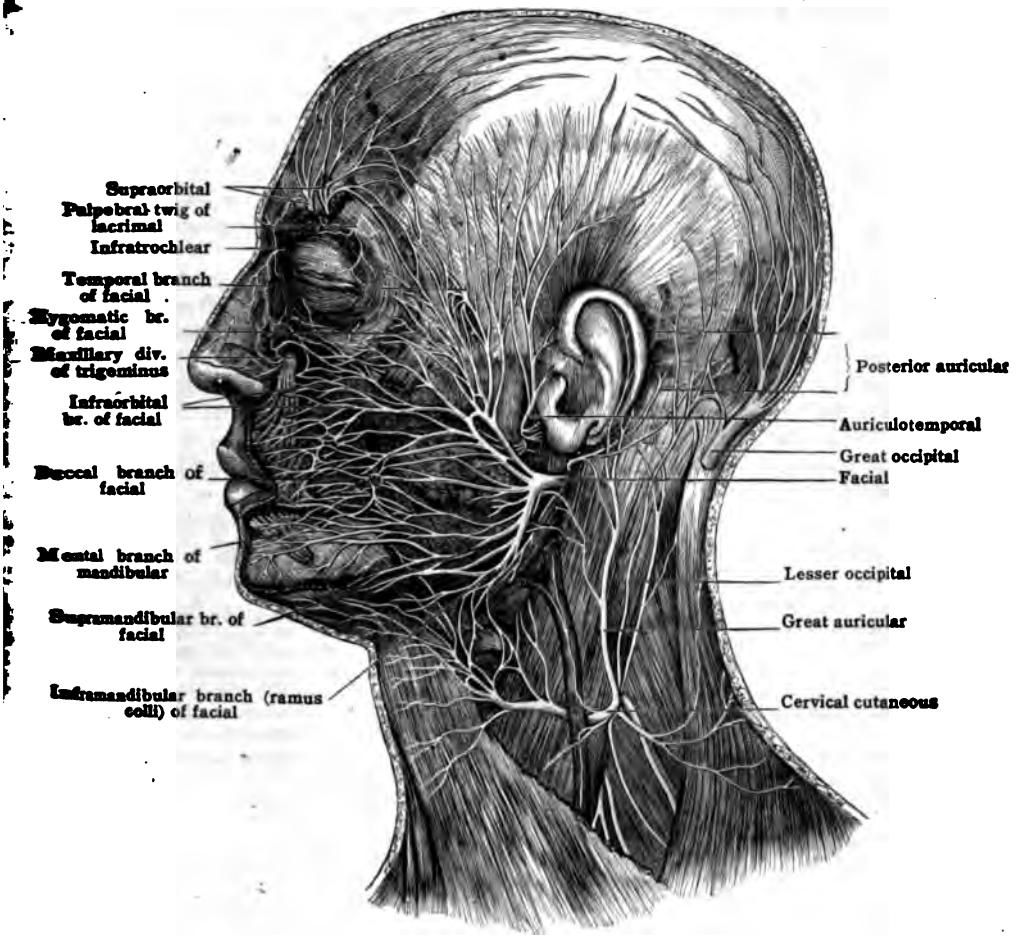
The **marginal mandibular (supramandibular) branch**, passing downward and forward under cover of the risorius and the depressors of the lower lip, communicates with the buccal branches and with the ramus colli of the facial nerve, and with the mental branch of the mandibular nerve. It supplies the quadratus labii inferioris and mentalis.

The **ramus colli (inframandibular branch)** runs downward and forward under cover of the platysma, which muscle it innervates (fig. 770). Beneath the platysma it forms one or

communicating loops, near its commencement, with the great auricular nerve, and longer , lower down, with the superficial cervical nerve.

Central connections.—The nucleus of origin of the facial in the rhombencephalon includes anterior and a posterior group of cells which give rise respectively to its upper and lower inal divisions. They are associated with the somesthetic area (lower third of the anterior al gyrus) by way of the pyramidal fasciculi of the opposite and same sides, and with the ei of the other cranial nerves, including the nucleus of termination of the trigeminus and opalatine, by way of the reticular formation and the medial longitudinal fasciculus.

FIG. 770.—SUPERFICIAL DISTRIBUTION OF THE FACIAL AND OTHER NERVES OF THE HEAD. (After Hirschfield and Leveillé.)



GLOSSOPALATINE NERVE

The **glossopalatine nerve** (*sensory root or pars intermedia of facial; nerve of Wrisberg*) contains both sensory and motor fibers. While it has a separate attachment to the medulla, it courses in close company with the facial and, in the internal auditory meatus, it is involved in the same sheath with the facial, which relation is maintained by its larger part thence through the facial canal till a short distance above the stylomastoid foramen (figs. 768, 769, 771). Here this larger part leaves the trunk of the facial as the *chorda tympani* nerve. The origin, central connections and peripheral distribution of the glossopalatine are similar to those of the glossopharyngeal nerve and suggest that it may be considered an aberrant portion of that nerve.

The **sensory portion** is much greater than the motor. Its fibers arise from cells situated in the geniculate ganglion which thus corresponds to a spinal ganglion. The *central processes* from these cells pass medialward in the facial canal (aqueduct of Fallopius) enclosed in the sheath of the facial nerve, which they

The **geniculate ganglion** is so named from the fact that it is embedded upo anterior border of the external genu (*geniculum*) of the facial nerve, behin hiatus Fallopii. It is somewhat triangular in form. From its superom angle leave the central processes of its cells, the root of the nerve; from its i lateral angle leave the fibers which later leave the sheath of the facial a chorda tympani, and its anterior angle is connected with the great supe petrosal nerve (figs. 769 and 771). The geniculate ganglion contains a rela large number of cell-bodies of sympathetic neurones many of whose pro run in this latter nerve, a relation mentioned below with the gangliated ce sympathetic plexus.

The **motor portion** of the glossopalatine consists for the most part of v efferent (autonomic) fibers, chiefly secretory. These arise in the medul longata from a small group of cells scattered in the reticular formation medial to the nucleus of the facial and in line with the dorsal efferent nuc the vagus below. It is called the *salivatory nucleus*. The fibers course v ward and lateralward to their exit, mingle with the entering sensory fibers glossopalatine in the sheath of the facial and, through the branches of the palatine, pass to terminate in sympathetic ganglia of the head, large and These ganglia send axones which terminate in the smooth muscle of vess about the cells of the glands of the lingual and palatine mucous membrane the salivary glands proper.

Some of the motor fibers of the nerve terminate in contact with the sympathetic maining in the geniculate ganglion and which give rise to sympathetic fibers issuing Most of the motor fibers pass into the great superficial petrosal nerve and the chorda to terminate in (chiefly) or pass through the sphenopalatine and submaxillary ganglia tively. Some may pass by the geniculotympanic branch and tympanic plexus to en otic ganglion. Many no doubt end in the smaller ganglia involved in the various sym plexuses. It is suggested that the motor part carries secretory impulses destined el the submaxillary and sublingual glands. A small gangliated plexus on the capsule of th side of the parotid gland has been frequently dissected and found to communicate fre twigs from the facial nerve and twigs concerned with the trigeminus. It is possible th glossopalatine visceral motor fibers terminate in these ganglia for secretory impulse parotid gland as well.

Central connections.—The nucleus of termination of the glossopalatine nerve (extension of the nucleus of termination of the sensory portion of the glossopharyn associated with the somesthetic area of the cerebral cortex of the opposite and same way of the medial lemniscus, and with the salivatory nucleus and motor nuclei of othe nerves by way of the reticular formation and medial longitudinal fasciculus. The nu origin of the motor portion (salivatory nucleus) may be associated not only with the of termination of the sensory part, but with the nuclei of termination of other cranial and perhaps with the motor area of the cortex of the opposite side by way of the py

'bipolar,' form. The *central processes* course with the cochlear nerve in the internal auditory meatus medialward, caudad and slightly downward, inferior to the accompanying facial and glossopalatine nerves, and, arching ventrally around the restiform body, they enter the medulla at the inferior border of the pons, lateral to the glossopalatine and facial and medial to the entrance of the cochlear nerve. They find their nucleus of termination spread in the floor of the fourth ventricle and grouped as the median, the lateral (Deiters'), the superior, and the nucleus of the spinal root of the vestibular nerve. In the internal auditory meatus, the vestibular nerve is connected by two small filaments of fibers with the glossopalatine nerve. These are either visceral motor fibers for the vessels of the domain of the vestibular or are aberrant fibers which course only temporarily with the vestibular and return to the glossopalatine.

The *peripheral processes* of the cells of the vestibular ganglion terminate in the neuroepithelium comprising the *maculæ* in the sacculus and the utriculus and the *cristæ* in the ampullæ of the three semicircular ducts. Thus there are five **terminal branches** of the nerve. None of its fibers terminates in the cochlea. The vestibular ganglion has a lobar form, one lobe giving rise to a superior **utriculoampullar** division which divides into three terminal branches; the other giving a **sacculoampullar** division which gives two terminals (fig. 772).

The superior or **utriculoampullar division** divides into the following terminal branches:

(1) The **utricular branch** passes through the superior macula cribrosa of the vestibule and terminates in the macula acustica of the utriculus.

(2) Accompanying the utricular branch through the superior macula cribrosa is a branch, the **superior ampullar,** to the crista acustica of the ampulla of the superior semicircular duct, and—

(3) A similar branch, the **lateral ampullar,** to the ampulla of the lateral semicircular duct.

The inferior or **sacculoampullar division** accompanies the cochlear nerve a short distance further than the superior, and divides into—

(4) A branch, the **posterior ampullar,** which passes through the foramen singulare and the inferior macula cribrosa and terminates in the ampulla of the posterior semicircular duct, and—

(5) A branch, the **saccular,** which passes through the middle macula cribrosa and terminates in the macula acustica of the sacculus.

The **central connections** of the vestibular nerve are described in detail on pp. 823, 860, 936. It large nucleus of termination, spread through the area acustica in the floor of the fourth ventricle, and divided into four sub-nuclei, is associated with the nuclei fastigii, globosus, and emboliformis of the cerebellum, with the nuclei of the eye-moving nerves, with the spinal cord, and with the cerebral cortex by way of the lemnisci.

THE COCHLEAR OR AUDITORY NERVE

The fibers of the cochlear nerve are distributed to the spiral organ (of Corti) in the cochlea, and so are considered as comprising the auditory nerve proper. They arise from the long, coiled **spiral ganglion** of the cochlea, the cells of which. like those of the vestibular ganglion, are bipolar. The *peripheral processes* of these cells are shorter than those of the vestibular ganglion. They terminate about the auditory or hair-cells of the spiral organ and thus collect impulses aroused by stimuli affecting these cells. The *central processes* of the ganglion cells continue through the modiolar canal and the tractus spiralis foraminosus of the cochlea, and thence, joining the vestibular nerve through the internal auditory meatus, accompanying the facial nerve and internal auditory artery, they course medialward and downward, approach and enclasp the restiform body (fig. 690) and enter the lateral aspect of brain-stem to terminate in their dorsal and ventral nuclei. A description of these nuclei and the further central connections of the cochlea with the superior olive, the nuclei of the eye-moving nerves, the inferior quadrigeminate bodies, the medial geniculate bodies, and with the cerebellum and temporal lobes of the cerebral hemispheres are given on pages 861, 877.

THE GLOSSOPHARYNGEAL NERVE

The glossopharyngeal or *ninth* cranial nerves are mixed nerves and each is attached to the medulla by several roots which enter the posterolateral sulcus, dorsal to the anterior end of the olivary body and in direct line with the facial nerve (fig. 761). Some of its sensory fibers are special sensory (taste) and many of its motor fibers are visceral motor (autonomic).

nerve and pass to the submaxillary ganglion, and others (sensory) continue forwar tongue, where, in company with fibers of the lingual nerve, they terminate in the ep covering the anterior two-thirds of the tongue. Some probably serve to convey sens taste, most of them are fibers of general sensibility. Before it joins the lingual nerve th tympani receives a communicating twig from the otic ganglion (figs. 768, 771).

THE VESTIBULAR NERVE

The vestibular nerve is purely sensory. With the peripheral process cells of origin terminating in the neuroepithelium of the semicircular ducts (and the vestibule, and their central processes conveying impulses to t substance of the medulla, cerebellum and spinal cord, the nerve comprises

FIG. 772.—THE LEFT MEMBRANOUS LABYRINTH OF A HUMAN FETUS OF 10 WEEKS (LATERAL ASPECT. Vestibular ganglion and nerve, red; cochlear nerve, yellow. (American Journal of Anatomy.)

a. 30mm. lateral.

important part of the apparatus for the equilibration of the body. It l customary to describe the vestibular [radix vestibularis] and the cochle cochlearis] nerves combined as the acoustic (auditory) or eighth crani While the two are blended in a common sheath from near the medul bottom of the internal auditory meatus, they are likewise partly enclos same sheath with the facial and glossopalatine nerves and the internal artery which accompany them in this meatus. At the bottom of the m vestibular and the cochlear are separate; they are separate at their entranc lateral aspect of the medulla oblongata; and their central connections, p distributions and functions are different.

The vestibular nerve arises as processes of the cells of the vestibular (ganglion of Scarpa), situated upon and blended within the nerve at th of the internal auditory meatus. Unlike the ordinary spinal ganglion t it corresponds, most of the cells of the vestibular ganglion retain an em

ganglion cells are those which are distributed to the mucous membrane (including taste-buds) of the tongue and pharynx, and the central processes pass medialward to the medulla. In the medulla they pass dorsalward and medianward through the reticular formation and, bifurcating into ascending and descending branches, they end in the nucleus of termination of the glossopharyngeal nerve, that is, in the superior part of the nucleus alæ cinereæ and of the nucleus of the tractus solitarius.

The motor fibers arise from the nucleus ambiguus in the lateral funiculus of the medulla, in line with the nucleus of origin of the facial nerve. From this nucleus they pass at first dorsalward and then, turning lateralward, they emerge and join the sensory fibers and run with them in the trunk of the nerve (fig. 687).

Van Gehuchten's observations point to the conclusion that one motor nucleus of the glossopharyngeal nerve is separate from and lies above and to the medial side of the nucleus ambiguus, and that a portion of the nucleus of the ala cinerea is also a motor nucleus common to the glossopharyngeal and vagus nerves. It is quite probable that the former motor nucleus is that now considered as the dorsal efferent nucleus of the vagus. An unknown number of the motor fibers are visceral motor and course in the various communications of the glossopharyngeal nerve with the cephalic (sympathetic) plexus.

Central connections.—The nuclei of termination of the glossopharyngeal nerve are associated with the motor nuclei of other cranial nerves by the medial longitudinal fasciculus, and with the somesthetic area of the cortex cerebri of the opposite side by the medial lemniscus fillet). The motor neurones of the nerve are associated with the somesthetic area by the pyramidal fibers.

THE HYPOGLOSSAL NERVE

The **hypoglossal nerves** are exclusively motor and probably exclusively somatic motor; they supply the geniohyoid and the extrinsic and intrinsic muscles of the tongue (except the glossopalatine). They are usually designated as the twelfth pair of cranial nerves. The fibers of each nerve issue from the cells of an elongated nucleus which lies in the floor of the central canal in the lower half of the medulla and in the floor of the fourth ventricle in the upper half beneath the trigonum hypoglossi. This nucleus is the upward continuation of the ventromedial group of cells of the ventral horn of the spinal cord. From their origin the fibers run ventralward and somewhat lateralward, probably joined in the medulla by a few fibers from the nucleus ambiguus which is a segment of the upward prolongation of the lateral group of cells of the ventral horn. The conjoined fibers issue from the medulla in the sulcus between the pyramid and the olivary body, in a series of from ten to sixteen root-filaments, which pierce the pia mater and unite with each other to form two bundles (fig. 761). These bundles pass forward and lateralward to the hypoglossal (anterior condyloid) foramen, where they pierce the arachnoid and dura mater. In the outer part of the foramen the two bundles unite to form the trunk of the nerve. At its commencement, at the base of the skull, the trunk of the hypoglossus lies on the medial side of the vagus, but as it descends in the neck it turns gradually around the dorsal and the lateral side of the latter nerve, lying between it and the internal jugular vein, and a little above the level of the hyoid bone it bends forward, and crosses lateral to the internal carotid artery, the root of origin of the occipital artery, the external carotid, and the loop formed by the first part of the lingual artery (fig. 773). After crossing the lingual artery it proceeds forward on the lateral surface of the hyoglossus, crossing to the medial side of the posterior belly of the digastric, and the stylohyoid muscles. It disappears in the anterior part of the submaxillary region between the mylohyoid and the hyoglossus, and divides into its terminal branches between the latter muscle and the genioglossus.

As it descends in the neck the trunk lies deeply between the internal jugular vein and the internal carotid artery under cover of the parotid gland, the styloid muscles, and the posterior belly of the digastric, and it is crossed superficially by the posterior auricular and the occipital arteries. As it turns forward around the root of the occipital artery the sternomastoid branch of that vessel hooks downward across the nerve, and as it turns forward on the hyoglossus muscle it lies immediately above the ranine vein. It is crossed by the posterior belly of the digastric and the stylohyoid muscle, and it is covered superficially, behind the mylohyoid, by the lower part of the submaxillary gland. Many of the twigs described as communications and branches contain few or no fibers of the hypoglossus proper.

Communications.—The hypoglossus is connected with the superior cervical ganglion of the sympathetic, with the ganglion nodosum of the vagus, with the loop between the first and second cervical nerves, and with the lingual nerve; the latter communication is established along the anterior border of the hyoglossus muscle (figs. 773 and 774).

The filaments, when traced lateralward, are seen to blend, in front of the flocculus, into a trunk which lies in front of the vagus nerve, but which passes through a separate opening through the arachnoid and the dura mater and through the jugular foramen. In the foramen this trunk lies in front, and lateral to the vagus nerve in a groove on the petrous portion of the temporal bone; and in this situation two ganglia are interposed in it, a superior or jugular, and an inferior or petrosal. After it emerges from the jugular foramen the glossopharyngeal nerve descends at first between the internal carotid artery and the internal jugular vein and to the lateral side of the vagus; then, bending forward and medialward, it descends medial to the styloid process and the muscles attached to it, and turning around the lower border of the stylopharyngeus it passes between the internal and the external carotid arteries, crosses the superficial surface of the stylopharyngeus, and runs forward and upward medial to the hyoglossus muscle and across the middle constrictor and the stylohyoid ligament, to the base of the tongue (fig. 773).

Ganglia.—The **superior or jugular ganglion** (ganglion of Ehrenritter), is a small, ovoid, reddish-gray body which lies on the back part of the nerve-trunk in the upper part of the jugular foramen. No branches arise from it. It is sometimes continuous with the petrosal ganglion or it may be absent.

The **inferior or petrosal ganglion** (ganglion of Andersch), is an ovoid gray body which lies in the lower part of the jugular foramen, and appears to include all the fibers of the nerve.

Branches and communications.—(1) The petrosal ganglion is connected with the superior cervical ganglion of the sympathetic by a fine filament.

(2) It also has a filament of communication with the auricular branch of the vagus which varies inversely in size with the latter branch and sometimes entirely replaces it. This filament may be absent.

(3) An inconstant communication with the ganglion of the root of the vagus.

(4) A short distance below the petrous ganglion the trunk of the nerve is connected by a twig with that branch of the facial nerve which supplies the posterior belly of the digastric muscle. There is also a small twig (probably sensory) to the stylohyoid.

(5) **From the petrosal ganglion: The tympanic branch** (nerve of Jacobson) arises from the petrosal ganglion and passes through a foramen, which lies in the ridge of bone between the carotid canal and the jugular fossa, into the tympanic canaliculus (**Jacobson's canal**), where it is surrounded by a small, fusiform mass of vascular tissue, the *intumescentia tympanica*. After traversing the tympanic canaliculus it enters the tympanum at the junction of its lower and medial walls, and, ascending on the medial wall, breaks up into a number of branches which take part in the formation of the **tympanic plexus** on the surface of the promontory (**fig. 769**). The continuation of the nerve emerges from this plexus as the *small superficial petrosal nerve*, which runs through a small canal in the petrous portion of the temporal bone, beneath the canal for the tensor tympani, and appears in the middle fossa of the cranium through a foramen which lies in front of the hiatus Fallopii. From this foramen it runs forward and passes through the foramen ovale, the canaliculus innominatus, or the sphenopetrosal suture, and enters the zygomatic fossa, where it enters the otic ganglion. While it is in the canal in the temporal bone the small superficial petrosal nerve is joined by a **geniculotympanic branch from the geniculate ganglion** of the glossopalatine nerve.

(6) **Branches from the tympanic plexus:** (*a*) The **tubal branch** (**ramus tubæ**), a delicate branch, which runs forward to the mucous membrane of the tuba auditiva (**Eustachian tube**) and sends filaments backward to the region of the fenestra vestibuli (**ovalis**) and the fenestra cochleæ (**rotunda**). (*b*) The **superior and inferior caroticotympanic (carotid) branches** pass medianward to the internal carotid plexus (figs. 769, 771).

The above communications carry fibers almost entirely concerned with the sympathetic plexuses of the head and they will be again mentioned below with the gangliated cephalic plexus.

Branches from the trunk of the nerve: (1) **Pharyngeal branches**, which may be two or three in number, arise from the nerve a short distance below the petrosal ganglion. The principal and most constant of these passes on the lateral side of the internal carotid artery, and after a very short independent course joins with the pharyngeal branch of the vagus and with branches of the superior cervical ganglion to form the **pharyngeal plexus** (**fig. 773**).

(2) A **muscular branch** is distributed to the **stylopharyngeus muscle**. This branch receives a communication from the facial nerve (fig. 773).

(3) The **tonsillar branches** are a number of small twigs which arise under cover of the hyoglossus muscle; they proceed to the tonsil, around which they form a plexus, the **circulus tonsillaris**. From this plexus fine twigs proceed to the glossopalatine arch and to the soft palate.

(4) The **lingual branches** are the terminal branches of the nerve and supply the mucous membrane of the posterior half of the dorsum of the tongue, where, chiefly as **taste-fibers**, they are distributed to the vallate papillæ. Some small twigs pass backward to the follicular glands of the tongue, and to the anterior surface of the epiglottis. Other twigs are distributed around the foramen cecum, where they communicate with the corresponding twigs of the opposite side.

The sensory fibers.—The sensory fibers of the glossopharyngeal nerve spring from the superior and petrosal ganglia and pass peripherally and centrally. **The peripheral processes of the**

(3) **The branches of the hypoglossus proper, the rami linguales,** supply the styloglossus hyoglossus, genioglossus, and the intrinsic muscular fibers of the tongue.

The nerve to the styloglossus is given off near the posterior border of the hyoglossus. It pierces the styloglossus, and its fibers pursue a more or less recurrent course within the muscle.

The nerves to the hyoglossus are several twigs which are supplied to the muscle as the hypoglossal nerve crosses it.

The nerve to the genioglossus arises under cover of the mylohyoid in common with the terminal branches to the intrinsic muscles of the tongue. It communicates freely with branches (sensory) of the lingual, forming long loops which lie on the genioglossus. From these loops twigs pass into the genioglossus and into the muscular substance of the tongue.

Central connections.—The nucleus of origin of the hypoglossus is associated with the somesthetic area (operculum) of the cortex cerebri of the opposite side by the pyramidal fibers, and it is correlated with the sensory nuclei (nuclei of termination) of other cranial nerves by way of the reticular formation and the medial longitudinal fasciculus.

THE VAGUS OR PNEUMOGASTRIC NERVE

The vagus or pneumogastric (tenth) nerves are the longest of the cranial nerves, and they are remarkable for their almost vertical course, their asymmetry, and their extensive distribution, for, in addition to supplying the lung and stomach, as the name 'pneumogastric' indicates, each nerve gives branches to the external ear, the pharynx, the larynx, the trachea, the esophagus, the heart, and the abdominal viscera.

Each nerve is attached to the side of the medulla, in the posterolateral sulcus, dorsal to the olivary body, by from twelve to fifteen root-filaments which are in linear series with the filaments of the glossopharyngeal nerve (fig. 761). The filaments contain both visceral and somatic sensory and motor fibers. They pierce the pia mater, from which they receive sheaths, and, traced outward, they pass into the posterior fossa of the cranium toward the jugular foramen and unite to form the trunk of the nerve, which passes through openings in the arachnoid and the dura mater which are common to it and to the spinal accessory nerve. In the jugular foramen a small spherical ganglion, the *jugular ganglion* (ganglion of the root), is interposed in the trunk which here turns at right angles to its former course and descends through the neck. As it leaves the jugular foramen it is joined by the internal or accessory portion of the spinal accessory nerve, and immediately below this junction occurs its large ovoid ganglion, the *ganglion nodosum* or ganglion of the trunk (fig. 773). As it descends through the neck the nerve passes ventral and somewhat lateral to the superior cervical sympathetic ganglion, and in front of the longus capitis and longus colli, from which it is separated by the prevertebral fascia. In the upper part of the neck it is placed between the internal carotid artery and the internal jugular vein, and in a plane dorsal to them, the artery being ventral and mesial, and the vein ventral and lateral. In the lower part of the neck it occupies a similar position in regard to the common carotid artery and the internal jugular vein, and the three structures are enclosed in a common sheath derived from the deep cervical fascia, but within the sheath each structure occupies a separate compartment (fig. 773). In the root of the neck and in the thorax the relations of the nerves of the two sides of the body differ somewhat, and they must, therefore, be considered separately (fig. 774).

The right vagus passes in front of the first part of the right subclavian artery in the root of the neck and then descends in the thorax, passing obliquely downward and backward on the right of the trachea, and behind the right innominate vein and the superior vena cava, to the back of the root of the right lung. Just before it reaches the right bronchus it lies close to the medial side of the vena azygos as the latter hooks forward over the root of the lung. At the back of the right bronchus the right vagus breaks up into a number of branches which join with the branches of the sympathetic to form the **right posterior pulmonary plexus,** and from this plexus it issues in the form of one or more cords, combined sensory, visceral motor and sympathetic, which descend on the esophagus and break up into branches which join with branches of the left vagus, forming the **posterior esophageal plexus.** At the lower part of the thorax fibers of this plexus become again associated in one trunk which passes through the diaphragm on the *posterior* surface of the esophagus, and is distributed to the *posterior* surface of the stomach and to the celiac (solar) plexus and its offsets.

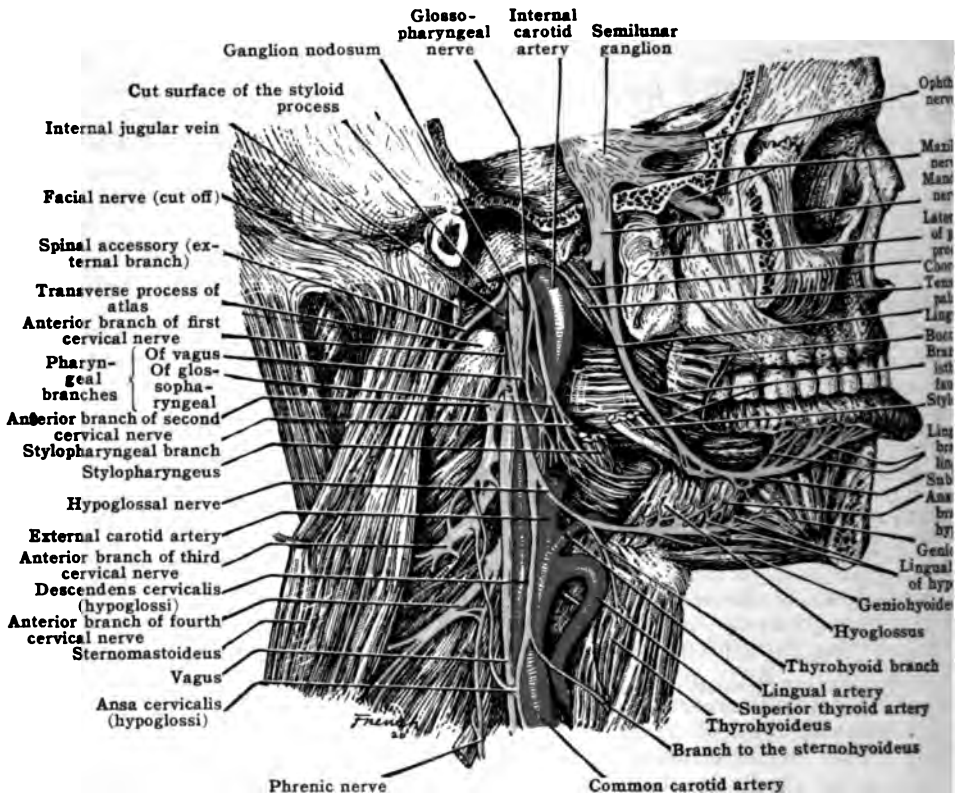
The left vagus descends through the root of the neck between the carotid and subclavian arteries and in front of the thoracic duct. In the upper part of the superior mediastinum it is crossed in front by the left phrenic nerve, and in the lower part of the same region it crosses in front of the root of the subclavian artery and the arch of the aorta and behind the left superior intercostal vein. Below the aortic arch it passes behind the left bronchus and divides into branches which unite with twigs of the sympathetic to form the **left posterior pulmonary plexus.**

Terminal branches.—These include (1) a meningeal branch; (2) branches from the cervical plexus; and (3) branches from the hypoglossus proper.

(1) A meningeal branch, frequently represented by two filaments, is given off in the hypoglossal (anterior condyloid) canal. It passes backward into the posterior fossa of the cranium and is distributed to the dura mater. It does not comprise fibers of the hypoglossus proper. It was believed at one time that the fibers of the meningeal branch were derived from the lingual nerve, but it is now deemed more probable that they are either sensory or visceral motor fibers from the cervical nerves, or from the vagus.

(2) **Branches which consist of fibers derived from the cervical plexus.**—The descendens cervicalis (hypoglossi) and the muscular twig to the thyrohyoid muscle, though apparently arising from the hypoglossal nerve, consists entirely of fibers which have passed into the hypoglossal nerve from the loop between the first two cervical nerves. Therefore, neither of these are branches of the hypoglossus proper. (See fig. 783).

FIG. 773.—THE HYPOGLOSSAL, GLOSSOPHARYNGEAL, AND LINGUAL NERVES. (From Spalteholz, modified.)



(a) The **descendens cervicalis (hypoglossi)** parts company with the hypoglossus at the where the latter hooks around the occipital artery (fig. 773). It runs downward and sl medialward on the sheath of the great vessels (occasionally within the sheath), and is at a variable level by branches from the second and third cervical nerves, forming with t loop, the cervical loop [ansa hypoglossi]. The cervical loop may be placed at any leve a point immediately below the occipital artery to about 4 cm. above the sternum. Fro loop all the muscles attached to the hyoid bone are supplied. A twig to the anterior b the omohyoid arises from the descendens cervicalis in the upper part of its course. The which supply the sternohyoid, sternothyroid, and posterior belly of the omohyoid are gi by the cervical loop. Twigs from the first two nerves pass downward in the muscles behi manubrium sterni and in rare cases communicate with the phrenic nerve within the t The nerve to the posterior belly of the omohyoid runs in a loop of the cervical fascia bel central tendon of the muscle.

(b) The **nerve to the thyrohyoid** leaves the hypoglossus near the tip of the great co the hyoid bone, and runs obliquely downward and medialward to reach the muscle. A fibers in (a) and (b) are derived from the first, second and third cervical nerves.

(c) The **nerve to the geniohyoid** arises under cover of the mylohyoid, where loo formed with the lingual nerve from which loops branches pass into the muscle. It pro *contains some* true hypoglossal fibers.

skull and in front of the upper part of the internal jugular vein. It is of flattened ovoid form and about 17 mm. long and 4 mm. broad (figs. 774 and 773). It is joined by the accessory part of the spinal accessory nerve, and is associated with the hypoglossal nerve, with the superior cervical ganglion of the sympathetic, and with the loop between the first two cervical nerves, and it gives off a pharyngeal, a superior laryngeal, and a superior cardiac branch. Both ganglia and especially the nodosal retain numerous cell-bodies of sympathetic neurones and the twigs issuing from the ganglia thus contain sympathetic fibers. The greater number of the cell-bodies are of sensory neurones.

It should be remembered that the visceral sensory fibers of the vagus arise in its ganglia and carry to the medulla impulses aroused in the viscera it supplies, chiefly the epithelium of the digestive and respiratory apparatuses; that its visceral motor fibers carry from the medulla efferent impulses which are transferred by synapses to sympathetic ganglion-cells and these in turn send fibers to the smooth and cardiac muscle and the glands of its domain, while its somatic motor fibers carry impulses from the medulla direct to skeletal muscle. Its somatic sensory fibers carry to the medulla impulses aroused, for the most part, in the skin.

Communications.—The vagus nerve is connected with the glossopharyngeal, spinal accessory and hypoglossal nerves, with the sympathetic, and with the loop between the first and second cervical nerves.

(1) Two communications exist between the vagus and glossopharyngeal nerves: one between their trunks, just below the base of the skull, and one, in the region of their ganglia, consisting of one or two filaments. When two filaments are present one passes from the jugular ganglion and the other from the auricular nerve to the petrosal ganglion of the glossopharyngeal nerve. Either or both of these filaments may be absent.

(2) Two twigs pass from the spinal accessory nerve to the ganglion nodosum, and at a lower level the accessory part of the spinal accessory nerve also joins the same ganglion (fig. 774). The majority of the fibers of the accessory part of the spinal accessory nerve merely pass across the surface of the ganglion and are continued into the pharyngeal and superior laryngeal branches of the vagus, but a certain number blend with the trunk of the vagus and are continued into its recurrent laryngeal and cardiac branches.

(3) Two or three fine filaments connect the ganglion nodosum with the hypoglossal nerve as the latter turns around the lower part of the ganglion (fig. 774).

(4) Fibers pass from the superior cervical ganglion of the sympathetic to both ganglia of the vagus (fig. 774).

(5) A twig sometimes passes from the loop between the first two cervical nerves to the ganglion nodosum (fig. 774).

Terminal branches of the vagus.—These are the meningeal, auricular, pharyngeal, superior laryngeal, recurrent (inferior laryngeal), cardiac, bronchial, pericardial, esophageal, and the abdominal branches.

(1) The **meningeal** or **recurrent branch** is a slender filament which is given off from the jugular ganglion. It takes a recurrent course through the jugular foramen, and is distributed to the dura mater around the transverse (lateral) sinus.

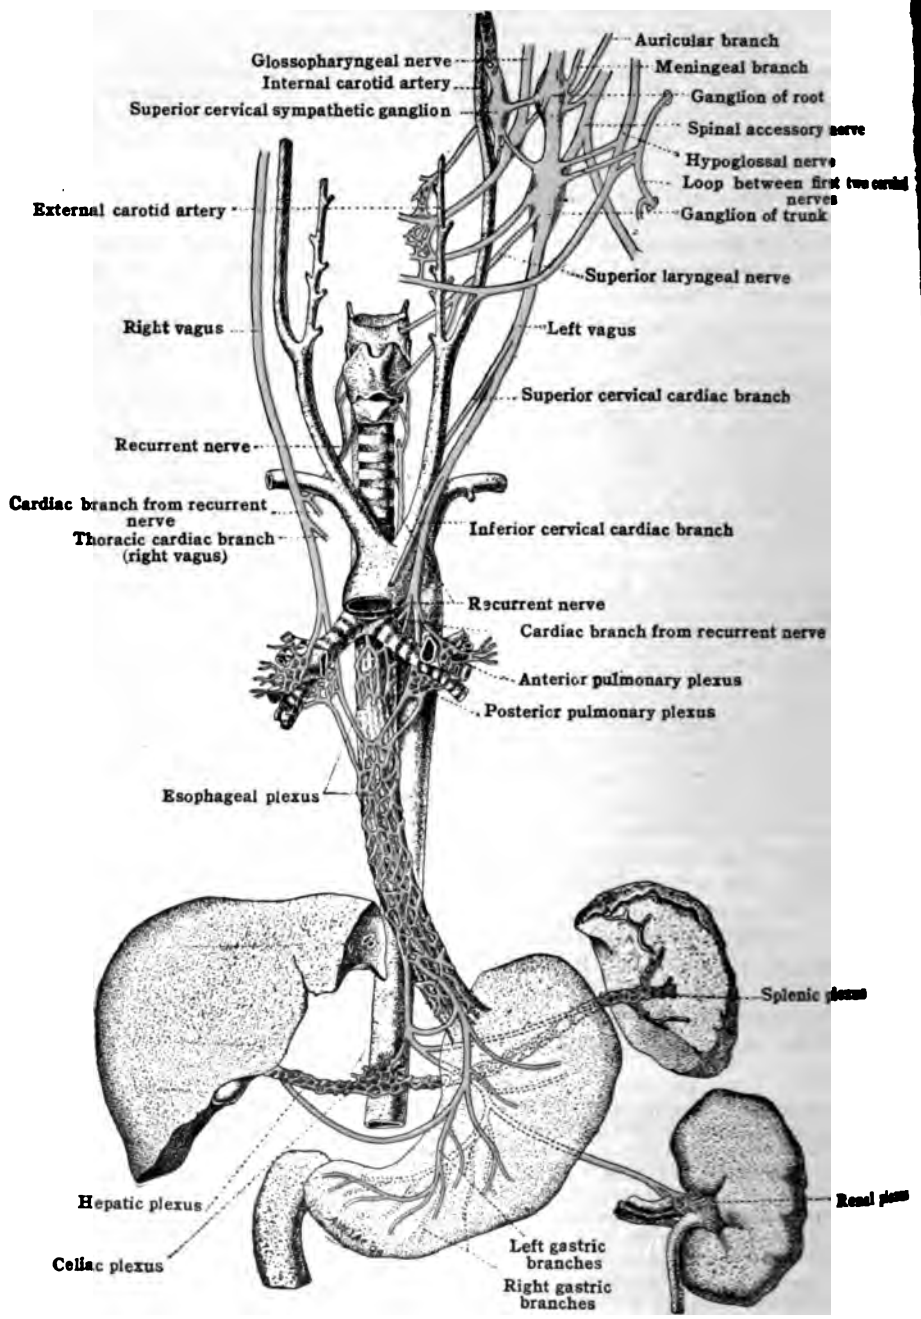
(2) The **auricular branch, or nerve of Arnold,** arises from the jugular ganglion in the jugular foramen. It receives a branch from the petrosal ganglion of the glossopharyngeal, enters the petrous part of the temporal bone through a foramen in the lateral wall of the jugular fossa, and communicates with the facial nerve or merely lies in contact with it as far as the stylomastoid foramen. It usually leaves the temporal bone by the stylomastoid foramen, but it may pass through the tympanomastoid fissure, and it divides, behind the auricle, into two branches, one of which joins the posterior auricular branch of the facial while the other supplies sensory fibers to the posterior and inferior part of the external auditory meatus and the back of the auricle. It also supplies twigs to the osseous part of the external auditory meatus and to the lower part of the outer surface of the tympanic membrane.

(3) The **pharyngeal branches** may be two or three in number. The principal of these joins the pharyngeal branch of the glossopharyngeal on the lateral surface of the internal carotid artery, and after passing with the latter medial to the external carotid artery it turns downward and medialward to reach the posterior aspect of the pharynx. Here the two nerves are joined by branches from the superior cervical ganglion of the sympathetic, with which they form the **pharyngeal plexus** (figs. 773, 774). Branches from this plexus supply sensory fibers to the mucous membrane of the pharynx, somatic motor fibers to the constrictores pharyngis, levator palatini, uvulæ, glossopalatinus, and pharyngopalatinus and probably visceral motor to sympathetic ganglion cells.

(4) The **superior laryngeal nerve** arises from the lower part of the ganglion nodosum, and passes obliquely downward and medialward, behind and medial to both the internal and external carotid arteries, toward the larynx. In this course it describes a curve with the convexity downward and lateralward and divides into (a) a larger internal and (b) a smaller external branch (fig. 774). Before its division it is joined by twigs with the sympathetic and with the pharyngeal plexus, and it gives a small branch to the internal carotid artery.

From this plexus the fibers of the left vagus issue as one or more cords that break up into anastomosing branches to form the anterior **esophageal plexus.** At the lower part of the thorax this plexus becomes a single trunk, which passes through the diaphragm on the *anterior* surface of the esophagus, and it is distributed to the *anterior* surface of the stomach and to the liver.

FIG. 774.—DIAGRAM OF THE BRANCHES OF THE VAGUS NERVES.



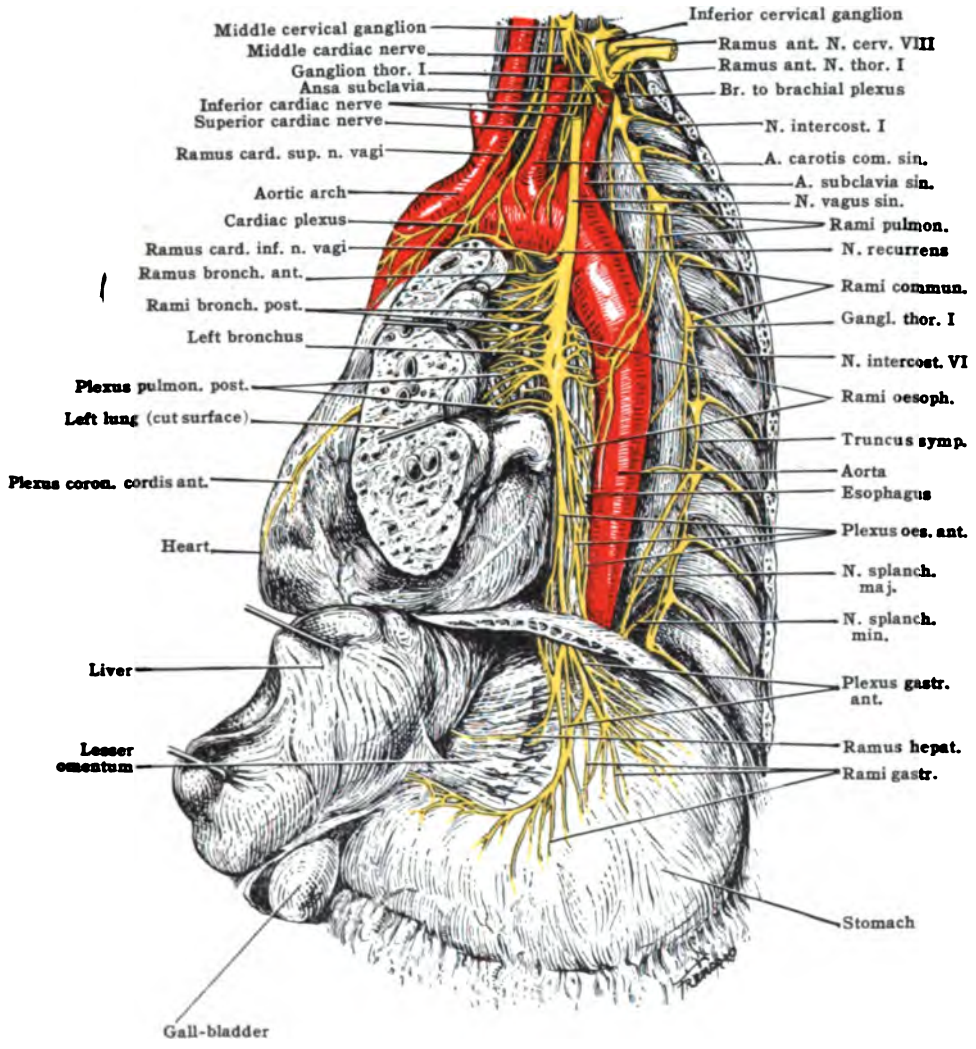
The **jugular ganglion** (ganglion of the root) is a **spherical gray mass** about 5 mm. in diameter which lies in the jugular foramen (**fig. 774**). It is connected with the spinal accessory nerve and with the superior cervical sympathetic ganglion, and it gives off an auricular branch, by means of which it becomes associated with the facial and glossopharyngeal nerves, and a recurrent meningeal branch.

The **ganglion nodosum** (ganglion of the trunk) lies below the base of the

(9) **Esophageal branches,** given off by the trunk of the nerve above the bronchial plexuses and from the esophageal plexuses lower down, pass to the wall of the esophagus.

(10) **Abdominal branches.**—The terminal part of the left vagus divides into many branches, some of which communicate freely along the lesser curvature of the stomach with filaments from the gastric plexus of the sympathetic, and to some extent with branches of the right vagus, to form the elongated **anterior gastric plexus** (figs. 774, 775). From this plexus as well as from the nerve-trunk, **gastric branches** are given to the anterior surface of the stomach. **Hepatic branches** from the trunk or from this plexus pass in the lesser omentum to the hepatic plexus (figs. 774, 775). The terminal part of the right vagus divides into many branches, and forms along the lesser curvature of the stomach an elongated **posterior gastric plexus** by communica-

FIG. 775.—THORACIC BRANCHES OF LEFT VAGUS AND OF ABDOMINAL PORTION OF LEFT SYMPATHETIC TRUNK. (After Spalteholz.)



tions with branches from the gastric plexus of the sympathetic and with branches from the right vagus. **Gastric branches** are given off by the trunk of the nerve and from this plexus. **Celiac branches** are given by the trunk to the celiac (solar) plexus, and **splenic** and **renal branches,** either directly or through the celiac (solar) plexus, are given to the splenic and renal plexuses (fig. 774).

Central connections.—The **sensory fibers** of the vagus are processes of the cells of the jugular ganglion and the ganglion nodosum. The peripheral fibers from these cells bring in sensory impulses from the periphery, and their central fibers convey the impulses to the brain. The latter fibers enter the medulla in the filaments of attachment in the posterolateral sulcus, and, in the reticular formation, they bifurcate into ascending and descending branches which end in the nuclei of termination of the vagus, namely, in the nucleus alæ cinereæ in the floor of the fourth ventricle and in the nucleus tractus solitarii. The tractus solitarius consists largely of the descending branches. These and the axones arising from the nuclei of termination of the vagus descend the spinal cord to terminate about ventral horn cells which give origin to the

phrenic nerve and to motor fibers supplying other muscles of respiration, and they al impulses which are distributed to visceral motor neurones along the spinal cord.

The **motor fibers** spring from the nucleus ambiguus and from the dorsal efferent motor) nucleus of the vagus, described on page 858. They join the sensory fibers in the formation. Some of the motor fibers, especially those from the dorsal efferent nu visceral motor fibers.

The central connections of the vagus are similar to those of the glossopharyng (fig. 688). Van Gehuchten's observations point to the conclusion that the chief t termination of the vagus nerve is that of the tractus solitarius.

THE SPINAL ACCESSORY NERVE

The spinal accessory (or eleventh) nerve [n. accessorius] is exclusively It consists of two parts, the accessory or superior, and the spinal or infer

The fibers of the **accessory or superior portion** [ramus internus] ('a vagus') spring chiefly from the inferior continuation of the nucleus ambi common with the motor fibers of the vagus above, and they pass thr reticular formation to the posterolateral sulcus of the medulla, where the as a series of filaments, below those of the vagus. The filaments pierc mater and unite, as they pass outward in the posterior fossa of the cra form a part of the nerve which enters the aperture in the dura mater co the vagus and spinal accessory nerves. In the aperture this trunk is join spinal portion of the nerve.

The **spinal** or **inferior portion** [ramus externus] arises from the cells of tral horn of the cord as low as the fifth, and rarely the seventh, cervic The fibers pass dorsalward and lateralward from their origins, chiefly fro eral part of the ventral horn, through the lateral funiculus of white subst they emerge from the lateral aspect of the cord behind the ligamentum d tum, along an oblique line, the lower fibers passing out immediately dor ligament. and the upper close to and sometimes in association with t roots of the upper two spinal nerves. As the spinal fibers pass out of th of the cord they unite to form an ascending strand (fig. 761) which e posterior fossa of the cranium, through the foramen magnum, and lateralward, blends more or less intimately with the accessory portio combined, the nerve enters the jugular foramen in company with the v here it is again separated into its two branches, which contain chiefly fibers as the original superior and inferior parts.

The **superior branch**, or accessory portion of the nerve, gives one or more filam jugular ganglion (ganglion of the root of the vagus), and then joins either the trunk o directly or its ganglion nodosum, the fibers of the branch being contributed to the p laryngeal, and cardiac branches of the vagus. Fibers corresponding to the white ram cantes, absent in the cervical nerves, probably enter the cervical sympathetic gangl this ramus of the spinal accessory nerve. The fibers which are accessory to the vag probably include visceral motor and cardioinhibitory fibers.

The **inferior branch** or the spinal portion runs backward and downward under c posterior belly of the digastric and the sternomastoid. It usually crosses in fro the lateral side of the internal jugular vein and between it and the occipital arte pierces the *sternomastoid*, supplies filaments to it, and interlaces in its substance wi of the second cervical nerve. It emerges from the posterior border of the ste slightly above the level of the upper border of the thyroid cartilage, passes obliquely and backward across the occipital portion of the posterior triangle, and disappears t trapezius at about the junction of the middle and lower thirds of the anterior border of (fig. 773). In the posterior triangle it receives communications from the third cervical nerves, and beneath the trapezius its fibers form a plexus with other bran same nerves. Its terminal filaments are distributed to the *trapezius* and they ca almost to the lower extremity of that muscle.

Central connections.—The nuclei of origin, like other motor nuclei, are connect somesthetic area of the cerebral cortex of the opposite side by the pyramidal fibers, a associated with the sensory nuclei of other cranial nerves by the medial longitudina and with sensations brought in by the spinal nerves directly and by the fibers of t proprii.

THE GANGLIATED CEPHALIC PLEXUS

The Sympathetic Ganglia of the Head and Their Associations with Cranial Nerves

The sympathetic system of the head, like that of the remainder of described below, is arranged in the form of a continuous gangliated ple vided into subplexuses. Unlike the great unpaired prevertebral plexu

oracic and abdominal cavities, all the larger sympathetic ganglia of the head are ired, ganglia corresponding to each other being found on either side. Thus, ssibly, they may be considered as an upward extension of the series of paired nbar, thoracic and cervical ganglia belonging to the sympathetic trunks lying ng either side of the vertebral column. Numerous small ganglia, many of em microscopic, occur in the subplexuses throughout the head. These are egular in size and position and those in the region of the median line are no ubt unpaired.

In origin, the ganglia of the cephalic plexus consist of cell-bodies which, in the early stages development, migrated from the fundaments of the ganglia of the vagus, glossopharyngeal d glossopalatine nerves, and most especially from that of the semilunar (Gasserian) ganglion the trigeminus—a developmental relation identical with that of the remainder of the sym thetic system to the ganglia of the spinal nerves. Just as is known for the spinal ganglia, me cell-bodies destined to develop into sympathetic neurones, instead of migrating, remained ithin the confines of the ganglia of the above nerves, in company with the cell-bodies of their nsory neurones. This is thought to be especially true for the geniculate, the petrosal and the gular ganglion. Therefore these ganglia must be considered as in small part sympathetic nglia.

The gangliated cephalic plexus could properly be included as a division of the general sym thetic system described later. However, because its larger ganglia are so intimately asso ated with branches of the oculomotor, trigeminal, masticator, glossopalatine, glossopharyngeal d vagus nerves, it is customary to describe it in connection with the cranial nerves.

The larger **ganglia,** one on either side of the head, comprise the ciliary ganglion, e sphenopalatine (Meckel's) ganglion, the otic and the submaxillary ganglion. o these must be added portions of the geniculate, petrosal, jugular and the gan - ion nodosum, and a part of the superior cervical sympathetic ganglion. The ief relations of the gangliated cephalic plexus to the cranial nerves are shown in g. 771.

The so-called **roots and branches of the ganglia** carry three varieties of fibers:) Sensory, visceral and somatic, (2) Motor (visceral motor or preganglionic), d (3) Sympathetic proper. Most roots and branches are mixed, the name of a ot being determined only by the variety of fibers predominating in it. Fibers sing from the cells of a ganglion and passing out of it, usually in one of its anches, are often referred to as postganglionic fibers (sympathetic proper).

A bundle of sensory fibers going to a ganglion is called its **sensory root.** Such, however, nnot comprise a true root since none of its fibers arises in the ganglion and very few or none ay terminate in it. The only sensory fibers terminating in a ganglion are the few which may proach it in any of the roots to terminate in its capsule or the capsules of its cells and convey pulses of general sensibility from the ganglion to the central nervous system. Almost all of e fibers of a 'sensory root' merely pass around or through a ganglion and into its branches yond, which they borrow as paths for reaching their allotted fields of distribution. In this lation it should be realized that while the ciliary, sphenopalatine, otic and submaxillary nglia are customarily described under the discussion of the trigeminus, this nerve has func onally less to do with them than any of the other cranial nerves with which they are associated. ndles of trigeminal (sensory) fibers, traceable in gross anatomy because medullated and of preciable size, pass to the ganglia, but only to pass through them as continuations of the ter inal branches of the trigeminus.

The so-called **motor root** of a ganglion may carry two kinds of fibers: (a) visceral motor reganglionic) fibers, arising in the nuclei of origin in the central system and passing in the unk and branches of a cranial nerve (oculomotor, masticator, etc.) to enter and terminate in ntact with the cell-bodies of the ganglion, which, in their turn, give fibers to the branches e ganglion; (b) fibers of the same origin, name and course but which may pass through the nglion to terminate in contact with the cells of a more distant ganglion. Any root, the motor pecially, may contain somatic motor fibers, that is, fibers of central origin which pass through e ganglion uninterrupted and into its branches to terminate directly upon the fibers of skeletal uscle.

A **sympathetic root** carries chiefly fibers conforming to the name: fibers arising in other nglia which pass through the ganglion in question to enter its branches and terminate upon eir allotted muscular or glandular elements. Obviously it may possibly also carry somatic otor and sensory and visceral sensory fibers. The larger ganglia of the head are described each possessing the three roots above mentioned.

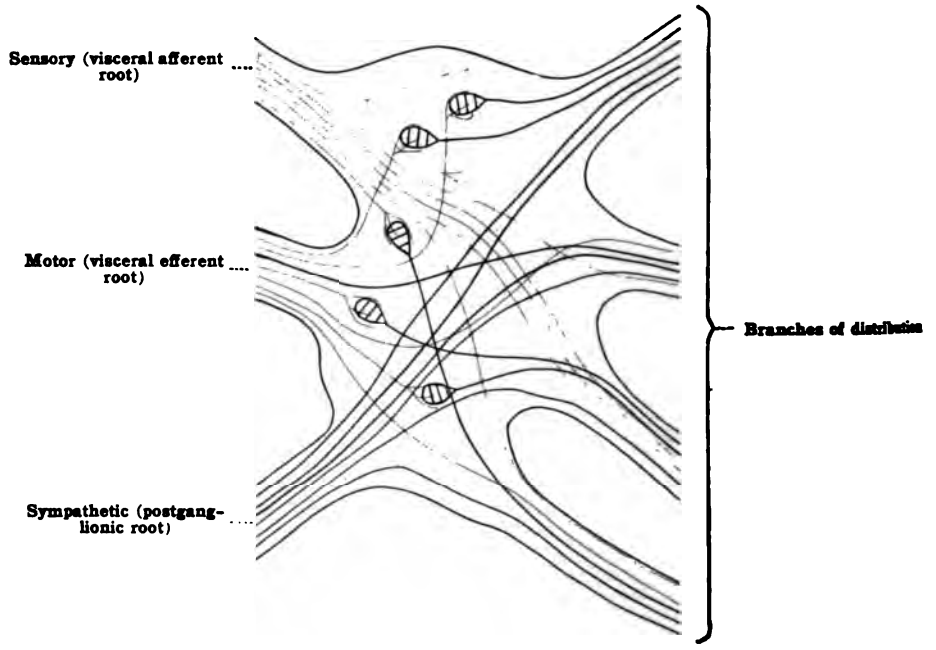
The **branches of distribution** of the ganglia, the larger of them often called nerves, are those ndles in which the fibers, both arising in or passing through the ganglia, course toward their rminations upon their allotted tissue elements of the head. In the branches pass fibers otor to the smooth muscle of the vessels of the head, to the intrinsic muscles of the eyeball, the lacrimal glands, the mucous membranes (gland cells) of the nasal and oral cavities and e salivary glands, and sensory fibers conveying impulses from these structures.

The **plexuses** into which the gangliated cephalic plexus is divided, including the roots and anches which connect the ganglia to form it, are numerous and vary greatly in size. They nderlie the mucous membranes and they surround all the vessels and glands. They are

named according to their locality. The largest of them are the tympanic plexus and the carotid and cavernous plexuses. They have been repeatedly referred to in their relations to the branches of the cranial nerves.

Of the numerous branches described from the superior cervical sympathetic ganglion, the two large ones which pass upward associate it especially with the gangliated cephalic plexus. That branch known as the internal *carotid nerve* may be considered as the direct continuation upward of the gangliated sympathetic trunk of the body. Through the branches of this nerve, the caroticotympanic and the deep petrosal nerves, and through the plexuses derived from it, the superior cervical ganglion may be associated with practically all the other sympathetic ganglia of the head (figs. 769 and 771). The other branch from the superior cervical ganglion, the *jugular nerve*, associates it with the ganglia of the glossopharyngeal and vagus nerves, with the petrosal ganglion by a direct branch and with the ganglia of the vagus through the nodosal plexus. These latter ganglia (and the nerves to which they belong) are connected chiefly by way of the tympanic nerve, which is from the petrosal ganglion, with the tympanic plexus (fig. 771).

FIG. 776.—DIAGRAM TO ILLUSTRATE THE STRUCTURAL RELATIONS OF THE ROOTS AND BRANCHES OF A CEPHALIC SYMPATHETIC GANGLION. Sensory fibers, blue; motor, red; sympathetic, black.



The tympanic plexus serves as a common point of distribution of fibers from the superior cervical spmpathetic ganglion, the ganglia of the vagus, the petrosal ganglion, and the geniculate ganglion, to the cavernous and carotid plexuses and to the sphenopalatine and otic ganglia. The superior cervical ganglion is associated with the cavernous and carotid plexuses direct by the internal carotid nerve and with the tympanic plexus by the inferior and superior caroticotympanic nerves. The tympanic plexus receives fibers from the geniculate ganglion by a small *geniculotympanic branch* and it is connected with the sphenopalatine ganglion by a small anastomotic or *tympanopetrosal branch* to the great superficial petrosal nerve, and it is connected with the otic ganglion by the small superficial petrosal nerve. It is not directly connected with either the ciliary or the submaxillary ganglion. However, these latter ganglia, as well as the sphenopalatine and otic, are connected with the carotid plexus either directly by named branches or indirectly by way of plexuses derived from the carotid. The geniculotympanic branch, the tympanic nerve, and twigs of the nodosal plexus may be considered as analogous to the rami communicantes of the spinal nerves.

The *parotid branches*, described above as branches of the auriculotemporal nerve (from the trigeminus) and as containing fibers from the glossopharyngeal, should be mentioned here as belonging to the gangliated cephalic plexus. These branches consist chiefly of sympathetic fibers arising in the otic ganglion (postganglionic) and passing as branches of the ganglion to the auriculotemporal in which they remain till this nerve enters the parotid gland and then they are distributed to the gland. The visceral motor or preganglionic fibers which terminate about their cells of origin in the otic ganglion are derived from the glossopharyngeal nerve and pass successively through the tympanic nerve, the tympanic plexus, and the small superficial petrosal nerve to the otic ganglion.

The *tympanic nerve* (tympanic branch of the glossopharyngeal, or nerve of Jacobson), the branch to the Eustachian tube (*ramus tubæ*), and the superior and inferior *caroticotympanic branches* are also described as branches of the glossopharyngeal nerve. These must likewise be considered as belonging to the gangliated cephalic plexus.

For purposes of dissection, it may be more expedient to consider separately, with its roots and branches, each of the larger ganglia of the gangliated cephalic plexus. Under this heading belong in part the *geniculate ganglion* of the glossopalatine nerve, and the *ganglia of the glossopharyngeal and vagus*, especially the petrosal ganglion of the former and the jugular ganglion of the latter, from the fact that these ganglia contain numerous cell-bodies of sympathetic neurones as well as those of the sensory neurones of their nerves.

These latter ganglia, however, have been described with their corresponding cranial nerves. The sensory and motor roots of their sympathetic portions are contained in the roots of their nerves. The geniculate probably has no sympathetic root. The sympathetic roots of the petrosal and jugular ganglia are contained in the branches of the jugular nerve. The chief branches of distribution of the geniculate are the geniculotympanic branch, the great superficial petrosal nerve, and the external superficial petrosal nerves. The branches of the petrosal ganglion are the tympanic nerve and its branches of the tympanic plexus. The chief branch of distribution from the jugular ganglion is contained in the auricular branch of the vagus, or nerve of Arnold, supplemented by sympathetic fibers in the trunk of the vagus itself.

The principal cephalic sympathetic ganglia are the ciliary, the sphenopalatine (Meckel's), the otic and the submaxillary.

The Ciliary Ganglion

The ciliary (lenticular, or ophthalmic) ganglion lies in the posterior part of the orbital cavity, about 6 mm. in front of the superior orbital (sphenoidal) fissure, to the lateral side of the optic nerve, and between the optic nerve and the external rectus muscle. It is a small, reddish, quadrangular body, compressed laterally, and it measures about 2 mm. from before backward (fig. 764).

Roots.—(*a*) Its motor or short (preganglionic) root enters its lower and posterior angle and is a visceral motor branch derived from the branch of the inferior division of the oculomotor nerve which supplies the inferior oblique muscle. The fibers of the motor root probably all terminate in the ciliary ganglion by synapses with the cell-bodies of its sympathetic neurones.

(*b*) The sensory or long root passes through the upper and back part of the ganglion. It is a branch of the nasociliary (nasal) nerve and is, therefore, composed of fibers from the trigeminus passing through the ganglion. This root also carries many sympathetic fibers, some of which arise from cell-bodies of the superior cervical sympathetic ganglion and gain the nasociliary nerve by way of the internal carotid nerve and the internal carotid and cavernous plexuses. All sympathetic fibers passing to the ganglion pass through it without interruption.

(*c*) The sympathetic root consists of fibers derived from the cavernous (and internal carotid) plexus of the sympathetic; it passes to the ganglion with the long root, and usually also as a separate sympathetic root carrying fibers similar to the sympathetic fibers of the long root.

Branches.—From three to six short ciliary nerves emerge from the anterior border of the ganglion; they divide as they pass forward and eventually form about twenty nerves which are arranged in an upper and a lower group, and the latter group is joined by the long ciliary branches of the nasociliary (nasal) nerve, now sensory and sympathetic (fig. 764). When they reach the eyeball, the ciliary nerves pierce the sclerotic around the optic nerve, and pass forward in grooves on the inner surface of the sclera. The sympathetic fibers contained are distributed as motor fibers to the ciliary muscle, the sphincter of the iris, and to the vessels of these and of the cornea. The dilator pupillæ or radial muscle of the iris is innervated by the fibers which arise in the superior cervical sympathetic ganglion and pass through the ciliary ganglion from either its long or its sympathetic root to enter the short ciliary nerves. These fibers are concerned in the '*skin-pupillary*') (*ciliospinal*) reflex chain by which the pupil dilates in response to stimulus of the skin (fig. 744).

The Sphenopalatine or Meckel's Ganglion

This ganglion is associated with the maxillary nerve (figs. 762, 765, 769). It is a small reddish-gray body of triangular form, which is flattened at the sides, and measures about 5 mm. from before backward. It lies deeply in the pterygopalatine (sphenomaxillary) fossa at the lateral side of the sphenopalatine foramen and in front of the anterior end of the pterygoid (Vidian) canal. It is attached to the maxillary nerve, from which it receives its sensory root, and it is connected with the Vidian nerve, which furnishes it with motor and sympathetic filaments.

The exact position of the ganglion depends upon the size and shape of the sphenoidal air-sinuses. When these are small, or high and narrow, the ganglion lies lateral to them; when they are large, or broad and flat, the ganglion lies inferior to them. Sometimes it may lie anterior to them if the sinuses are short from in front backward. The ganglion may be reached with ease by chipping away the bone around the sphenoidal air-sinuses after the skull is divided sagitally.

Roots.—(*a*) Its motor root, consisting of visceral motor fibers of the glossopalatine nerve, is contained in the great superficial petrosal nerve which is incorporated in the Vidian nerve.

It springs from the anterior angle of the geniculate ganglion and passes through the hiatus of the facial canal (hiatus Fallopii) into the middle fossa of the cranium, where it runs forward and medialward, in a groove on the upper surface of the petrous part of the temporal bone, to the foramen lacerum, and in this part of its course it passes beneath the semilunar (Gasserian) ganglion and the masticator nerve. In the foramen lacerum it joins with the great deep petrosal nerve to form the Vidian nerve (nerve of the pterygoid canal), which passes forward through the pterygoid (Vidian) canal, and its visceral motor fibers terminate in the sphenopalatine ganglion in the pterygopalatine (sphenomaxillary) fossa. The great superficial petrosal nerve contains sensory as well as sympathetic and motor fibers. The sensory fibers pass through the ganglion and, in the small palatine nerve, descend to the soft palate, where they terminate in the epithelium covering it and some are probably concerned with taste organs found there. They arise from the cells of the geniculate ganglion and therefore belong to the glossopalatine nerve.

(*b*) The **sympathetic root** is the great deep petrosal portion of the Vidian nerve. This root, which is of reddish color and of soft texture, springs from the carotid plexus which lies on the outer side of the internal carotid artery in the carotid canal. It enters the foramen lacerum through the apex of the petrous portion of the temporal bone, and unites with the great superficial petrosal branch of the glossopalatine nerve to form the Vidian nerve. The great superficial petrosa nerve also carries sympathetic fibers derived from the geniculate ganglion and from the tympanic plexus as well as from the carotid plexus.

The **Vidian nerve** [**n. canalis pterygoidei**] commences by the union of the great superficial and deep petrosal nerves in the foramen lacerum, and runs forward through the pterygoid (Vidian) canal into the pterygopalatine (sphenomaxillary) fossa to the sphenopalatine ganglion. The Vidian nerve often may be seen in a ridge of bone along the floor of the sphenoidal cells and its direction there depends upon the position of the sphenopalatine ganglion. While it is in the pterygoid canal the Vidian nerve is joined by a sphenoidal filament from the otic ganglion, and it gives branches to the upper and back part of the roof and septum of the nose, and to the lower end of the Eustachian tube.

(*c*) The **sensory roots** consist of the sensory fibers mentioned above in the great superficial petrosal nerve and of (usually) two sphenopalatine branches from the maxillary nerve. The majority of the fibers of these roots do not join the ganglion, but pass by its medial side and enter the palatine branches.

Branches.—The branches of the ganglion, containing sensory and vasomotor and secretory fibers, are orbital or ascending, internal or nasal, descending or palatine, and posterior or pharyngeal.

Ascending branches.—The **orbital** or **ascending branches** are two or three small twigs which enter the orbit through the inferior orbital (sphenomaxillary) fissure and proceed, within the periosteum, to the inner wall of the orbit, where they pass through the posterior ethmoidal foramen and through the foramina in the suture behind that foramen to be distributed to the mucous membrane which lines the posterior ethmoidal cells and the sphenoidal sinus.

Internal branches.—The internal or nasal branches are derived in part from the medial side of the ganglion, but are also largely made up of sensory fibers which pass from the sphenopalatine branches of the maxillary nerve without traversing the ganglionic substance. They are disposed in two sets, the lateral and the medial (septal) posterior superior nasal branches.

The **lateral posterior superior nasal branches** are six or seven small twigs which pass through the sphenopalatine foramen, and are distributed to the mucous membrane covering the posterior parts of the superior and middle nasal conchæ (turbinated bones) (**fig. 762**). They also furnish twigs to the lining membrane of the posterior ethmoidal cells.

The **medial posterior superior nasal (septal) branches**, two or three in number, pass medialward through the sphenopalatine foramen. They cross the roof of the nasal fossa to reach the back part of the nasal septum, where the smaller twigs terminate. The largest nerve of the set, the **nasopalatine nerve**, or **nerve of Cotunnius**, runs downward and forward in a groove in the vomer between the periosteum and the mucous membrane to the incisive (anterior palatine) canal, where it communicates with the nasal branch of the anterior superior alveolar nerve. The two nasopalatine nerves then pass through the foramina of Scarpa in the intermaxillary suture, the left nerve passing through the anterior of the two foramina. In the lower part of the incisive (anterior palatine) canal the two nerves form a plexiform communication (formerly described as Cloquet's ganglion) and they furnish twigs to the anterior or premaxillary part of the hard palate behind the incisor teeth. In this situation they communicate with the anterior palatine nerves.

Descending branches.—The descending branches are the great or anterior, the posterior, and the middle (external) palatine nerves. Like the internal set of branches, they are in part derived from the ganglion and in part are directly continuous with the sphenopalatine nerve (fig. 762)

The **great** or **anterior palatine** nerve, its sensory fibers derived from the maxillary nerve, arises from the inferior angle of Meckel's ganglion, and passes downward through the pterygopalatine canal, accompanied by the descending palatine artery. Emerging from the canal at the greater (posterior) palatine foramen it divides into two or three branches, which pass forward in grooves in the hard palate and supply the glands and mucous membrane of the hard palate and the gums on the inner aspect of the alveolar border of the upper jaw. During its course through the pterygopalatine canal the anterior palatine nerve gives off the **posterior inferior nasal nerves**. These nerves pass through small openings in the perpendicular plate of the palate bone to supply the mucous membrane covering the posterior part of the inferior nasal concha (turbinated bone) and the adjacent portions of the middle and inferior meatuses of the nose.

The **posterior** or **small palatine nerve** passes downward through a lesser palatine foramen (accessory palatine canal), and enters the soft palate, distributing branches to that organ, to the uvula, and to the tonsil. Its sensory fibers are derived from the glossopalatine nerve,

through the great superficial petrosal nerve, and pass through the sphenopalatine ganglion. It was formerly believed to convey motor fibers from the facial nerve to the levator veli palatini and azygos uvulæ, but it is now believed that these muscles are supplied by the spinal accessory nerve through the pharyngeal plexus.

The **middle (external) palatine nerve,** the smallest of the three, in part, likewise from the glossopalatine nerve, traverses a lesser palatine foramen and supplies twigs to the tonsil and to the adjacent part of the soft palate (fig. 762).

Posterior branch.—The small **pharyngeal branch** of the ganglion passes backward and somewhat medialward through the pharyngeal canal accompanied by a pharyngeal branch of the sphenopalatine artery. It is distributed to the mucous membrane of the uppermost part of the pharynx, to the upper part of the choanæ, to the opening of the Eustachian tube, and to the lining of the sphenoidal sinus. Its sensory fibers are derived from the maxillary nerve.

The Otic Ganglion

The otic (Arnold's) ganglion is a small reddish-gray body which is associated with the mandibular nerve. It lies deeply in the zygomatic fossa, immediately below the foramen ovale, on the inner side of the trunk of the mandibular nerve. It is in relation medially with the tensor veli palatini, which separates it from the Eustachian tube. In front of it is the posterior border of the pterygoideus internus, and behind it lie the middle and small meningeal arteries. It is compressed laterally, and its greatest diameter, which lies anteroposteriorly, is about 3 mm.

Roots.—The ganglion is closely connected with the nerve to the pterygoideus internus, through which it may receive a motor root from the masticator nerve. Through the small superficial petrosal nerve, which joins the upper and back part of the ganglion, it receives a motor root from the glossopalatine nerve and sensory and motor fibers from the glossopharyngeal nerve. It receives also a slender *sphenoidal filament* from the Vidian nerve. The **sympathetic roots** are derived from the small supe ficial petrosal nerve and from the sympathetic plexus on the middle meningeal artery.

Branches.—The communicating branches which pass from the ganglion are: (1) The filaments to the chorda tympani, some of whose fibers probably pass through the otic to terminate in the submaxillary ganglion; (2) filaments to the auriculotemporal nerve; (3) filaments to the spinous nerve (the recurrent branch of the mandibular nerve). The branches of distribution are sympathetic to the vessels and somatic motor branches to the tensor tympani, and tensor veli palatini, with sensory fibers (probably) to all of these.

The Submaxillary Ganglion

The submaxillary ganglion is suspended from the lingual division of the mandibular nerve by anterior and posterior branches. It is a small reddish body, of triangular or fusiform shape, which lies between the mylohyoideus and hyoglossus and above the duct of the submaxillary gland.

Roots.—The **sensory root** is received from the lingual nerve. The **motor root** (preganglionic) is from both the masticator nerve by way of the lingual nerve, and from the glossopalatine nerve by way of the chorda tympani. The motor fibers pass from the chorda tympani after it has joined the lingual, and the sensory fibers come directly from the lingual nerve. The **sympathetic root** is formed by filaments from the sympathetic plexus on the facial artery.

Branches.—(*a*) Five or six glandular (postganglionic) branches are given to the submaxillary gland and to Wharton's duct. (*b*) Branches to the lingual nerve and the sublingual gland. (*c*) To the mucous membrane of the floor of the mouth.

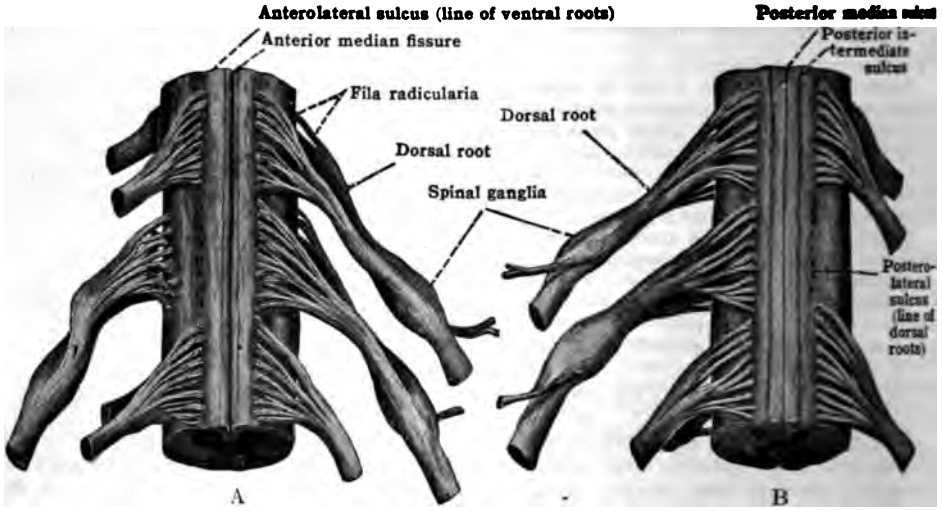
II. THE SPINAL NERVES

The spinal nerves are arranged in pairs, the nerves of each pair being symmetrical in their attachment to either side of their respective segment of the spinal cord, and, in general, symmetrical in their course and distribution. There are usually thirty-one pairs of functional spinal nerves. For purposes of description these are topographically separated into *eight* pairs of *cervical* nerves, *twelve* pairs of *thoracic* nerves, *five* pairs of *lumbar*, *five* pairs of *sacral*, and *one* pair of *coccygeal* nerves. Occasionally the coccygeal or thirty-first pair is rudimentary, while, on the other hand, there may be found small filaments representing one or even two additional pairs of coccygeal nerves below the thirty-first pair. These **rudimentary coccygeal nerves** are probably not functional. They never pass outside the vertebral canal, and often even remain within the tubular portion of the filum terminale. There sometimes occurs an increase in the number of vertebræ in the vertebral column and in such cases there is always a corresponding increase in the number of the spinal nerves.

Origin and attachment.—Each spinal nerve (unlike the cranial nerves) is attached to the spinal cord by two roots: a sensory or afferent **dorsal root** [radix posterior] and a motor or efferent **ventral root** [radix anterior]. Each dorsal root has interposed in its course an ovoid mass of nerve-cells, the **spinal ganglion**, and the nerve-fibers forming the root arise from the cells of this ganglion and are thus of peripheral origin. The fibers composing the ventral root, on the other hand, are of central origin; they arise from the large motor cells of the ventral horn of the gray column within the spinal cord (figs. 777, 779).

Each dorsal root-fiber upon leaving its cell of origin pursues a short tortuous course within the spinal ganglion and then undergoes a T-shaped bifurcation, one product of which passes toward the periphery, where it terminates for the collection of sensations and is known as the *peripheral branch*, or, since it conveys impulses toward the cell-body, the *dendrite* of the spinal ganglion neurone. It is more correct, however, to consider the T-fiber as a bifurcated axone. The other product of the bifurcation, the *central branch*, passes into the spinal cord and in its course toward the cord contributes to form the dorsal root proper.

FIG. 777.—VENTRAL AND DORSAL VIEWS OF SPINAL CORD SHOWING MANNER OF ATTACHMENT OF DORSAL AND VENTRAL ROOTS.



The central branches, upon emerging from the spinal ganglia, form a single compact bundle at first, which passes through the dura mater of the spinal cord and then breaks up into a series of root-filaments [fila radicularia]. These thread-like bundles of fibers spread out vertically in a fan-like manner and enter the cord in a direct linear series along its posterolateral sulcus. The fibers of the ventral root emerge from the cord in a series of more finely divided root filaments, which, unlike the entering filaments of the dorsal root, are not arranged in direct linear series, but make their exit over a strip of the ventrolateral aspect of the cord in some places as much as 2 mm. wide.

As they enter the spinal cord the fibers of the dorsal roots undergo a Y-shaped division, both products of which course in the cord longitudinally, an ascending and a descending branch. The descending or caudal branches are usually shorter than the ascending, and soon enter and terminate about the cells within the gray column of the cord, forming either associational, commissural, or immediate reflex connections, or about cells whose fibers form cerebellar or cerebral connections. The ascending or cephalic branches are either short, intermediate, or long. The short and intermediate branches are similar in function to the descending branches, save that they transfer impulses to the gray substance of segments of the cord above rather than below the level of their entrance. The long branches convey impulses (chiefly proprioceptive) destined for the structures of the brain, and pass upward in the fasciculus gracilis or fasciculus cuneatus of the cord, and terminate in the nuclei of these fasciculi in the medulla oblongata (figs. 660 and 662).

Aberrant spinal ganglia.—In serial sections on either side of the spinal ganglion of a nerve there may often be found outlying cells either scattered or in groups of sufficient size to be called small ganglia. Such are more often found in the dorsal roots of the lumbar and sacral nerves. These cells are nothing more than spinal ganglion-cells displaced in the growth processes, and have the same origin and function as those in the ganglion. In some animals occasional cells very rarely have been found in the outer portion of the ventral root. These probably represent afferent fibers which enter the cord by way of the ventral root. Likewise, especially in the birds and amphibia, it has been shown that occasional efferent fibers may pass from the gray substance of the cord to the periphery by way of the dorsal instead of the ventral root.

Relative size of the roots.—The sensory or dorsal root, with one constant exception, is larger than the ventral root, indicating that the sensory area to be supplied is greater and perhaps more abundantly innervated than the area requiring motor fibers.

It has been shown that in the entire thirty-one spinal nerves of one side of the body of man the dorsal root-fibers number 653,627, while all the corresponding ventral roots contain but 233,700 fibers, a ratio of 3.2 : 1. (Ingbert.) In the increase in the size of the nerves for the supply of the limbs the gain of dorsal root or sensory fibers is far greater than the gain of ventral root-fibers. The first cervical or the suboccipital nerve is always an exception to the rule; its dorsal root is always smaller than its ventral, and in rare cases may be rudimentary or entirely absent. The spinal ganglion and, therefore, the sensory root of the coccygeal nerve, is also quite frequently absent.

The dorsal and ventral root-fibers of each spinal nerve proceed outward from their segment of attachment to the spinal cord, pierce the pia mater and arachnoid, collect to form their respective roots, and pass into their respective intervertebral foramina. On the immediate peripheral side of the spinal ganglion the two roots blend, giving origin to the thus mixed **nerve-trunk.** As the trunk, the sensory and motor fibers make their exit rom the vertebral canal through the intervertebral foramen.

Relation to the meninges.—The root-filaments of each nerve receive connective tissue support from the pia mater and arachnoid in passing through them. In the subarachnoid cavity they become assembled into their respective nerve-roots; and the roots, closely approaching each other, pass into the dura mater, from which they receive separate sheaths at first, but at the peripheral side of the ganglion these sheaths blend into one, which, with the subsequent blending of the roots, becomes the sheath or epineurium of the nerve-trunk. By means of the sheaths derived from the meninges, especially the dura, the nerve-roots and the trunk are attached to the periosteum of the margins of the intervertebral foramina and thus are enabled to give some lateral support to the spinal cord in the upper portion of the canal.

The majority of the spinal ganglia lie in the intervertebral foramina, closely ensheathed, and thus outside the actual sac or cavity of the dura mater. The ganglia of the last lumbar and first four sacral nerves lie inside the vertebral canal, but since the sheath derived from the dura mater closely adheres to them, they are still outside the sac of the dura mater. The ganglia of the last sacral and of the coccygeal nerves (when present) lie in tubular extensions of the subdural cavity, and thus not only within the vertebral canal, but actually within the sac of the dura mater. The trunk of the first cervical nerve is assembled within the sac of the dura mater, and, therefore, the spinal ganglion of this nerve, when present, may lie within the sac.

Course and direction of emergence.—Invested with the connective tissue sheath derived from the meninges, each thoracic, lumbar and sacral nerve emerges from the vertebral canal through the intervertebral foramen below its corresponding vertebra, and all the nerves are in relation with the spinal rami of the arteries and veins associated with the blood-supply of the given localities of the spinal cord.

The first cervical nerve does not pass outward in an intervertebral foramen proper, but between the occipital bone and the posterior arch of the atlas and beneath the vertebral artery. Thus the eighth or last cervical nerve emerges between the seventh cervical and the first thoracic vertebra.

The first and second pairs of cervical nerves pass out of the vertebral canal almost at right angles to the levels of their attachment to the spinal cord. During the early periods of development the level of exit of each pair of spinal nerves is opposite the level of its attachment to the cord, but, owing to the fact that in the later periods the vertebral column grows more rapidly than the cord and increases considerably in length after the cord has practically ceased growing, all the spinal nerve roots, with the exception of the first two pairs, pass downward as well as outward. The obliquity of their course from the level of attachment to the level of exit increases progressively from above downward, and, as the cord ends at the level of the first or second lumbar vertebra, the roots of the lower lumbar and of the sacral nerves pass at first vertically downward within the dura mater, and form around the filum terminale a tapering sheaf of nerve-roots, the **cauda equina** (horse's tail) (fig. 655).

Topography of attachment.—The relations between the levels of attachment of the spinal nerves to the cord and the spinous processes of the vertebræ situated opposite these levels have been investigated by Nuhn and by Reid. The following table compiled by Reid gives the extreme limits of attachment as observed in six subjects.

TABLE OF TOPOGRAPHY OF ATTACHMENT OF SPINAL NERVES TO THE SPINAL CORD. (

(A) signifies the highest level at which the root filaments of a given nerve are at to the cord, and (B) the lowest level observed. For example, the root filaments of th thoracic nerve *may* be attached as high as the lower border of the spinous process of the thoracic vertebra, or some may be attached as low as the upper border of the spinous pro the fifth thoracic vertebra, but in a given subject they do not necessarily extend either or as low as either of the levels indicated.

Nerves

Relative size of the nerves.—The size of the different spinal nerves greatly. Just as the spinal cord shows marked enlargements in the cervi lumbar regions necessitated by the greater amount of innervation required o

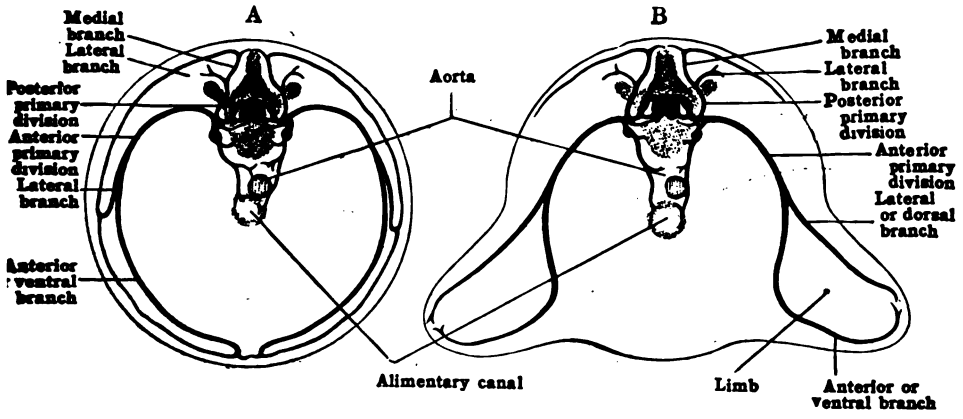
gions for the structures of the upper and lower limbs, so the nerves attached to ese regions are considerably larger than elsewhere.

The smaller nerves are found at the two extremities of the cord and in the midthoracic gion. The smallest nerve is the coccygeal, and the next in order of size are the lower sacral d the first two or three cervical nerves. The largest nerves are those which contribute ost to the great nerve trunks for the innervation of the skin and muscles of the limbs:—the wer cervical and first thoracic for the upper limbs and the lower lumbar and first sacral for e lower limbs. The nerves gradually increase in the series in passing from the smaller toward e larger.

The primary divisions of the nerve-trunk (figs. 778, 793).—A typical spinal erve (middle thoracic, for example), just as it emerges from the intervertebral oramen, divides into four branches;—the two large primary divisions; viz., **he posterior primary division** [ramus posterior] and the **anterior primary division** amus anterior]; third, the small **ramus communicans,** by which it is connected

FIG. 778.—DIAGRAMS ILLUSTRATING THE ORIGIN AND DISTRIBUTION OF A TYPICAL SPINAL NERVE.

A, in thoracic region; B, in region of a limb (highly schematic).



ith the sympathetic; and fourth, the smaller, **ramus meningeus** (*recurrent anch*), which immediately turns centralward for the innervation of the membranes and vessels of the spinal cord.

In general, **the posterior primary division** passes dorsalward between the arches r transverse processes of the two adjacent vertebræ in relation with the anterior ostotransverse ligament, and then divides (with the exception of the first cervical, the fourth and fifth thoracic, and the coccygeal nerves) into **a medial anch** and **a lateral branch.** The medial branch turns toward the spinous rocesses of the vertebræ, and supplies the bones and joints and the muscles about hem, and may or may not supply the skin overlying them. The lateral branch urns dorsalward and also supplies the adjacent muscles and bones, and, if the nedial branch has not supplied the overlying skin, it also terminates in cutaneous wigs.

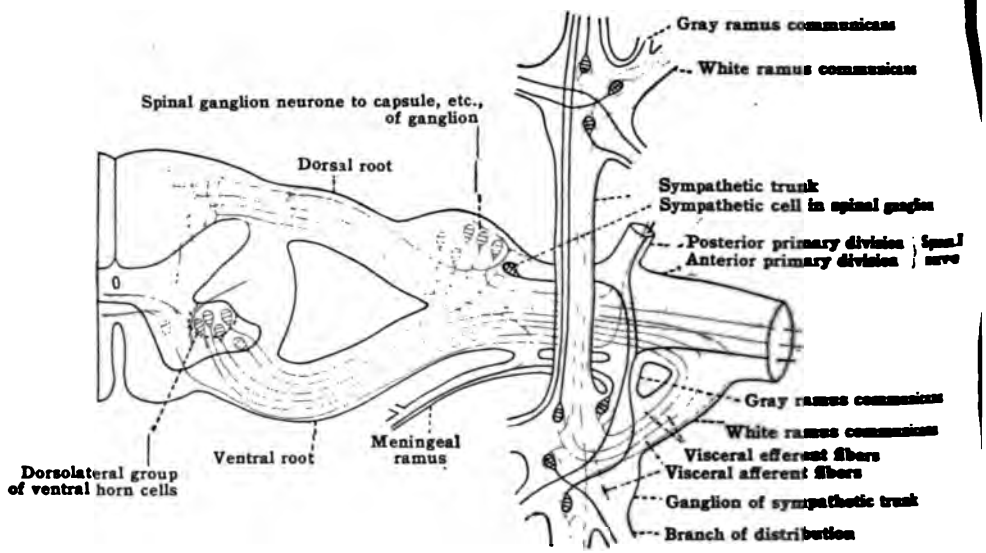
In the upper half of the spinal nerves the medial branches supply the skin; in the lower half, is the lateral branches which do so. Both branches of almost all the posterior divisions, specially those of the lower nerves, show a tendency to run caudalward and thus are distributed muscles and skin below the levels of their respective intervertebral foramina. They never pply the muscles of the limbs, though their cutaneous distribution extends upon the buttock, e shoulder, and the skin of the back of the head as far upward as the vertex. The posterior rimary divisions, with the exception of those of the first three cervical nerves, are much smaller han the anterior primary divisions.

As their mixed function suggests, the posterior primary divisions contain nerve-fibers both om the ventral roots and peripheral processes of the spinal ganglion-cells. If the nerve-trunk n the immediate peripheral side of the spinal ganglion be teased, bundles of ventral root-fibers ay be seen crossing the trunk obliquely to enter the posterior division, and fibers from the pinal ganglion may be also traced into it. Also the sympathetic fibers, derived chiefly by ay of the ramus communicans, are known to course in it for distribution in the walls of the lood-vessels, etc., of the area it supplies (fig. 779).

The anterior primary divisions run lateralward and ventralward. With the xception of those of the first two cervical nerves, which contribute the hypoglos-

sal loop, they are larger than the posterior primary divisions, and appear as direct continuations of the nerve-trunks. Only in case of most of the thoracic nerves do they remain independent in their course. In these they run lateralward and ventralward in the body-wall. In general, these divisions supply the lateral and ventral parts of the body, the limbs, and the perineum. In the cervical, lumbar, and sacral regions they lose their anatomical identity by dividing, subdividing, and anastomosing with each other so as to give rise to the three great spinal plexuses of the body—the **cervical**, the **brachial**, and the **lumbosacral plexuses**. The majority of the thoracic nerves retain the typical or primitive character in both their anterior and posterior primary divisions. In them the anterior division (intercostal nerve) divides into a **lateral** and an **anterior** (or ventral) branch, both of which subdivide. The lateral branch is chiefly cutaneous; it pierces the superficial muscles and, in the subcutaneous connective tissue, divides into a smaller posterior and a larger anterior **ramus**, which respectively supply the skin of the sides and the lateral part of the ventral surface of the

FIG. 779.—DIAGRAM ILLUSTRATING THE ORIGIN OF THE COMPONENT NERVE-FIBERS OF THE PRIMARY DIVISIONS OF A TYPICAL THORACIC OR LUMBAR SPINAL NERVE.



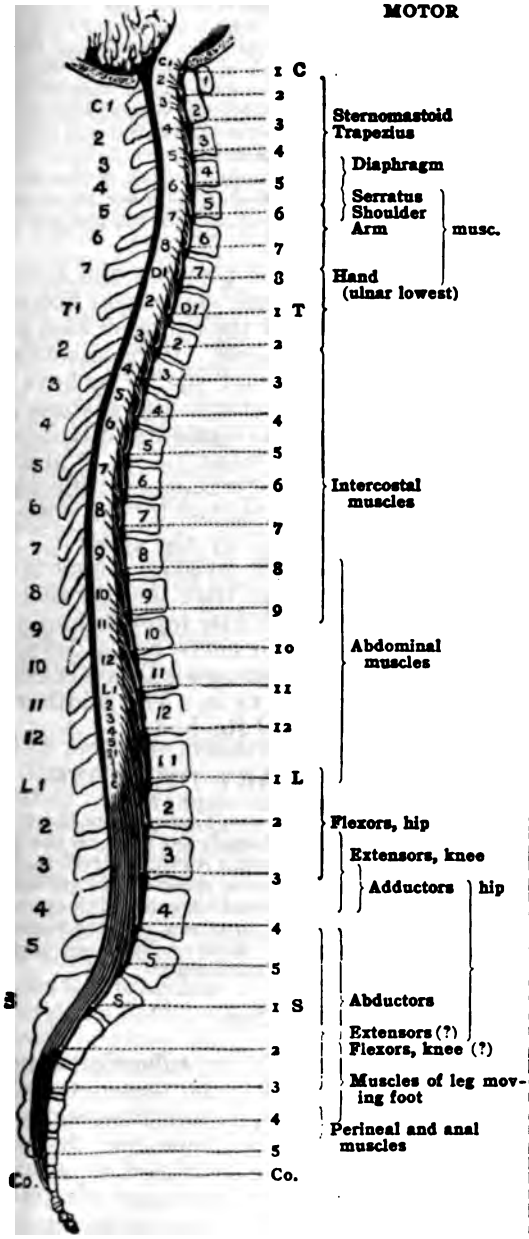
body. The anterior branch continues ventralward in the body-wall, giving off twigs along its course to the adjacent muscles and bones, and, as it approaches the ventral midline of the body, it turns sharply lateralward and sends rami medialward and lateralward to supply the skin of the ventral aspect of the body. In the region of the limbs the typical arrangement is interfered with in that what corresponds to the lateral and anterior branches of the division are carried out into the limbs for the skin and muscles there, instead of supplying the lateral and ventral parts of the body-wall.

Nerve-fibers arising in the spinal ganglion and fibers from the ventral root pass directly from the nerve-trunk into the anterior primary division of the spinal nerve. This division also receives sympathetic nerve-fibers by way of the ramus communicans. These latter accompany the division and are distributed to their allotted elements in the territory it supplies.

The rami communicantes are small, short, thread-like branches by which the nerve-trunks are connected with the nearest ganglion of the vertically running gangliated cord of the sympathetic (sympathetic trunk). The trunk or anterior primary division of every spinal nerve has at least one ramus; most of the nerves have two, and sometimes there are three. The nerves of the cervical region usually have but one, and this is composed largely of sympathetic fibers (gray ramus). Where there are two, one usually contains medullated fibers, chiefly visceral motor from the ventral root, sufficient to give it a whiter appearance (white ramus).

In the upper cervical and in the sacral regions one sympathetic ganglion may be connected h two or more spinal nerves, and sometimes one nerve is connected with two ganglia. The ai communicantes of the spinal nerves are equivalent to the communicating rami connecting tain of the cranial nerves with the sympathetic system (trigeminus, glossopharyngeal, vagus). e medullated fibers of the rami and, therefore, the white rami consist chiefly of fibers from spinal nerves, viz,, fibers from the spinal ganglion-cells which enter and course to their dis-

p. 780.—TABLE GIVING THE APPROXIMATE AREAS OF DISTRIBUTION OF THE DIFFERENT SPINAL NERVES WITH A DIAGRAM SHOWING THEIR RESPECTIVE LEVELS OF EXIT FROM THE VERTEBRAL COLUMN. (Arranged by Dr. Gowers.)



bution through branches of the sympathetic nerves, **visceral afferent fibers,** and fibers from e ventral roots of the spinal nerves which terminate in the sympathetic ganglia, **visceral erent** (preganglionic) **fibers.** Thus the white rami have been termed the **visceral divisions** the spinal nerves. The gray rami consist chiefly of sympathetic fibers, most of which are n-medullated or partially medullated, and which course to their distribution by way of the inal nerves. The usual absence of white rami communicantes from the cervical nerves is plained on the grounds—(1) that probably relatively fewer visceral efferent fibers are given the sympathetic from this region of the cord; (2) that many of the visceral efferent fibers

which do arise from this region of the cord probably join the rootlets of the spinal ac nerve and pass to the sympathetic system through the trunk of this nerve, and throu yagus with which it anastomoses; and (3) that such of these fibers, as are given off, es from the lower segments of the cervical region, descend the cord and pass out by the upper thoracic nerves which give very evident white rami to the sympathetic. In the white rami (visceral efferent fibers) of the thoracic and lumbar nerves terminat ganglia of the sympathetic trunk, while such fibers of the cranial and sacral nerves strea the trunk to terminate in more distant sympathetic ganglia.

The meningeal or recurrent branch (figs. 778, 777, and 793) is very small and v and is often difficult to find in ordinary dissections. It is given off from the nerve-tr before its anterior and posterior primary divisions are formed. It consists of a few p branches of spinal ganglion cells (senosry fibers) which leave the nerve-trunk and re-e vertebral canal for the sensory innervation of the meninges, and which are joined b from the gray ramus or directly from the nearest sympathetic ganglion (vasomoto There is considerable evidence, both physiological and anatomical, obtained chiefly animals, which shows that at times certain of the peripheral spinal ganglion or sens may turn backward in the nerve-trunk and pass to the meninges within the ventral ro of contributing to a recurrent branch. The occurrence of such fibers in the ventral roo the physiological phenomenon known as '*recurrent sensibility*.' Likewise, sympathe entering the trunk through the gray ramus may pass to the meninges by way of th root, and at times the recurrent branch is probably absent altogether, its place be entirely by the meningeal fibers passing in the ventral root. Possibly, some reach the by way of the dorsal root.

Areas of distribution of the spinal nerves.—Both the posterior and primary divisions divide and subdivide repeatedly, and their component f distributed to areas of the body more or less constant for the nerves of e but the distribution of the different nerves is very variable. Correspo their attachment, each to a given segment of the spinal cord, the nerves marily a segmental distribution, but, owing to the developmental cha displacement of parts during the growth of the body, the segmental dis becomes greatly obscured and in some nerves practically obliterated. N it is more retained by the nerves supplying the trunk than by those contri the innervation of the limbs and head, and the areas supplied by the primary divisions are less disturbed than those supplied by the anteri segmental areas of cutaneous distribution of the posterior divisions are n dent than the areas of muscle supplied by these divisions, from the fact segmental myotomes from which the dorsal muscles arise fuse together a lap each other considerably during development. No nerve has a d prescribed area of distribution, cutaneous or muscular, for its area is always ably overlapped by the areas of the nerves adjacent to it. The mid nerves more nearly supply a definitely prescribed belt of the body.

A. DISTRIBUTION OF POSTERIOR PRIMARY DIVISION

As above stated, the posterior primary divisions of the spinal nerves spring from t immediately outside the intervertebral foramina, and they pass dorsalward between cent transverse processes. With the exceptions of the first and second cervical nerve smaller than the corresponding anterior primary divisions, which in these nerves a from the fact that a large portion of them go over into the hypoglossal (or cervical) lo posterior primary divisions, after passing between the transverse processes into the the back, divide into medial and lateral branches. This division, however, does no the cases of the first cervical, the last two sacral, and the coccygeal nerves.

1. Cervical Nerves (Figs. 781, 782)

The posterior primary division of the first cervical or suboccipit springs from the trunk, between the vertebral artery and the posterior the atlas, passes dorsalward into the suboccipital triangle, and breaks branches which supply the superior oblique, the inferior oblique, and tl rectus capitis posterior muscles, which form the lateral boundaries of the It also gives a branch across the posterior surface of the major rectus ca terior to the minor rectus capitis posterior, and a branch to the sem capitis (complexus) in the roof of the triangle.

It communicates with the medial branch of the posterior primary division of t cervical nerve, either through or over the inferior oblique muscle, and it occasionall cutaneous branch to the skin of the upper part of the back of the neck and the low the scalp.

The posterior primary division of the second cervical nerve is the lar [redacted]erior division of all the cervical nerves. It divides into a small lateral br

very large medial branch. The **lateral branch** gives a twig to the inferior oblique and terminates in branches which supply the splenius and longissimus capitis (trachelomastoid) muscles. The **medial branch** is the **great occipital nerve** (fig. 784). It turns around the lower border of the inferior oblique, crosses the suboccipital triangle obliquely, pierces the semispinalis capitis (complexus), the tendon of the trapezius, and the deep cervical fascia, passing through the latter immediately below the superior nuchal line of the occipital bone, and it divides into several terminal sensory branches which ramify in the superficial fascia of the scalp.

It gives one or two motor twigs to the semispinalis capitis (complexus), and its terminal branches, which are accompanied by branches of the occipital artery, supply the skin of the scalp, above the superior nuchal line, as far forward as the vertex. Occasionally one branch reaches the pinna and supplies the skin on the upper part of its medial aspect. As it turns around the inferior oblique it gives branches which join with the medial branches of the posterior primary divisions of the first and third cervical nerves, and in this manner a small looped plexus is formed beneath the semispinalis capitis (complexus) muscle, the *posterior cervical plexus of Cruveilhier*.

The posterior divisions of the third, fourth, and fifth cervical nerves divide at the lateral border of the semispinalis colli into medial and lateral branches. **The medial branches** of the third, fourth, and fifth nerves run backward between the semispinalis colli and capitis (complexus), supplying both muscles. Then, after passing backward between the semispinalis capitis and the ligamentum nuchæ, they pierce the origin of the trapezius and supply the skin of the back of the neck. The greater part of the medial branch of the third nerve, which runs upward in the superficial fascia to the scalp, is an inconstant branch called the **third occipital nerve**; it interlaces with the great occipital nerve, and it supplies the skin of the upper part of the back of the neck, near the midline, and the skin of the scalp in the region of the external occipital protuberance.

The medial branches of the posterior primary divisions of the **sixth, seventh, and eighth cervical nerves** pass to the medial side of the semispinalis cervicis, between it and the subjacent multifidus spinæ, and they end in the neighboring muscles. The **lateral branches** of the posterior primary divisions of the **last five cervical nerves** are small and they are distributed to the longissimus capitis (trachelomastoid), the iliocostalis cervicis (cervicalis ascendens), the longissimus cervicis (transversalis cervicis), the semispinalis capitis (complexus), and the splenius muscles.

2. Thoracic Nerves

The **posterior primary divisions of all the thoracic nerves** divide into medial and lateral branches while in the vertebral groove (fig. 781). **The medial branches of the upper six thoracic nerves** pass dorsalward between the semispinalis dorsi and the multifidus spinæ; they supply the spinalis dorsi, the semispinalis dorsi, the multifidus spinæ, the rotatores spinæ, the intertransversales, and the interspinales muscles; and they end in cutaneous branches which, after piercing the trapezius, turn lateralward in the superficial fascia of the back, and supply the skin as far as the middle of the scapula. The cutaneous branch of the second nerve is the largest; it can be traced lateralward as far as the acromion process. **The medial branches of the lower six thoracic nerves** run dorsalward, between the longissimus dorsi and the multifidus spinæ; they chiefly end in twigs to the adjacent muscles, but not uncommonly they give small cutaneous twigs which pierce the latissimus dorsi and the trapezius and end in the skin near the midline of the back.

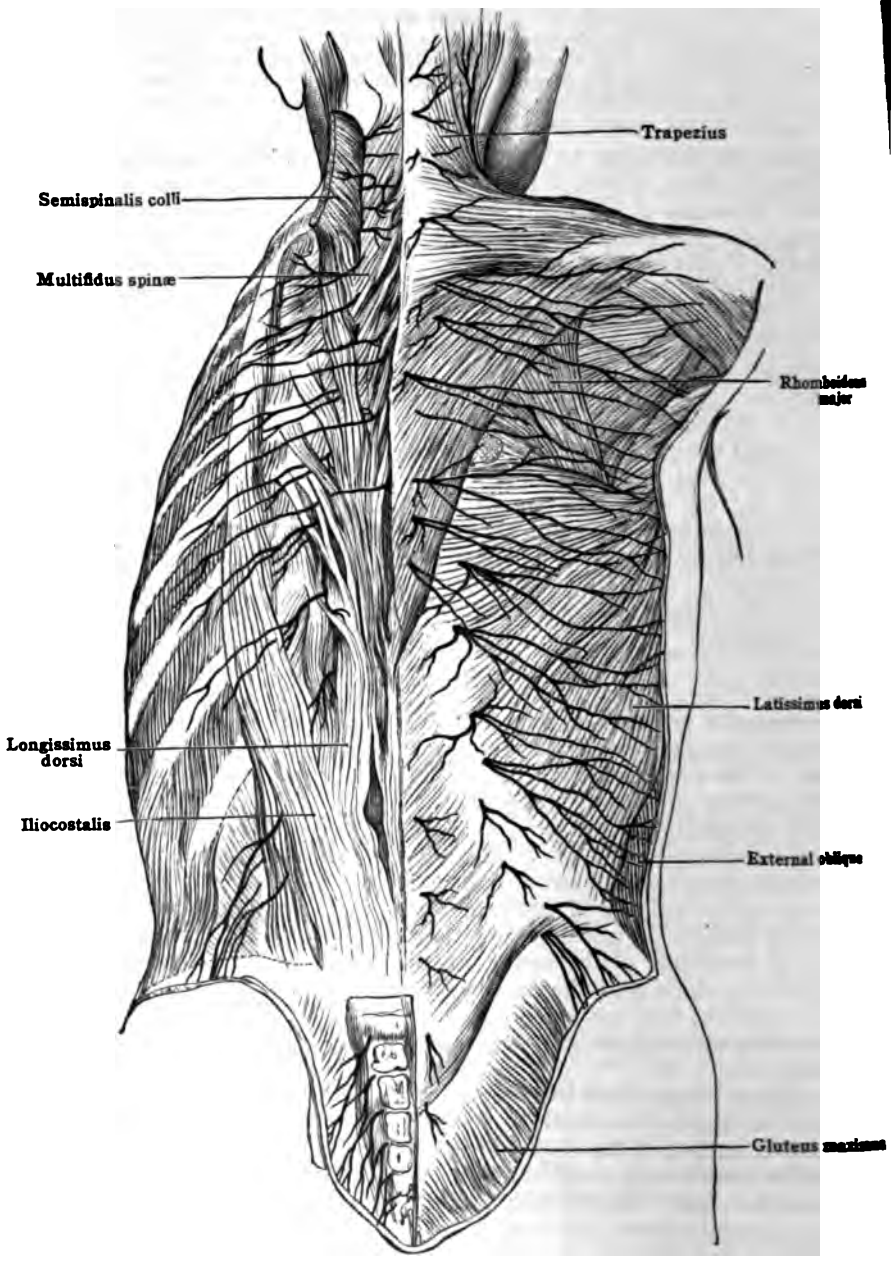
The lateral branches of the upper six thoracic nerves pass between the longissimus dorsi and the iliocostalis dorsi (accessorius) and end in those muscles, but **the lateral branches of the six lower nerves** are longer; they pass into the interval between the longissimus dorsi and the iliocostalis dorsi and give branches to them, and then they pierce the latissimus dorsi and are distributed to the skin of the lower and lateral part of the back.

3. Lumbar Nerves (Fig. 781)

The **medial branches** of the posterior primary divisions of all the lumbar nerves end in the multifidus spinæ and those of the three lower nerves send very small branches to the skin of the sacral region.

The **lateral branches of the upper three nerves** pass obliquely lateralward, supplying twigs to the adjacent muscles, pierce the posterior layer of the lumbar aponeurosis at the lateral border of the sacrospinalis (erector spinæ) and enter the subcutaneous tissue. They are, for the most part, cutaneous, forming the **superior clunial nerves,** which cross the crest of the ilium and pass downward to occupy different planes in the thick superficial fascia which covers the upper part of the gluteus medius.

FIG. 781.—DISTRIBUTION OF THE POSTERIOR PRIMARY DIVISIONS OF THE SPINAL NERVES. (Henle.)



The branch from the first lumbar nerve is comparatively small, and occupies the most superficial plane. The second occupies an intermediate position. The lateral branch from the third nerve is the largest of the three, and occupies the lowest position; it distributes branches over the gluteus maximus as far as the great trochanter. The three branches anastomose with one another and also with the cutaneous branches from the posterior primary divisions of the two upper sacral nerves.

The lateral branch of the fourth lumbar nerve is of small size and ends in the lower part of the sacrospinalis (erector spinæ). That of the **fifth lumbar** is distributed to the sacrospinalis and communicates with the first sacral nerve.

4. Sacral Nerves (Fig. 781)

The posterior primary divisions of the upper four sacral nerves escape from the vertebral canal by passing through the posterior sacral foramina; those of the fifth sacral nerve pass out through the hiatus sacralis between the posterior sacrococcygeal ligaments. Those of the upper three sacral nerves divide in the ordinary manner into medial and lateral branches. Those of the lower two sacral nerves remain undivided.

The medial branches of the upper three sacral nerves are of small size, and are distributed to the multifidus spinæ. The **lateral branches** anastomose with one another and with the lateral branch of the last lumbar nerve, forming loops on the posterior surface of the sacrum from which branches proceed to the posterior surface of the sacrotuberous (great sacrosciatic) ligament, where they anastomose and form a second series of loops, from which loops two or three branches are given off. These branches pierce the gluteus maximus and come to the surface of that muscle in a line between the posterior superior spine of the ilium and the tip of the coccyx. Then, as the **middle clunial nerves,** they are distributed to the integument over the medial part of the gluteus maximus, and communicate, in their course through the superficial fascia, with the posterior branches of the lumbar nerves.

The posterior primary divisions of the **lower two sacral nerves** unite with one another, with the posterior division of the third sacral, and with the coccygeal nerve, forming loops from which twigs pass to the integument over the lower end of the coccyx.

The posterior primary division of the coccygeal nerve is also undivided. It separates from the anterior division in the sacral canal and emerges through the hiatus sacralis, pierces the ligaments which close the lower part of that canal, receives a communication from the posterior division of the last sacral nerve, and ends in the skin over the dorsal aspect of the coccyx.

B. ANTERIOR PRIMARY DIVISIONS

The anterior primary divisions of the spinal nerves are larger than the posterior primary divisions, and each is joined near its origin by a gray ramus communicans from the sympathetic trunk (figs. 782, 783, 793). Beginning with the first thoracic nerve and ending with the second or third lumbar nerve, each anterior division sends to the sympathetic trunk a white ramus communicans. The same is true of the second and third or of the third and fourth sacral nerves. These white rami are appropriately designated the **visceral branches** of the spinal nerves, being composed chiefly of visceral efferent (preganglionic) and some visceral afferent fibers. The anterior primary divisions of the cervical, lumbar, sacral, and coccygeal nerves unite with one another to form **plexuses,** but the anterior primary divisions of the thoracic nerves, except the first and last, remain separate, pursue independent courses, and each divides, in a typical manner, into a lateral and an anterior or ventral branch. The separation of the anterior primary division into lateral and anterior branches is not confined to the thoracic nerves, however, it occurs also in the lower cervical, the lumbar, and the sacral nerves. But such a separation cannot be clearly distinguished either in the upper cervical nerves or in the coccygeal nerve.

1. CERVICAL NERVES

The anterior primary divisions of the **upper four cervical nerves** unite to form the **cervical plexus,** and each receives a communicating branch from the superior cervical sympathetic ganglion. The anterior divisions of the **lower four cervical nerves** are joined by the greater part of the first thoracic nerve and they unite to form the **brachial plexus** (figs. 782, 785, 786). The fifth and sixth cervical nerves receive communicating branches from the middle cervical sympathetic ganglion, and the seventh and eighth from the inferior cervical ganglion, while the first thoracic nerve is connected with the first thoracic sympathetic ('stellate') ganglion by a gray ramus (figs. 782, 814) and also by one or two white rami communicantes (Johnson and Mason).

THE CERVICAL PLEXUS

The cervical plexus (figs. 782,—784) is formed by the anterior primary divisions of the upper four cervical nerves which constitute the roots of the plexus. It

lies in the upper part of the side of the neck, under cover of the sternomastoid, and upon the levator scapulæ and the scalenus medius. It is a looped plexus, consisting of three loops.

A large part of the anterior primary division of the **first cervical nerve** is given to the hypoglossal (or cervical) loop; the remainder passes to the cervical plexus and in doing so it runs lateralward on the posterior arch of the atlas beneath the vertebral artery, then it turns forward, between the vertebral artery and the outer side of the upper articular process of the atlas, and finally it descends, in front of the transverse process of the atlas, and unites with the upper branch of the second nerve, forming with it the first loop of the plexus. It gives branches to the rectus capitis lateralis, longus capitis (major rectus capitis anterior), and to the rectus capitis anterior (minor). The division communicates with the ganglion of the trunk of the vagus and with the superior cervical ganglion of the sympathetic system (fig. 783). From the first loop of the plexus, two branches of the division pass over into the sheath of the hypoglossal nerve and descend with it to contribute to the **hypoglossal loop** [ansa hypoglossi] or better, the *cervical loop*. The fibers entering the sheath of the hypoglossus, after giving a few twigs to the geniohyoid and thyrohyoid muscles, leave the sheath as the **descendens cervicalis** (*hypoglossi*) and this latter joins the *communicans cervicalis*, (the portion of the loop from the second and third cervical nerves) and thus completes the hypoglossal (cervical) loop.

This loop usually may be found between the sheaths of the sternomastoid muscle and the carotid artery, superficial to the internal jugular vein; sometimes it may lie in the carotid sheath between the carotid artery and the internal jugular vein; rarely it may lie dorsal to both the artery and vein. Sometimes it is relatively long, descending toward the sternum below the level of the thyroid cartilage; again it is quite short and occurs near the level of the hyoid bone. The descendens cervicalis (hypoglossi) parts company with the hypoglossal nerve at the level at which the nerve curves around the occipital artery. It runs downward and slightly medialward on the sheaths of the great vessels and occasionally within the sheath of one of them.

The **second cervical nerve** (anterior primary division) passes behind the upper articular process of the axis and the vertebral artery, and between the intertransverse muscles extending from the first to the second cervical vertebræ, to the interval between the scalenus medius and the longus capitis (rectus capitis anterior major), where it divides into two parts. The upper part ascends and unites with the first nerve to form the first loop of the plexus, and the lower branch passes downward and dorsalward and joins the upper branch of the third nerve in the second loop of the plexus (figs. 782, 783). This branch gives off the small occipital nerve and a filament to the sternomastoid, which communicates with the spinal accessory nerve in the substance of the muscle, and it gives branches which assist in forming the hypoglossal or cervical loop [ansa hypoglossi] the cervical cutaneous and the great auricular nerves.

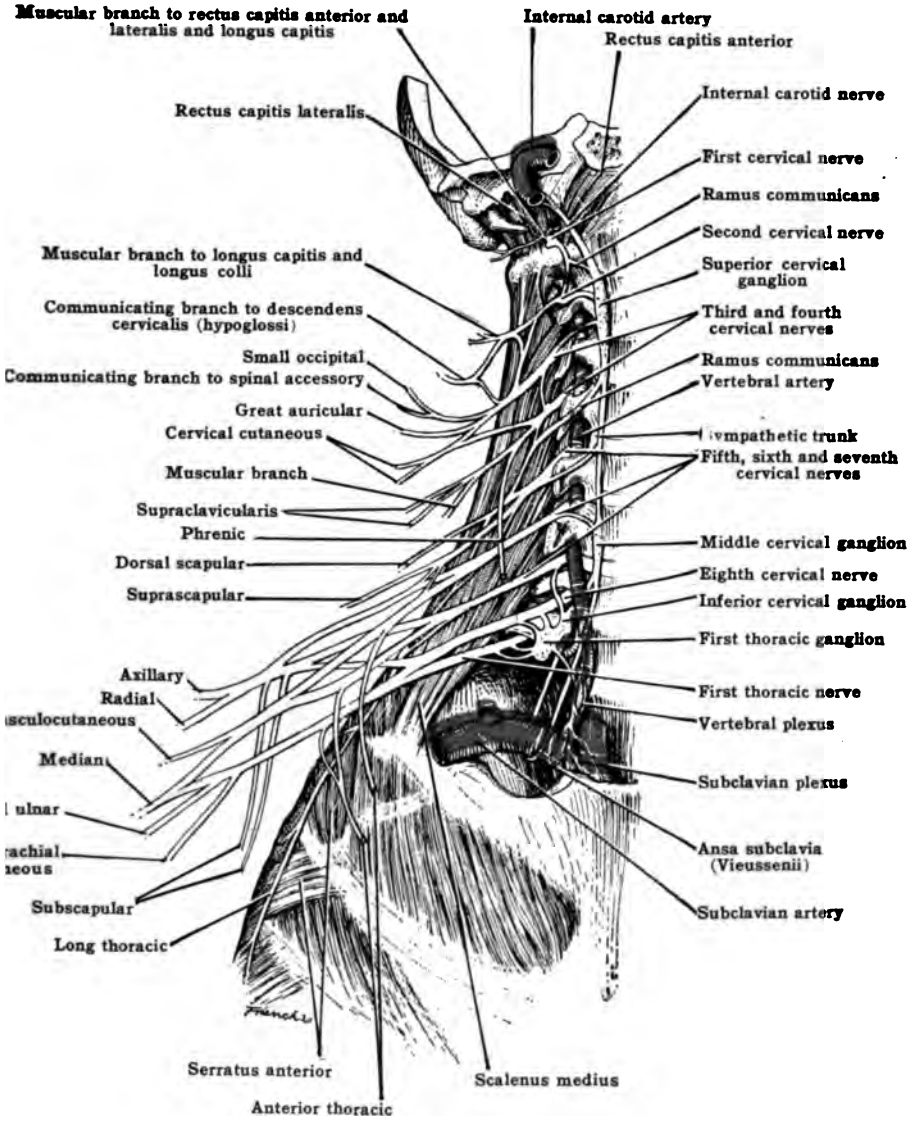
The anterior primary divisions of the **third** and **fourth cervical nerves** are about double the size of the preceding. They pass behind the vertebral artery (fig. 782) and between the intertransverse muscles to the interval between the scalenus medius and the longus capitis (rectus capitis anterior major), where the third unites with the second and fourth nerves and completes the lower two loops of the plexus. The third gives off branches to the hypoglossal loop, to the larger part of the great auricular and cervical cutaneous nerves, a branch to the phrenic, a branch to the supraclavicular nerves, and muscular branches to the scalenus medius, levator scapulæ, longus capitis, and trapezius (fig. 783). The trapezius branch joins the spinal accessory nerve beneath the muscle. The fourth nerve gives a branch to the phrenic, a branch to the supraclavicular nerves, and muscular branches to the scalenus medius, levator scapulæ, longus colli, and trapezius. The branch to the trapezius unites with the one from the third nerve and joins the spinal accessory nerve beneath the muscle.

The fibers forming the hypoglossal (cervical) loop innervate all the muscles of the infrahyoid group, though twigs to the geniohyoid and thyrohyoid seemingly enter these muscles from the trunk of the hypoglossus (fig. 783).

The nerve to geniohyoid is given off from the trunk of the hypoglossus under cover of the mylohyoid in common with the terminal branches of the hypoglossus proper going to the intrinsic muscles of the tongue. The nerve to the thyrohyoid muscle leaves the trunk of the hypoglossus near the tip of the great cornu of the hyoid bone, running obliquely downward and

anward to reach its muscle. A twig to the anterior belly of the omohyoid is given from the r part of the descendens cervicalis and the nerves for the sternohyoid, the sternothyroid the posterior belly of the omohyoid are supplied from the turn of the loop (fig. 783). nerves to the sternohyoid and sternothyroid send twigs downward in the muscles behind the ibrium sterni and fibers from these in rare cases join the phrenic nerve in the thorax. The to the posterior belly of the omohyoid courses as a loop in the cervical fascia below the al tendon of its muscle.

782.—Origin of the Cervical and Brachial Plexuses. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



ach root of the cervical plexus receives a communicating gray ramus from uperior cervical ganglion of the sympathetic, and from the roots and loops of lexus a number of branches arise which form two main groups, the superficial he deep.

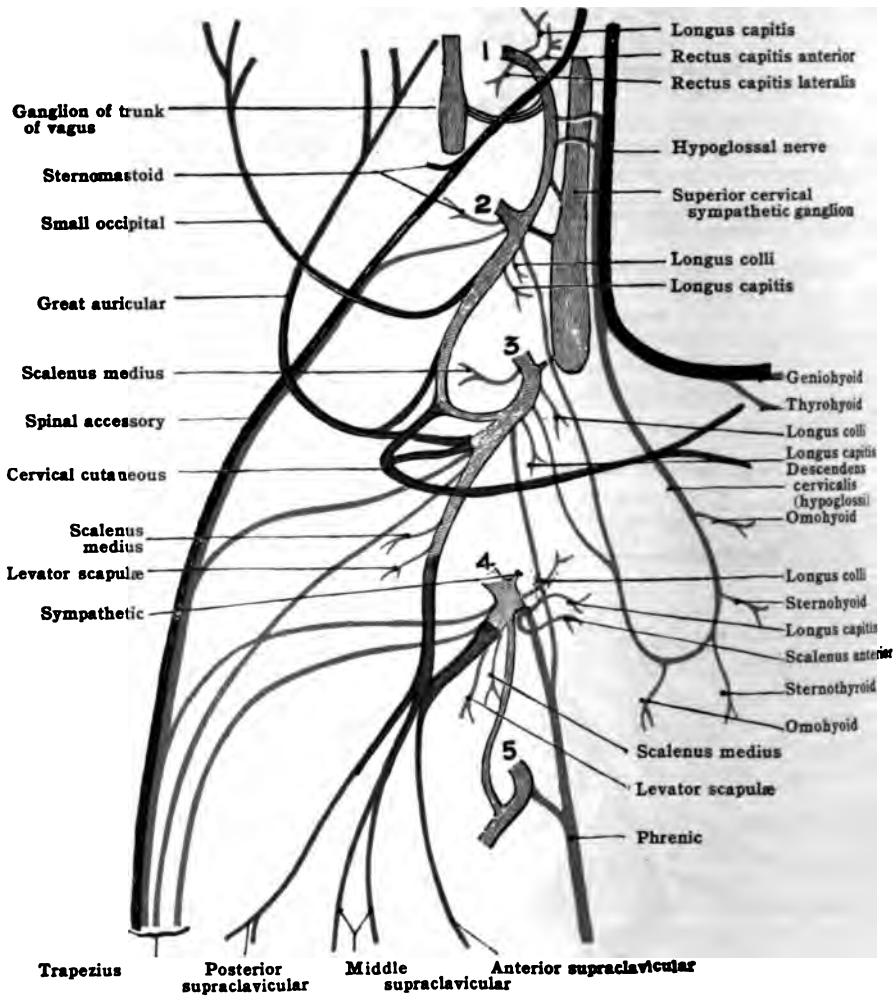
Superficial Branches of the Cervical Plexus

he superficial branches are described, according to the direction in which run, as ascending, transverse, and descending branches (fig. 784). The

ascending branches are the small occipital and the great auricular nerves. The is only one *transverse branch*, the superficial cervical cutaneous (transverse cervical) nerve. The *descending branches* are distinguished as the supraclavicular nerves and the cervical (hypoglossal) loop.

The ascending branches.—(1) The **small occipital nerve** (figs. 783, 784) arises from the second and third cervical nerves, or from the loop between them, and runs upward and dorsalward to the posterior border of the sternomastoid, where

FIG. 783.—DIAGRAM OF THE CERVICAL PLEXUS.



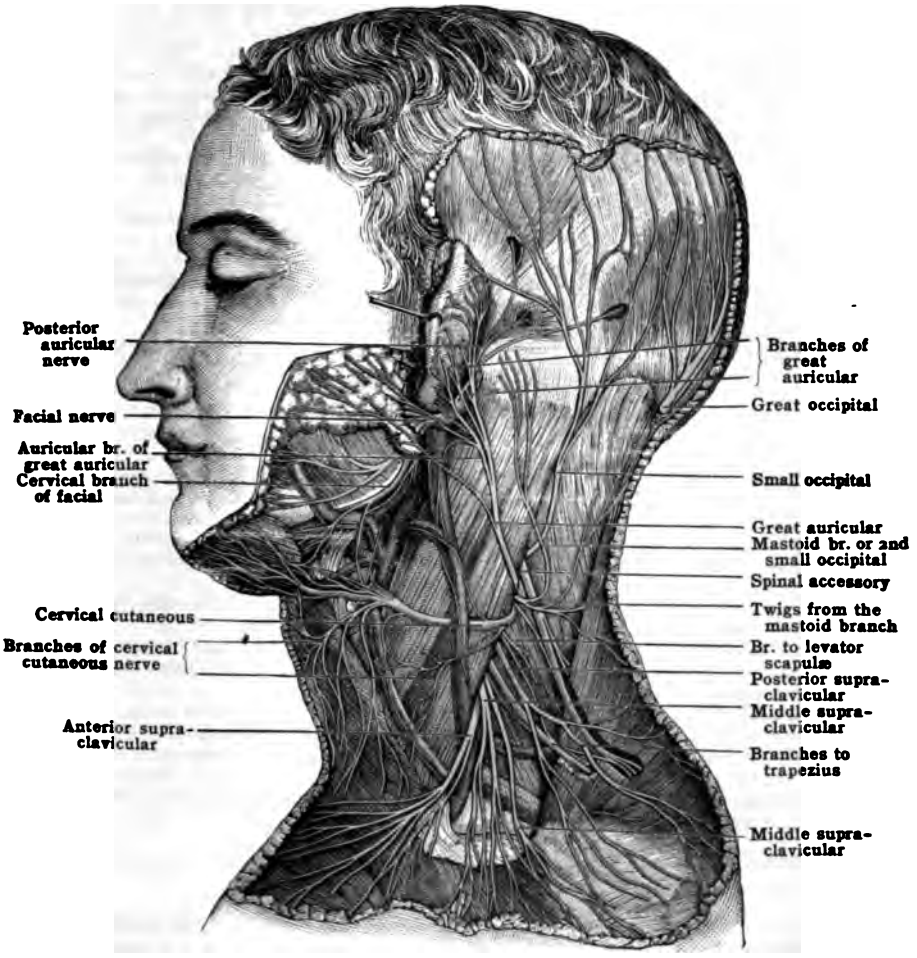
hooks around the lower border of the spinal accessory nerve and then ascends along the posterior border of the muscle to the mastoid process. It pierces the deep cervical fascia and passes across the posterior part of the insertion of the sternomastoid into the superficial fascia of the scalp, in which it breaks up into auricular, mastoid, and occipital terminal branches.

(*a*) The **auricular branch** runs upward and slightly forward to reach the integument of the upper median part of the auricle (pinna), which it supplies. (*b*) **The mastoid branch** is distributed to the skin covering the base of the mastoid process. (*c*) **The occipital branches** run over the occipitalis muscle and are distributed to the skin of the scalp; they communicate with one another and with the great occipital nerve. The branches of the small occipital anastomose with twigs of the posterior auricular, great auricular, and great occipital nerves (fig. 784).

(2) The **great auricular nerve** arises from the second and third cervical nerves (figs. 783, 784). It accompanies the small occipital to the posterior border of the sternomastoid, but at that point it diverges from the small occipital and runs upward and forward across the sternomastoid toward the angle of the mandible. When it is about half-way across the muscle it begins to break up into its terminal branches, which are named, according to the area of their distribution, mastoid, auricular, and facial.

As the nerve ascends obliquely across the sternomastoid it is embedded in the deep cervical fascia, is covered by superficial fascia and the platysma, and it lies parallel with and slightly dorsal to the external jugular vein. (*a*) The **mastoid branch** is small, and is distributed to the integument covering the mastoid process. It anastomoses with the posterior auricular and

FIG. 784.—SUPERFICIAL BRANCHES OF THE CERVICAL PLEXUS.
(After Hirschfeld and Leveillé.)



small occipital nerves. (*b*) The **auricular branches** are three or four stout twigs which interlace with the branches of the posterior auricular nerve; they cross the superficial surface of the posterior auricular branch of the facial, and are distributed to the skin on the back of the auricle with the exception of its uppermost part. One or two twigs pass through fissures in the cartilage of the auricle, and are distributed to the integument on the lateral surface of the lobule and the lateral surface of the lower part of the helix and anthelix. (*c*) The **facial branches** pass upward and forward among the superficial lobules of the parotid gland, and supply the skin over that gland and immediately in front of it, and they anastomose in the substance of the gland with the cervicofacial division of the facial nerve. In some cases fine twigs may be traced forward nearly to the angle of the mouth.

Transverse branch.—The **cervical cutaneous nerve** [n. cutaneus colli] arises from the second and third cervical nerves (figs. 782, 783), and appears at the posterior border of the sternomastoid, a little below the great auricular nerve.

It passes transversely across the sternomastoid under cover of the integument, platysma, and external jugular vein, and divides into a number of twigs which spread out after the manner of a fan, and, as they approach the middle line, extend from the chin to the sternum (fig. 784).

The upper two or three of these twigs unite, beneath the platysma, with the cervical (infra-mandibular) branch of the facial and thus form loops. From the terminal branches of the nerve numerous twigs arise which pierce the platysma and end in the skin of the front part of the neck.

The descending or supraclavicular branches.—These are derived from the third and fourth cervical nerves (figs. 782, 783), and arise under cover of the sternomastoid. At their commencements they are usually united with the muscular branches destined for the trapezius. They become superficial at the middle of the posterior border of the sternomastoid, and as they pass downward they pierce the deep cervical fascia (fig. 784). They include the following:

(1) The **anterior supraclavicular (suprasternal) branches** are small, and cross over the clavicular attachment of the sternomastoid to reach the integument over the upper part of the manubrium sterni. They also supply the sternoclavicular joint. (2) The **middle supraclavicular nerves** are of considerable size. They cross in front of the middle third of the clavicle under cover of the platysma, and are distributed to the skin covering the upper part of the pectoralis major as low as the third rib. (3) The **posterior supraclavicular (supra-acromial) branches** cross the clavicular insertion of the trapezius and the acromion process. They are distributed to the skin which covers the upper two-thirds of the deltoid muscle and they supply the acromioclavicular joint.

Deep Branches of the Cervical Plexus

The deep branches of the plexus (figs. 782, 783) pass lateralward and dorsalward, or ventralward and medialward; therefore they form two series, the lateral and the medial.

The **lateral branches** of the deep series include communicating branches from the second, third, and fourth cervical nerves to the spinal accessory nerve, and muscular branches to the sternomastoid and the scalenus medius, levator scapulæ, and trapezius.

The **communicating branches.**—The communicating branch from the second cervical nerve is ultimately distributed to the sternomastoid, and those from the third and fourth nerves end in the trapezius.

1. The **nerve to the sternomastoid** arises from the second cervical nerve. It pierces the deep surface of the sternomastoid, and communicates within the muscle with the spinal accessory nerve.

2. The **nerves to the scalenus medius** are derived from the third or fourth to the eighth cervical nerves close to their exit from the intervertebral foramina.

3. The **nerves to the levator scapulæ** are derived from the third and fourth cervical nerves, and occasionally from the second or fifth. They pierce the superficial surface of the levator scapulæ, and supply the upper three divisions of that muscle.

4. The **branches to the trapezius** are usually in the form of two stout twigs which are given off by the third and fourth cervical nerves. They emerge from under cover of the sternomastoid at its posterior border and cross the posterior superior triangle of the neck at a lower level than the spinal accessory nerve (fig. 784). They pass under cover of the trapezius in company with the last-named nerve, and communicate with it to form the **subtrapezial plexus**, from which the trapezius is supplied.

The **medial branches** of the deep series also comprise communicating and muscular branches.

The **communicating branches** (figs. 782, 783) include (1) branches which connect each of the first four cervical nerves with the superior cervical ganglion of the sympathetic; (2) a branch to the vagus; (3) a branch to the hypoglossus; and (4) branches which pass from the second and third cervical nerves to the *descendens cervicalis* (*hypoglossi*). The ultimate distribution of the twigs connected with the sympathetic and the vagus nerves is not known, but the fibers which pass to the hypoglossal nerve pass from it to the thyrohyoideus muscle and to the descendens cervicalis, and the latter joins with the branches from the second and third cervical nerves, forming with them the cervical or **hypoglossal loop [ansa hypoglossi]** which lies on the carotid sheath. From this loop the two bellies of the omohyoid muscle and the sternohyoid and sternothyroid muscles are supplied as described above.

The **muscular branches** supply the rectus capitis lateralis, the longus capitis (rectus capitis anterior major), the rectus capitis anterior (minor), the scalenus anterior, and the diaphragm. The nerve to the latter muscle is the **phrenic.**

1. The **branch to the rectus capitis lateralis** is furnished to that muscle by the first cervical nerve as it crosses the deep surface of the muscle.

2. The **nerve to the rectus capitis anterior** (minor) is given off by the first nerve at the upper part of the loop in front of the transverse process of the atlas.

3. The **longus capitis** (rectus capitis anterior major) receives twigs from the upper four cervical nerves.

4. The **longus colli** receives branches from the second, third, and fourth cervical nerves, and additional branches also from the fifth and sixth nerves.

5. The **phrenic nerve** (fig. 783) springs chiefly from the fourth cervical nerve, but it usually receives a twig from the third and another from the fifth cervical nerve, a small communicating branch from the sympathetic, and, rarely, a branch from the vagus. The twig from the fifth cervical nerve is frequently connected with the nerve to the subclavius. After the union of its roots the phrenic nerve passes downward and medialward on the scalenus anterior (figs. 501, 786). In this part of its course it is crossed by the tendon of the omohyoid and by the transverse cervical and transverse scapular (suprascapular) arteries. It is overlapped by the internal jugular vein, and it is covered by the sternomastoid muscle. At the root of the neck the left phrenic nerve lies behind the terminal portion of the thoracic duct, and each nerve passes off the anterior border of the scalenus anterior and descends in front of the first part of the subclavian artery and the pleura immediately below that artery; each nerve passes dorsal to the terminus of the subclavian vein, crosses either in front of or dorsal to the internal mammary artery and gains the medial surface of the pleural sac. From the root of the neck the relations of the phrenic nerves differ (fig. 501).

The right phrenic nerve descends along the medial surface of the right pleural sac and crosses in front of the root of the lung. It is accompanied by the pericardiacophrenic artery (comes nervi phrenici), and it is in relation medially, and from above downward, with the right innominate vein, the superior vena cava, and the pericardium, the latter membrane separating it from the wall of the right atrium. The **left phrenic nerve** descends along the medial surface of the left pleural sac accompanied by the pericardiacophrenic artery. In the superior mediastinum it lies between the left common carotid and the left subclavian arteries, and it crosses in front of the left vagus, the left superior intercostal vein, and the arch of the aorta. Below the arch of the aorta it crosses in front of the root of the left lung, and then lies along the left lateral surface of the pericardium, which separates it from the wall of the left ventricle.

Branches.—Both phrenic nerves distribute branches to the pericardium and to the pleura. The right nerve gives off a branch, **pericardiac**, which accompanies the superior vena cava and supplies the pericardium. Each phrenic nerve divides into numerous terminal **phrenicoabdominal** branches. As a rule, the *right phrenic* nerve divides into two main terminal branches, an anterior and a posterior. The *anterior* branch runs forward and one of its terminal filaments anastomoses with the phrenic of the opposite side in front of the pericardium; others descend between the sternal and costal attachments of the diaphragm into the abdomen, where some of them supply the diaphragm and others descend in the falciform ligament to the peritoneum on the upper surface of the liver. The *posterior* branch passes through the vena caval opening and ramifies upon the lower surface of the diaphragm, anastomosing with the diaphragmatic plexus of the sympathetic, and its terminal branches supply the muscular fibers of the right half of the diaphragm, the inferior vena cava, and the right suprarenal gland.

The *left phrenic* nerve divides into several branches. One of the most anterior branches anastomoses with the right phrenic nerve; the others pierce the diaphragm and ramify on its lower surface, where they anastomose with filaments of the left diaphragmatic plexus of the sympathetic and supply the left half of the diaphragm and the left suprarenal gland. The left phrenic nerve is considerably longer than the right nerve, partly on account of the lower level of the diaphragm on the left side, and partly on account of the greater convexity of the left side of the pericardium.

THE BRACHIAL PLEXUS

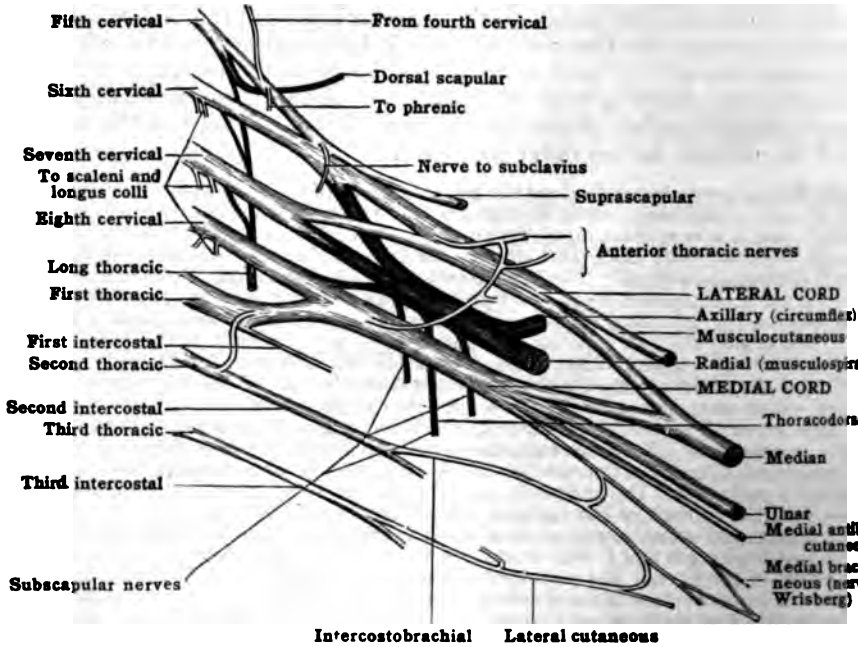
The **brachial plexus** (figs. 782, 785, 786) is formed by the anterior primary divisions of the **four lower cervical nerves** and the greater part of that of the **first thoracic nerve.** It is usually joined by small twigs from the **fourth cervical** and **second thoracic nerves.**

The anterior primary divisions of the lower four cervical nerves, after passing dorsal to the vertebral artery and between the anterior and posterior parts of the intertransverse muscles, pass into the posterior triangle in the interval between the adjacent borders of the anterior and middle scalene muscles, where those of the fifth and sixth nerves receive a gray ramus communicans each from the middle cervical sympathetic ganglion, and those of the seventh and eighth nerves each receives a gray ramus from the inferior cervical sympathetic ganglion. The anterior primary division of the first thoracic is connected by two rami communicantes with the first thoracic sympathetic ganglion, and it divides into a smaller and a larger branch. The smaller branch passes along the intercostal space as the

first intercostal nerve, and the larger branch, after being joined by a twig from the second thoracic nerve, passes upward and lateralward, in front of the neck of the first rib and behind the apex of the pleural sac, into the lower part of the posterior triangle of the neck, where it takes part in the formation of the plexus.

Trunks and branches.—The anterior primary divisions of those cervical nerves that form the brachial plexus show typically the following relations (fig. 785). The fifth and sixth cervical divisions unite to form the *upper trunk;* the seventh cervical forms the *middle trunk;* the eighth cervical and first thoracic form the *lower trunk* of the plexus. Each of these trunks divides into an *anterior* and a *posterior branch.* Variations in the mode of formation of the trunks and branches are so numerous that many different forms of the plexus have been described.

FIG. 785.—DIAGRAM OF A COMMON FORM OF BRACHIAL PLEXUS.
The posterior branches and cord of the plexus are darkly shaded.



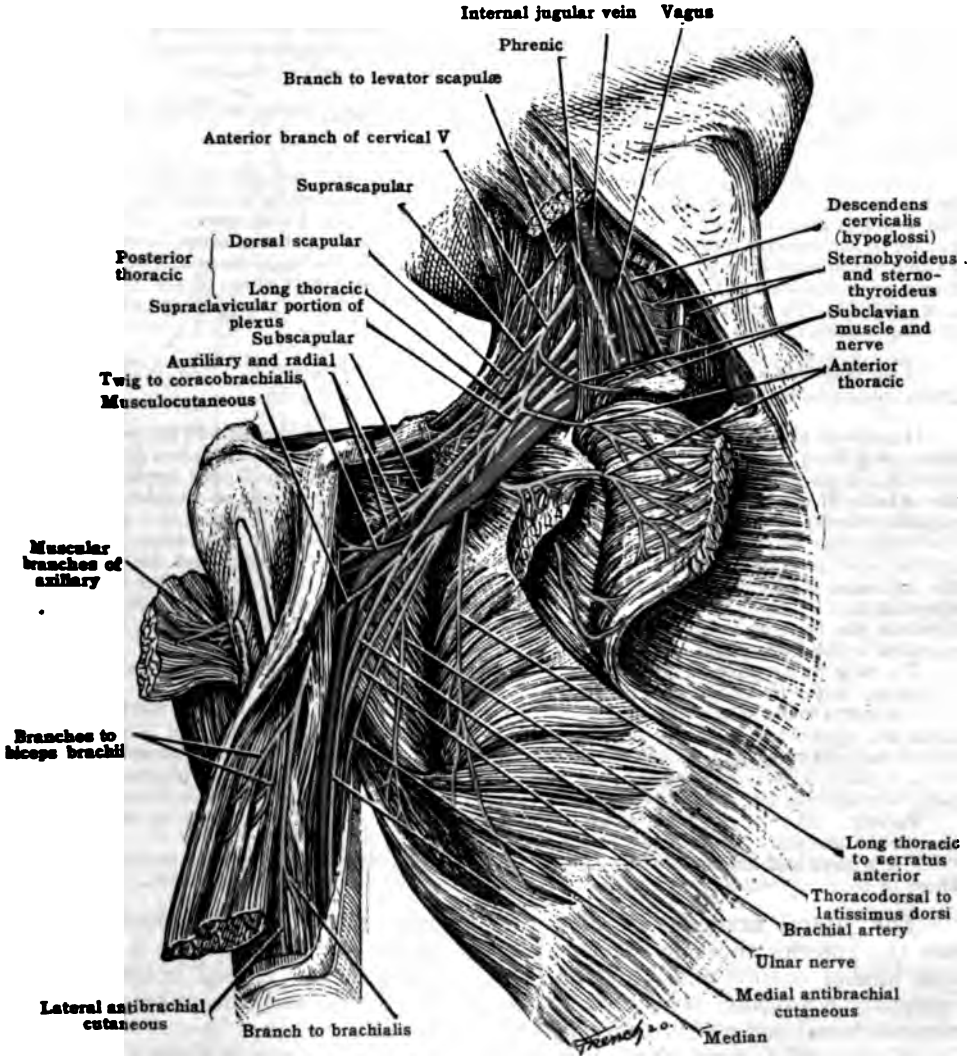
Three cords [fasciculi] are formed from these branches in the following manner:—(1) The **lateral** (outer) **cord** [fasciculus **lateralis**] is formed by the anterior branches of the upper and middle trunks (**anterior primary divisions** of the fifth, sixth, and seventh nerves); (2) the **medial (inner) cord** [fasciculus medialis], by the anterior branch of the lower trunk (**eighth cervical** and first thoracic nerves); and (3) the **posterior cord** [fasciculus **posterior**], by the posterior branches of all of these trunks and nerves.

In a study of 175 brachial plexuses, Kerr found that over 62 per cent. of them receive a communication from the anterior primary division of the fourth cervical nerve. Of those which receive no branch from this nerve, nearly 30 per cent. of the 175 plexuses studied receive the entire anterior primary division of the fifth cervical nerve. In most of the remaining 10 per cent., a part of the fifth nerve helps to form the cervical plexus. Brachial plexuses receiving the branch from the fourth cervical nerve are found more cephalic with reference to the vertebral column than these which do not receive it. Those which receive the largest part of the fifth cervical nerve are most caudal. He divides the plexuses studied into three groups and within these pictures eight types of forms.

Relations.—The plexus extends from the lateral border of the scalenus anterior, where the roots of its constituent nerves appear, to the lower border of the pectoralis minor, where each of its three cords divides into two terminal branches, and it lies in the posterior triangle, in the root of the neck, and in the axillary fossa. In the posterior triangle and in the root of the neck it is in relation behind with the scalenus medius (figs. 782, 786). In the posterior triangle it is covered superficially by the skin and superficial fascia, the platysma, the supraclavicular branches of the cervical plexus, and the deep fascia, and it is crossed by the lower part of the external jugular vein, by the nerve to the subclavius, the transverse cervical vein and the transverse scapular (suprascapular) vein, the posterior belly of the omohyoid muscle, and by

transverse cervical artery. At the root of the neck it lies behind the clavicle and the subclavius muscle, and the transverse scapular (suprascapular) artery crosses in front of it. In the axillary fossa the cords are arranged around the axillary artery, the lateral cord lying lateral to the artery, the medial cord medial to it, and the posterior cord dorsal to the artery. In this region the posterior relations of the plexus are the fat in the upper part of the fossa and the subscapularis muscle, and it is covered in front by the pectoral muscles and the coracoclavicular fascia. The lower border of the plexus is in relation in the posterior triangle and at the root of the neck with the pleura and the first rib, and it is overlapped in front by the third part of the subclavian artery. In the axillary fossa the medial cord, which forms the lower border of the plexus, is overlapped anteriorly by the axillary vein. The upper and lateral border of the plexus has no very important relations.

FIG. 786.—THE BRACHIAL PLEXUS AND ITS BRANCHES OF THE REGION OF THE NECK AND SHOULDER. (After Toldt, Atlas of Human Anatomy,' Rebman, London and New York.)



In summary the brachial plexus may be formulated as beginning with five nerves and terminating in five nerves, with its intermediate portions displayed in sets of threes. It begins with the fifth, sixth, seventh and eighth cervical and first thoracic nerves (anterior primary divisions); it terminates as a plexus with the formation of the musculocutaneous, radial, axillary, median, and ulnar nerves; in its intermediate portions, first, three main trunks are formed and these divide into two sets of threes which, by union, give rise to three cords. The **branches from the cords** are three main lateral branches from each and the terminal branches of the plexus. The *lateral branches*, according as they are given off

above, below, and dorsal to the clavicle, are grouped as the *supraclavicular*, the *infraclavicular* and the *subscapular portions* of the plexus (figs. 785, 786).

The branches of the supraclavicular portion.—After the roots of the plexus have received communications from the sympathetic, which have already been referred to, they give off a series of muscular branches, viz.—the posterior thoracic nerves (the dorsal scapular and the long thoracic nerve), the suprascapular nerve, a twig to the phrenic, the nerve to the subclavius, and small twigs to the scalene muscles and the longus colli muscle.

The **posterior thoracic nerves** are two in number:—(*a*) the **dorsal scapular** (nerve to the rhomboids) arises principally from the fifth cervical nerve, but it frequently receives a twig from the fourth nerve (fig. 782).

It passes downward and dorsalward, across the middle scalene, parallel with and below the spinal accessory nerve to the anterior border of the levator scapulæ, under which it disappears. It continues its descent under cover of the levator scapulæ and the rhomboids almost to the lower angle of the scapula, lying a little medial to the posterior border of the bone, and it supplies the lower fibers of the levator and the smaller and larger rhomboid muscles.

(*b*) The **long thoracic nerve** (external respiratory nerve of Bell) supplies the serratus anterior.

It usually arises, by three roots, from the fifth, sixth, and seventh cervical nerves. The last is sometimes absent (figs. 782 and 785). The upper two roots traverse the substance of the scalenus medius; the root from the seventh passes in front of that muscle. Twigs are furnished to the superior portion of the serratus anterior by the upper two roots; lower down they unite and are subsequently joined by the root from the seventh when present. The trunk of the nerve passes downward behind the brachial plexus and the first stage of the axillary artery and runs along the axillary surface of the serratus anterior (magnus), supplying twigs to each of the digitations of that muscle (fig. 786).

The **suprascapular nerve** (figs. 782, 785, 786) supplies the supraspinatus and infraspinatus muscles.

It receives fibers from the fifth and sixth cervical nerves, and in about 50 per cent. of cases also a twig from the fourth nerve. It is a nerve of considerable size, and it passes downward and dorsalward parallel with the dorsal scapular nerve, at first along the upper border of the posterior belly of the omohyoid muscle, then internal to the latter muscle and under cover of the anterior border of the trapezius to the suprascapular notch, where it comes into relation with the transverse scapular (suprascapular) artery. It is separated from the artery at the notch by the superior transverse ligament, the nerve passing through the notch and the artery above the ligament. After entering the supraspinous fossa the nerve supplies branches to the supraspinatus and a branch to the shoulder-joint; then it descends through the great scapular notch between the bone and the inferior transverse ligament to the infraspinous fossa, where it terminates in the infraspinatus muscle.

The **twig to the phrenic** (figs. 782, 785) arises from the fifth cervical nerve close to the point where the latter nerve receives its twig from the cervical plexus.

The **nerve to the subclavius** (figs. 785, 786) is a small twig which arises from the fifth nerve or from the upper trunk of the plexus, but occasionally it receives additional fibers from the fourth and sixth nerves. It runs downward in front of the lower part of the plexus and the third stage of the subclavian artery and, after giving off sometimes a branch to the phrenic, pierces the posterior layer of the coracoclavicular fascia, and enters the subclavius at its lower border.

Variety.—In rare cases the entire phrenic nerve may pass *via* the nerve to the subclavius in front of the third stage of the subclavian artery.

The *scaleni* and *longus colli* (figs. 782, 785) are supplied by twigs which arise from the lower three or four cervical nerves immediately after their exit from the intervertebral foramina.

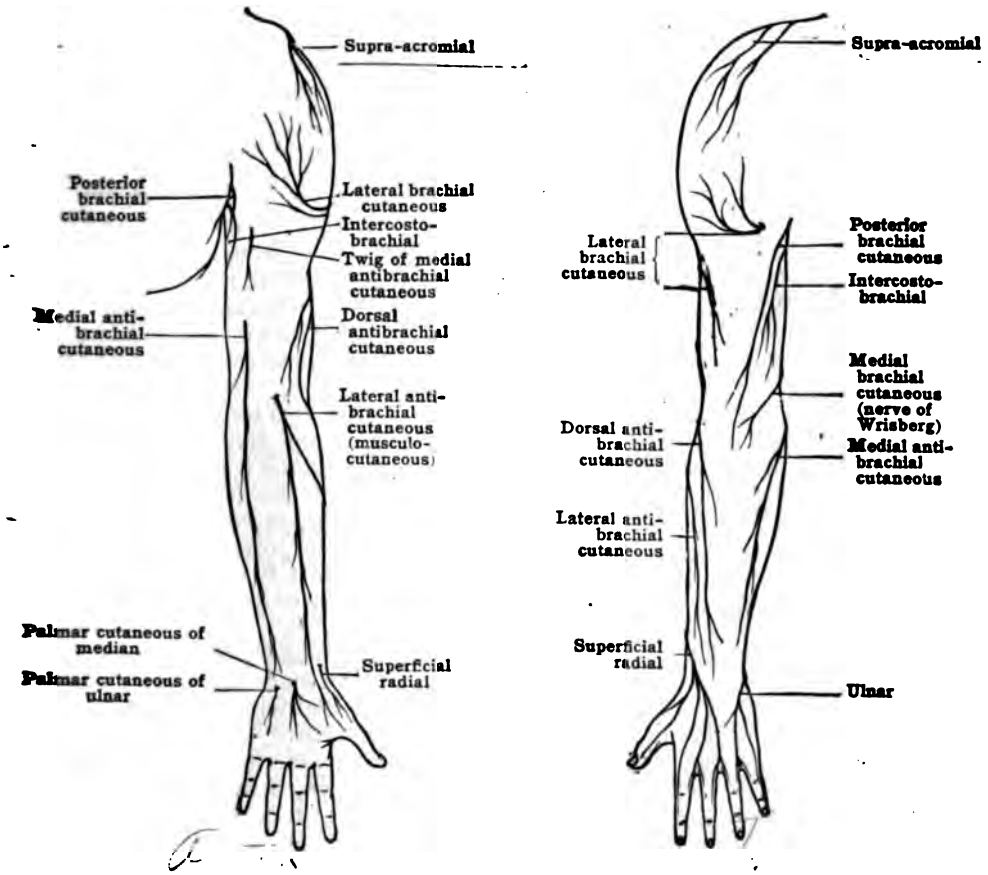
The lateral branches of the infraclavicular portion of the brachial plexus are the anterior thoracic nerves, from the lateral and medial cords respectively; the medial antibrachial (internal) cutaneous and the medial brachial (lesser internal) cutaneous nerves, from the medial cord, and the subscapular and thoracodorsal nerves from the posterior cord.

The **lateral anterior thoracic nerve** joins with the medial to form a loop which supplies the pectoralis major and minor.

It arises from the lateral cord of the plexus and contains fibers from the fifth, sixth, and seventh cervical nerves (figs. 782, 785, 786). After joining the medial anterior thoracic it pierces the coracoclavicular fascia and ends in branches that supply the pectoralis major muscle. The medial anterior thoracic nerve arises from the medial cord (figs. 782, 785, 786), contains fibers from the eighth cervical and first thoracic nerves, and passes forward between the first stage of the axillary artery and the axillary vein. It unites with a branch from the lateral anterior thoracic, to form a loop which is placed in front of the first stage of the axillary artery; it gives branches to the pectoralis minor, and branches which pass through the latter muscle and end in the pectoralis major. From the loop additional branches are furnished to the pectoralis major.

The medial brachial (lesser internal) **cutaneous nerve,** (or nerve of Wrisberg, 785, 787), arises from the medial cord of the brachial plexus and in 90 per . of the cases contains fibers from the eighth cervical and first thoracic nerves, sometimes fibers from the first thoracic nerve alone. It runs downward on medial side of the axillary vein, being separated by that vessel from the r nerve, and it continues downward with a slight inclination dorsalward er cover of the deep fascia on the inner side of the arm. At the middle of the it pierces the deep fascia, and near the bend of the elbow it turns somewhat ply dorsalward to supply the integument which covers the olecranon cess (fig. 787).

. 787.—Distribution of Cutaneous Nerves on the Anterior and Posterior Aspects of the Upper Extremity.



As it traverses the axilla the medial brachial cutaneous nerve communicates with the intercostobrachial nerve, forming one, or sometimes two loops (fig, 785). In its course down the arm it gives a few fine twigs to the integument, This nerve may be absent, its place being taken by the intercostobrachial or by part of the posterior brachial (internal) cutaneous branch of the radial (musculospiral) or, rarely, by a branch from the first intercostal nerve. It usually leaves the plexus as a single branch, but sometimes it leaves combined with the medial antibrachial cutaneous nerve.

The medial antibrachial (internal) **cutaneous nerve** (figs. 782, 785) arises from the medial cord in close relation with the ulnar nerve. It contains fibers from the eighth cervical and first thoracic nerves. At its origin it lies directly on the medial side of the axillary artery (fig. 786), but it soon becomes more superficial and then lies in the groove between the artery and the vein. In the upper two-thirds of the arm it lies in front and to the medial side of the brachial artery. It divides into two branches (volar and ulnar) which supply the medial aspect of the forearm.

At the junction of the middle and lower thirds of the arm this nerve pierces the de in company with the basilic vein, and divides into an anterior and a posterior branch. to its division it gives off twigs which pierce the deep fascia and supply the integume upper and medial part of the arm. The volar (anterior) branch is larger than the ul terior); it passes in front of or dorsal to the median basilic vein, and divides into seve which run down the forearm, supplying the integument covering its anterior and medi as far as the wrist, and anastomosing with the branches of the ulnar nerve. The ul terior) branch passes downward and dorsalward in front of the medial condyle of the h and divides into branches which supply the skin on the posteromedial aspect of the It anastomoses with the dorsal antibrachial (inferior external) cutaneous branch of t (musculospiral) nerve and the dorsal branch of the ulnar nerve.

The subscapular nerves are branches of the posterior cord (fig. 785). are usually three in number, distinguished as upper, thoracodorsal or mid lower, and are distributed to the subscapularis, latissimus dorsi, and tere muscles.

The upper or short subscapular nerve is derived from the fifth and sixth cervica It lies in the upper and posterior part of the axillary fossa, and it is distributed exclu the subscapularis muscle. It is occasionally double.

The thoracodorsal (middle, or long subscapular) nerve consists mainly of fiber seventh and eighth cervical nerves, but it may contain fibers from the fifth or the six It passes behind the axillary artery, accompanies the subscapular artery along th margin of the subscapularis muscle, and ends in the latissimus dorsi (fig. 786).

The lower subscapular nerve, carrying fibers from the fifth and sixth cervical nerv behind the subscapular artery, below the circumflex branch (dorsalis scapulæ), and is d to the teres major, and furnishes to the subscapularis one or two twigs which enter th near its axillary margin. In about 50 per cent. of the cases, the subscapular nerves, the upper and lower, may carry fibers from the fourth cervical nerves.

The terminal branches of the brachial plexus are two from each co posterior cord divides into the axillary (circumflex) and the radial (m spiral) nerves. The lateral cord divides into the musculocutaneous ne the lateral root of the median nerve. The medial cord divides into the uln and the medial root of the median nerve, the median nerve as a whole bei the five terminal branches of the plexus.

The axillary (circumflex) nerve is the smaller of the two terminal br the posterior cord, and contains fibers from the fifth and sixth cervica (figs. 782 and 785). At the lower border of the subscapularis it passes do and accompanies the posterior circumflex artery through the quadrilater which is bounded by the teres major, long head of triceps, and subscapul cles, and the surgical neck of the humerus, and it divides into a smaller and a larger inferior division. Previous to its division it furnishes an twig to the shoulder-joint. This twig pierces the inferior part of the capsule.

The superior division accompanies the posterior circumflex artery ar neck of the humerus, and gives off a number of stout twigs which enter toid muscle (fig. 786). A few fine filaments pierce the deltoid and en integument which covers the middle third of that muscle.

The inferior division divides into cutaneous and muscular branch cutaneous branch, the lateral brachial cutaneous nerve, turns around terior border of the deltoid, pierces the deep fascia, and supplies the skin the lower third of the deltoid and a small area of integument below the in the muscle (fig. 787). One muscular branch is distributed to the teres swells out into an ovoid or fusiform, reddish, gangliform enlargemen entering the muscle. Other branches supply the lower and posterior pa deltoid.

The radial (musculospiral) nerve [n. radialis] is the largest branc brachial plexus. It contains fibers from the sixth, seventh, and eighth and often from the fifth cervical or first thoracic nerve (figs. 782, 78 fourth cervical nerve also occasionally contributes fibers to it. It co at the lower border of the pectoralis minor, as the direct continuatio posterior cord of the brachial plexus, and passes downward and lateralwa axillary fossa behind the third part of the axillary artery (fig. 786) and i the subscapularis, latissimus dorsi, and teres major muscles. From t border of the axillary fossa it descends into the arm, where it lies, at fir medial side of the upper third of the humerus, behind the brachial arte front of the long head of the triceps; then it runs obliquely downward an

behind the middle third of the humerus, in the groove for the radial nerve (musculospiral groove), and between the lateral and medial heads of the triceps. It is accompanied, in this part of its course, by the profunda artery. At the junction of the middle and lower thirds of the humerus it reaches the lateral side of the arm, pierces the external intermuscular septum, and runs downward and forward between the brachioradialis and extensor carpi radialis longus externally, and the brachialis internally (fig. 789), and it terminates, a short distance above the epitrochlear, by dividing into deep and superficial terminal branches. In the last part of its course it is accompanied by the anterior terminal branch of the profunda artery.

Branches.—The branches of the radial (musculospiral) nerves are *cutaneous*, *muscular*, *articular*, and *terminal*, but for practical purposes it is best to consider them in association with the situations of their origins. While it is in the axillary fossa the radial nerve gives branches to the medial and long heads of the triceps (fig. 789), and a medial cutaneous branch. The branch to the long head of the triceps at once enters the substance of the muscle, that to the medial head breaks into branches which terminate in the muscle at different levels, and one of them, the *ulnar collateral nerve*, accompanies the ulnar nerve to the lower part of the arm. The **posterior brachial (internal) cutaneous branch** crosses the tendon of the latissimus dorsi, passes dorsal to the intercostobrachial (intercostohumeral) nerve, pierces the deep fascia, and is distributed to the skin of the middle of the back of the arm below the deltoid.

While it lies behind the middle third of the humerus, the radial nerve gives branches to the lateral and medial heads of the triceps and to the anconeus. The latter branch descends in the substance of the median head of the triceps, close to the bone, and it is accompanied by a small branch of the profunda artery. The **dorsal antibrachial (external) cutaneous branch,** passing down between the lateral and median heads of the triceps, divides near the elbow into its upper and lower branches (fig. 787), each of which perforates either the lateral head of the triceps muscle near its attachment to the humerus or the external intermuscular septum.

The upper branch, much the smaller, pierces the deep fascia in the line of the external intermuscular septum; it accompanies the lower part of the cephalic vein, and supplies the skin over the lower half of the lateral and anterior aspect of the arm. The **lower branch** is of considerable size. It pierces the deep fascia a little below the upper branch, runs behind the external condyle, and supplies the skin of the middle of the back of the forearm as far as the wrist, anastomosing with the medial antibrachial (internal) cutaneous and musculocutaneous nerves (fig. 790).

After the radial nerve has pierced the external intermuscular septum it gives branches to the brachioradialis, extensor carpi radialis longus, and to the lateral portion of the brachialis (fig. 790). From one of these branches an articular filament is distributed to the elbow-joint.

The **terminal branches** of the radial nerve are:—a motor branch, the *deep radial*, to the supinator and extensor muscles of the forearm, and a sensory branch, the *superficial radial*, which supplies the dorsal aspect of the radial half of the hand.

The deep radial nerve [ramus profundus] (posterior interosseous) runs downward in the interval between the brachialis and extensor carpi radialis longus. It passes in front of the lateral part of the elbow-joint, and after giving off branches to supply the extensor carpi radialis brevis and supinator, it is crossed in front by the radial recurrent artery (fig. 790). It then runs downward and dorsalward through the substance of the supinator, and enters the interval between the superficial and deep layers of muscles at the back of the forearm, where it comes into relation with the posterior interosseous artery, and accompanies it across the abductor pollicis longus. At the lower border of the latter muscle it gives off a branch to the extensor pollicis longus, and another which crosses this muscle to the extensor indicis proprius.

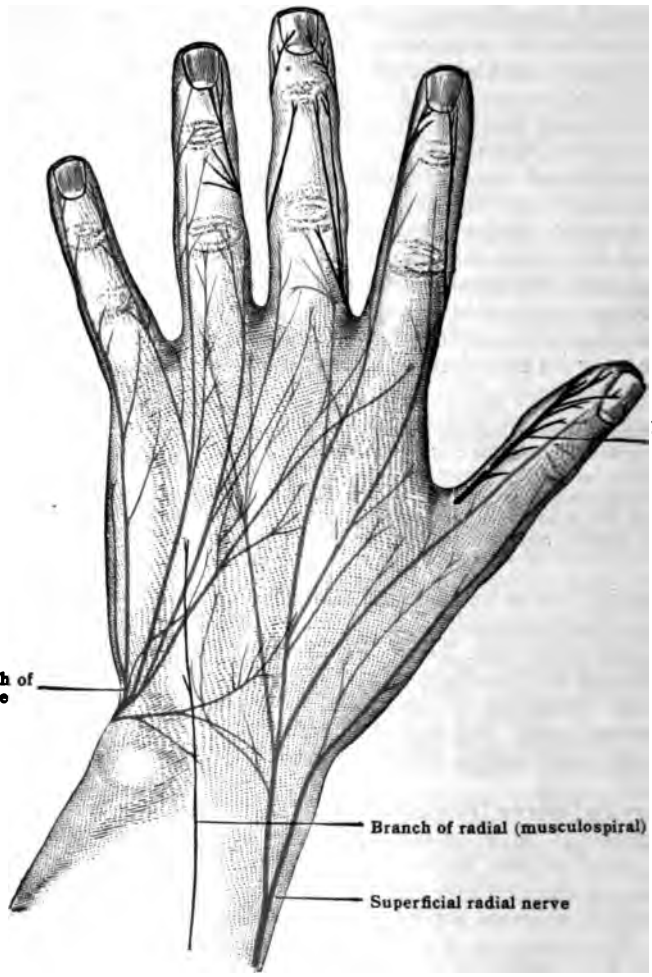
Continuing distalward as the *dorsal antibrachial interosseous* nerve the deep radial leaves the posterior interosseous artery, dips beneath the extensor pollicis longus, and joins the volar interosseous artery. It accompanies this artery upon the interosseous membrane and upon the back of the radius, passes through the groove for the extensor digitorum communis and extensor indicis proprius to the dorsum of the wrist, and terminates in a gangliform enlargement which gives branches to the carpal articulations. The muscles supplied by the deep radial nerve

are the extensor carpi radialis brevis, brachioradialis (supinator longus), extensor dig communis, extensor digiti quinti proprius, extensor carpi ulnaris, extensor indicis propri the extensor muscles of the thumb. The supinator (brevis) receives two twigs, one of is given off before the nerve pierces the muscle and the other while it is passing thro The characteristic 'wrist-drop' due to paralysis of the deep radial nerve is shown in fig. 112

The **superficial radial** (radial) **nerve** [ramus superficialis n. radialis] is what smaller than the deep radial (posterior interosseous), and is a purely neous nerve. It runs downward under cover of the brachioradialis, passi front of the elbow-joint, the radial recurrent artery, and the supinator (br At the lower border of the supinator it approaches the radial artery at an angle, and runs parallel to the lateral side of that vessel in the middle third

FIG. 788.—A DISSECTION OF THE CUTANEOUS NERVES ON THE DORSAL ASPECT OF THE AND FINGERS. (H. St. J. B.)

The branches of the median nerve are shown in black.



forearm, across the pronator teres. At the lower border of the pronator bends dorsalward on the deep surface of the tendon of the brachioradia appears on the back of the forearm. It pierces the deep fascia and is across the dorsal carpal (posterior annular) ligament toward the dorsum wrist, where it divides into its terminal branches (fig. 790).

The most lateral of these branches supplies the skin on the radial part of the ba nence; the most medial, designated the ulnar anastomotic branch, communicates with t branch of the ulnar nerve. The other terminal branches, the dorsal digital nerves, su

variable extent the skin on the dorsum of the first digit, both sides of the second and the radial side of the third digit. These branches usually extend to the base of the nail of the first digit, to the distal interphalangeal joint of the second, not quite to the proximal interphalangeal joint of the third, and to the metacarpophalangeal joint of the fourth digit.

The terminal branches of the lateral cord of the brachial plexus are the musculocutaneous and the *lateral component* of the median nerve. The latter nerve will be described with the medial cord.

The musculocutaneous nerve is composed of fibers derived chiefly from the anterior divisions of the fifth and sixth cervical nerves, together in about 50 per cent. of the cases with some fibers from the fourth and seventh (figs. 782. 785). The nerve to the coracobrachialis usually consists of two or three twigs given off from the nerve close to its origin before it enters the muscle (fig. 786). Sometimes, however the fibers from the seventh cervical nerve pass directly to this muscle without joining the main trunk. The musculocutaneous nerve is placed at first close to the lateral side of the axillary artery (fig. 786), but soon it leaves that vessel and, piercing the coracobrachialis muscle, it passes obliquely downward and lateralward between the biceps and brachialis muscles. Soon after piercing the coracobrachialis it gives off **muscular branches** to each head of the *biceps* and to the *brachialis* (fig. 789). It also gives twigs to the *humerus*, to the *nutrient artery*, and gives the chief supply to the *elbow-joint*. Below the branch to the brachialis the cutaneous portion of the nerve forms the **lateral antibrachial cutaneous nerve** (figs. 787, 789). This portion continues downward between the biceps and brachialis, pierces the deep fascia at the lateral border of the former muscle a little above the bend of the elbow, receives a communication from the upper branch of the dorsal antibrachial (upper external) cutaneous branch of the radial (musculospiral) nerve, passes dorsal to the median cephalic vein, and divides into an anterior and a posterior branch.

The **anterior branch** runs downward on the lateral and anterior part of the forearm, supplying the integument of that region, and it terminates in the skin covering the middle part of the thenar eminence (fig. 790). A short distance above the wrist, after it has received a communicating twig from the superficial radial nerve, it gives off an articular branch to the carpal joints. This branch pierces the deep fascia and accompanies the radial artery to the dorsum of the wrist. The **posterior terminal branch** is small, and is directed downward and backward in front of the external condyle of the humerus, to be distributed to the skin on the lateral and posterior aspect of the forearm as low as the wrist (fig. 787). In anastomoses with the superficial radial and with the lower branch of the dorsal antibrachial (lower external) cutaneous branch of the radial nerve.

The **terminal branches of the medial cord** of the brachial plexus are the ulnar nerve and the *medial component* of the median nerve. Neither of these gives any branches in the upper arm, and thus they differ from the other terminal branches of the plexus. They both supply the muscles and joints of the forearm, and the muscles, joints, and integument of the hand.

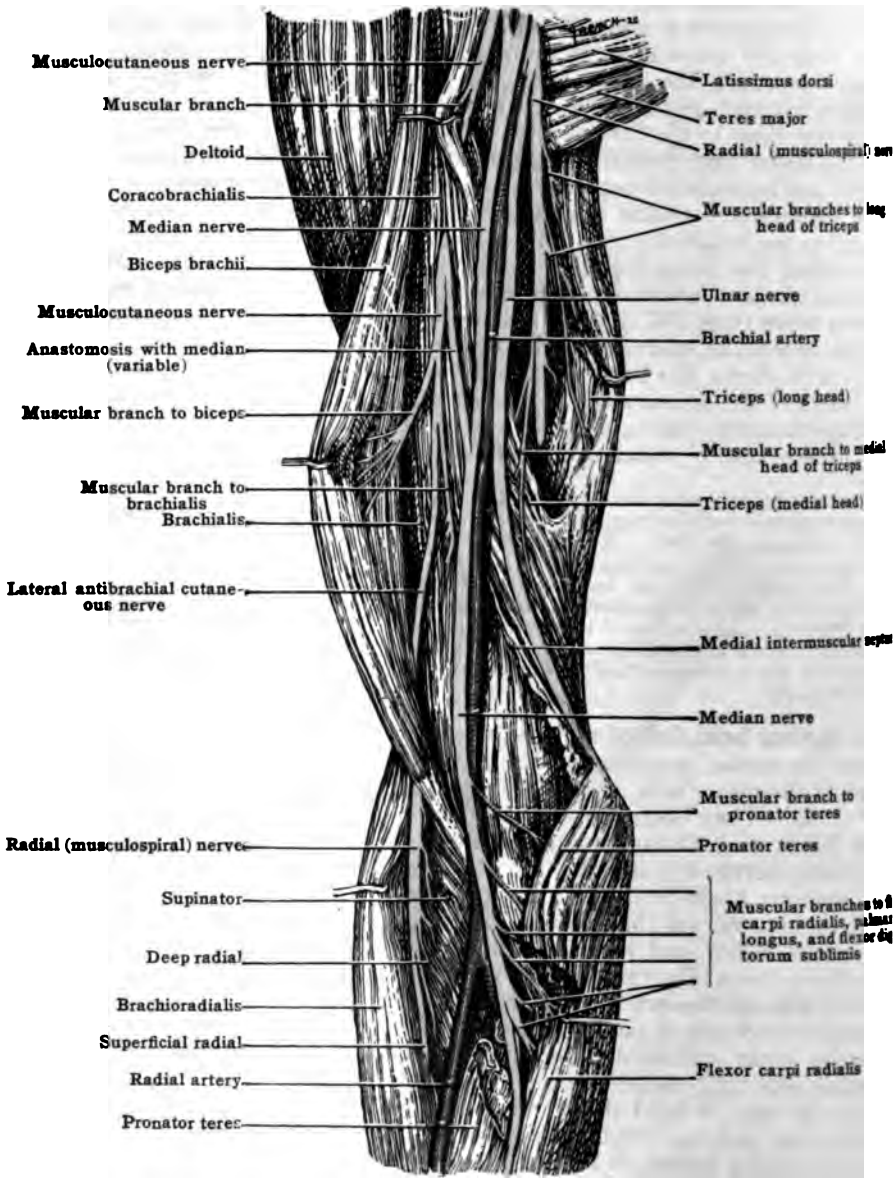
The ulnar nerve, which is the largest branch of the medial cord of the brachial plexus, contains fibers from the anterior primary divisions of the eighth cervical and first thoracic nerves (figs. 785 and 786). It commences at the lower border of the pectoralis minor and runs downward in the axillary fossa in the posterior angle between the axillary artery and vein. In the upper half of the arm it lies on the medial side of the brachial artery (fig. 786), but at the level of the insertion of the coracobrachialis it passes backward at an acute angle, and, accompanied by the superior ulnar collateral (inferior profunda) artery, it pierces the internal intermuscular septum. After passing through the septum it runs downward, in a groove in the medial head of the triceps (fig. 789), to the interval between the olecranon process and the medial condyle of the humerus, and in this part of its course it is closely bound to the muscle by the deep fascia. Immediately below the medial condyle it passes between the two heads of the flexor carpi ulnaris, along the medial side of the medial collateral ligament of the elbow, and it comes into relation with the dorsal ulnar recurrent artery.

In the upper forearm the ulnar nerve lies on the flexor digitorum profundus, covered by the flexor carpi ulnaris. Near the junction of the upper and middle thirds of the forearm it is joined by the ulnar artery, which accompanies it to its termination, lying throughout on its radial side (fig. 790). In the lower part of the forearm it still rests on the flexor digitorum profundus, but between the flexor carpi ulnaris and flexor digitorum sublimis, and is covered by skin and fascia. At a variable point in this part of the forearm, usually about 5 to 8 cm. from the carpus

the nerve divides into its two terminal branches, a dorsal branch to the dorsal aspect of hand and a volar branch to the volar aspect.

Branches.—The ulnar resembles the median nerve in not furnishing branches to the upper arm. As it passes between the olecranon process and medial condyle it gives off two or three fine filaments to the elbow-joint. the upper part of the forearm it supplies the flexor carpi ulnaris and the med

FIG. 789.—NERVES OF THE RIGHT UPPER ARM VIEWED FROM IN FRONT. (Spaltehol



portion of the flexor digitorum profundus, and in the lower half it gives off three cutaneous branches. In the palm of the hand it supplies the integument of the hypothenar eminence, the fifth digit, and half of the fourth digit, and ulnar half of the skin of the dorsum. It also supplies the short intrinsic mu of the hand with the exception of the abductor pollicis, the opponens, the la head of the flexor pollicis brevis, and the two lateral lumbricales. The effec of paralysis of the ulnar nerve are shown in fig. 1130 B and C.

nerves to the flexor carpi ulnaris and to the medial two divisions of the **flexor digitorum us** arise from the ulnar nerve in the upper third of the forearm.

ıneous branches.—About the middle of the forearm the ulnar nerve gives off two **us** branches:—one pierces the fascia and anastomoses with the volar branch of the **antibrachial** (internal) cutaneous nerve, and the other, the **palmar cutaneous branch,** **wnward** in front of the ulnar artery (fig. 790) and is conducted by this vessel into the **g. 792).** It furnishes some filaments to the vessel, supplies a few twigs to the skin of the

the thumb, and the medial head, and occasionally the lateral head, of the flexor pollicis brevis. The **superficial branch** gives off a branch to supply the palmaris brevis muscle, an anastomosing branch to the median nerve, and then divides into two branches, the **proper volar digital branch** which is distributed to the medial side of the fifth digit on its volar aspect, and the **common volar digital branch,** which passes underneath the palmar aponeurosis and divides into two branches, which supply the contiguous margins of the fourth and fifth digits. These branches usually supply also the dorsal surface of the second and third phalanges of the same digits.

The **median nerve** contains fibers of the sixth, seventh, and eighth cervical nerves and of the first thoracic, and sometimes of the fifth cervical nerve. The trunk is formed a little below the lower margin of the pectoralis minor, by the union of two components, one from the medial and one from the lateral cord of the brachial plexus. The medial component passes obliquely across the third part of the axillary artery (fig. 786), and in the upper part of the trunk the fibers of the two components are felted together. From its commencement the median nerve runs almost vertically through the lower part of the axillary fossa and through the arm and forearm to the hand.

In the fossa it lies lateral to the axillary artery and it is overlapped, on its lateral side by the coracobrachialis muscle. In the upper half of the arm it lies along the lateral side of the brachial artery, and it is overlapped by the medial border of the biceps. At the mid...

e arm it passes in front of the brachial artery, and it descends, on the medial side of the y, to the elbow. In the upper part of the antecubital fossa it is still at the medial side of the ial artery, but separated from it by a small interval, and in the lower part of the fossa it lies the medial side of the ulnar artery. In case of the high division of the brachial artery, the radial and the ulnar arteries lie together in the upper arm, the median nerve may pass een them and then one or the other of the arteries will be superficial to the nerve. As ves the antecubital fossa it passes between the two heads of the pronator teres, and it es in front of the ulnar artery (fig. 790), from which it is separated by the deep head of the ator. In the forearm it passes vertically downward, accompanied by the median (comes mediani) artery. In the upper two-thirds of this region it lies deeply, between the flexor orum sublimis and the flexor digitorum profundus, but in the lower third it becomes more rficial, and is placed beneath the deep fascia, between the flexor carpi radialis on the radial

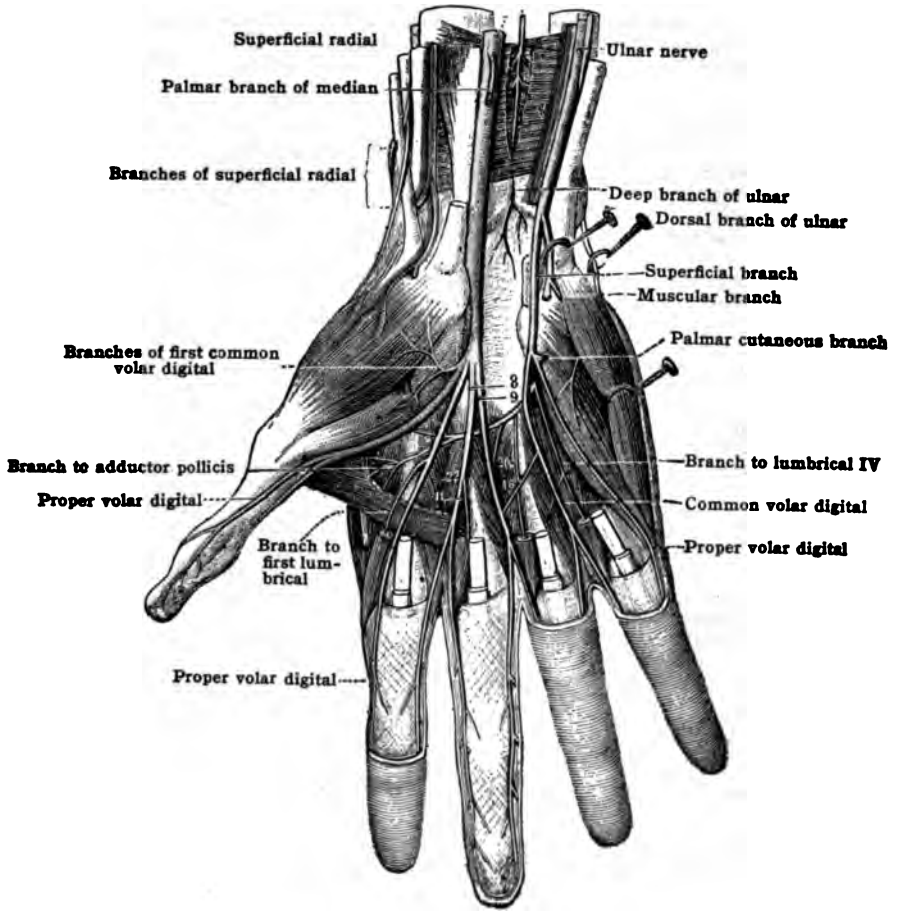
transverse carpal (anterior annular) ligament, superficial volar arch, the flexor tendons of the digits, and the proximal portions of the lumbrical muscles have been removed.



nd the palmaris longus and flexor digitorum sublimus tendons on the ulnar side. It crosses ith the transverse carpal (anterior annular) ligament, in front of the flexor tendons, and palm at the lower border of the ligament it enlarges and divides into three branches, the non volar digital nerves (fig. 791).

Branches.—The median nerve does not supply any part of the upper arm. rarely, it may receive a small branch from the musculocutaneous nerve. ront of the elbow-joint it furnishes one or two filaments to that articulation. he forearm it supplies all the superficial anterior muscles (with the exception e flexor carpi ulnaris) directly from its trunk, and it supplies the deep muscles h the exception of the ulnar half of the flexor digitorum profundus) by its r (anterior) interosseous branch. Thus in general it supplies the pronator flexor muscles of the forearm (radial side). In the hand it supplies the p of short muscles of the thumb, which are placed on the radial side of

the tendon of the flexor pollicis longus, the two lateral lumbricales, the integument covering the central part of the palm and ulnar aspect of the thenar eminence, and the dorsal and palmar aspects of the first, second, third, and radial half of the fourth digits. The effects of paralysis of the median nerve are shown in fig. 1130 A.

The **nerve to the pronator teres** usually arises a little above the bend of the elbow, and pierces the lateral border of the muscle (figs. 790 and 792). It may arise in a common trunk with the following nerves:—

The nerves to the **flexor carpi radialis, palmaris longus,** and **flexor digitorum sublimis** arise a little lower down, and pierce the pronator-flexor mass of muscles to end in the respective members of the group for which they are destined (fig. 789).

The **volar (anterior, antibrachial) interosseous nerve** arises from the median at the level of the bicipital tubercle of the radius (fig. 790), and runs downward, on the interosseous membrane, accompanied by the volar (anterior) interosseous artery. It passes under cover of the pronator quadratus, and pierces the deep surface of that muscle, which it supplies. The volar interosseous nerve also furnishes a twig to the front of the wrist-joint, and supplies the flexor digitorum profundus and the flexor pollicis longus. The nerve to the former muscle arises from the volar interosseous near its commencement; it supplies the lateral two divisions of the muscle, and it communicates within the substance of the muscle with twigs derived from the ulnar nerve.

It also supplies a branch to the interosseous membrane which runs downward upon, or in, the membrane, supplying it and giving branches to the volar (anterior) interosseous and nutrient arteries and to the periosteum of the radius, the ulna, and the carpus.

The **palmar cutaneous branch** [ramus palmaris] arises immediately above the transverse carpal (anterior annular) ligament and passes between the tendons of the flexor carpi radialis and the palmaris longus (fig. 790). It then crosses the superficial surface of the transverse carpal ligament, and is distributed to the integument and fascia on the central, depressed surface of the palm. It also supplies a few twigs to the medial border of the thenar eminence; these twigs communicate with the musculocutaneous and superficial radial nerves.

The three **common volar digital nerves** pass in the palm of the hand dorsal to the superficial volar arch and its digital branches, while the **proper volar digitals,** branches of these nerves, lie on the volar side of the digital arteries.

The **first** of the common volar digital nerves gives off a branch to supply the abductor pollicis, the opponens, and the superficial head of the flexor pollicis brevis, and joins by a delicate branch with the deep branch of the ulnar nerve. It then divides into three **proper volar digitals** (fig. 792). The lateral of these passes obliquely across the long flexor tendon of the thumb and runs along the radial border of the thumb to its extremity. It gives numerous branches to the pulp of the thumb, and a strong twig which passes to the dorsum to supply the matrix of the nail. The second of these proper volar digitals supplies the medial side of the volar aspect of the thumb and gives off a twig to the matrix of the thumb nail. The third supplies the radial side of the second digit and gives a twig to the first lumbrical muscle.

The **second** common volar digital sends a twig to the second lumbrical muscle, and divides a little above the metacarpophalangeal articulation into two **proper volar digitals,** which respectively supply the adjacent sides of the second and third digits (fig. 791).

The **third** common volar digital communicates with the ulnar nerve, often gives a branch to the third lumbrical muscle, and divides into two **proper volar digitals** which supply the adjacent sides of the third and fourth digits.

As the proper volar digitals pass along the margins of the fingers they give off twigs for the innervation of the skin on the dorsum of the second and third phalanges and the matrix of their nails. Each of the nerves terminates in filaments to the pulp of the finger.

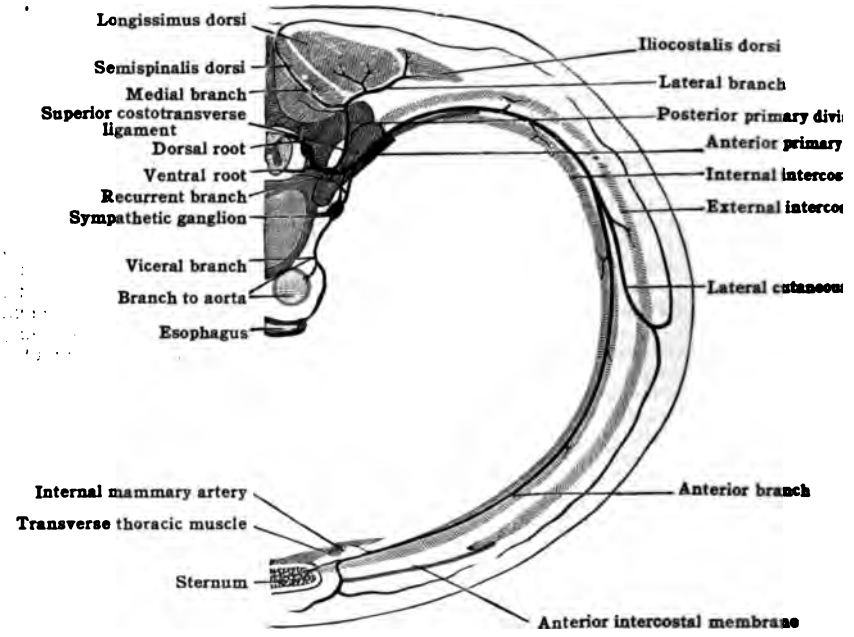
2. THE THORACIC NERVES

The **anterior primary divisions of the thoracic nerves,** with the exception of the first and usually the twelfth, retain, in the simplest form, the characters of anterior primary divisions of the typical spinal nerve. They do not form plexuses, but remain distinct from each other. Each divides into an easily recognizable lateral or dorsal and anterior or ventral branch (figs. 793 and 794), and they are not distributed to the limbs. The first, second, and last thoracic nerves, on account of their peculiarities, require separate description. The remainder are separable into two groups, an upper and a lower. The **upper group** consists of four nerves, the third to the sixth inclusive, which are distributed entirely to the thoracic wall. The **lower group** contains five nerves, the seventh to the eleventh inclusive, which are distributed partly to the thoracic and partly to the abdominal wall. The upper group is therefore purely thoracic in distribution, and the lower thoracoabdominal. All the thoracic nerves are connected with the smpathetic trunk by means of both white and gray rami communicantes.

The first thoracic nerve is connected with the first thoracic sympathetic ganglion, and it frequently is joined by a small branch with the second nerve (fig. 785). Its anterior primary division is distributed chiefly to the upper limb. Opposite

The **second thoracic nerve,** as it lies between the pleura and the costotransverse ligament of the third rib, gives a branch to the first ne it pierces the posterior intercostal membrane and passes between the ext

FIG. 793.—DIAGRAM OF THE DISTRIBUTION OF A TYPICAL THORACIC NER



internal intercostal muscles in the second intercostal space. In the do of the space it sends branches backward, through the external intercosta to supply the second levator costæ and the serratus posterior superior, it divides into a *lateral* and an *anterior* branch (fig. 793). The two bra forward together to the midaxillary line, where the lateral branch pi external intercostal muscle and passes between two digitations of the

thoracic intercostal nerves (upper group).—The anterior primary divi- the third, fourth, fifth, and sixth thoracic nerves, in the posterior parts

ıtercostal spaces, give **muscular branches** to the levatores costarum, the he fourth also giving branches to the serratus posterior superior. They ward a short distance between the external and internal intercostals,

giving twigs to these muscles, and divide into two branches, lateral and anterior (figs. 793, 794).

The **lateral cutaneous branches** continue forward between the intercostal muscles, and, near the midaxillary line, pierce the external intercostals and serratus anterior and divide each into two branches, posterior and anterior. The *posterior branches* pass backward over the latissimus dorsi to supply the skin in the lower part of the scapular region. The *anterior branches*, in the four nerves, increase in size from above downward. They pass around the lateral border of the great pectoral muscle and are distributed to the integument over the front of the thorax and mamma, sending filaments, the *lateral mammary branches*, into the latter organ. The lowest two nerves also supply twigs to the upper digitations of the external oblique muscle.

The **anterior branches** run obliquely forward and medialward through the substance of the internal intercostal muscles, reaching the deep surface of these muscles at the extremity of the costal cartilages (fig. 793). They continue forward between these muscles and the pleura, pass in front of the internal mammary artery, turn abruptly ventralward a short distance from the sternum, pierce the internal intercostals, the anterior intercostal membrane, and the pectoralis major, and give off three sets of terminal branches. One set supplies the transverse thoracic muscle and the back of the sternum. A second set, cutaneous, runs mesially. The third set passes laterally over the pectoralis major, supplying the skin in that region, and, in the female, the mammary gland through the **medial mammary branches.** The anterior branches in their course supply the intercostal and subcostal muscles and give filaments that supply the ribs, the periosteum, and the pleura.

The thoracoabdominal nerves (lower group).—The relations of the posterior portions of the anterior primary divisions of the seventh, eighth, ninth, tenth, and eleventh thoracic nerves to the thoracic wall are similar to those of the upper thoracic intercostal nerves. Each divides in a similar manner into a *lateral* and an *anterior* branch, but these branches are distributed partly to the abdominal and partly to the thoracic wall, and the smaller muscular branches have also different distributions (fig. 794).

The **lateral cutaneous branches,** *lateral cutaneous nerves of the abdomen,* pierce the external intercostal muscles and pass through or between the digitations of the external oblique into the subcutaneous tissue, where they divide in the typical way into anterior and posterior branches. The *posterior branches* pass backward over the latissimus dorsi. The *anterior branches* give filaments to the digitations of the external oblique and extend forward, medialward and downward to the lateral border of the sheath of the rectus.

The **anterior cutaneous branches** pass forward between the external and internal intercostal muscles, to the ends of the intercostal spaces; there they insinuate themselves between the interdigitating slips of the diaphragm and the transversus abdominis and enter the abdominal wall. Those of the seventh, eighth, and ninth nerves, in their transit from the thoracic to the abdominal wall, pass behind the upturned ends of the eighth, ninth, and tenth costal cartilages respectively. Having entered the abdominal wall the nerves run forward between the transversus abdominis and the internal oblique muscles to the lateral border of the rectus abdominis, where they pierce the posterior lamella of the internal oblique aponeurosis and enter the sheath of the rectus. In the sheath they pass through the substance of the rectus. Finally they turn directly forward, pierce the anterior part of the sheath, and become **anterior cutaneous nerves of the abdomen.**

The muscular branches.—Muscular branches from all the thoracoabdominal nerves are distributed to the levatores costarum, the intercostal muscles, the transversus abdominis, the internal oblique, and to the rectus abdominis, and the ninth, tenth, and eleventh nerves gives branches also to the serratus posterior inferior. Branches are also distributed from a variable number of the lower nerves to the costal portions of the diaphragm.

The last thoracic nerve. - The anterior primary division of the last thoracic nerve is distributed to the wall of the abdomen and to the skin of the upper and front part of the buttock (fig. 794). It appears in the thoracic wall immediately below the last rib, where a ramus joins it with the sympathetic trunk, and gives off

a communicating branch to the first lumbar nerve. It passes from the thorax into the abdomen beneath the lateral lumbocostal arch (external arcuate ligament), accompanied by the subcostal artery, and it runs across the upper part of the quadratus lumborum, dorsal to the kidney and to the ascending or the descending colon according to the side considered. At the lateral border of the quadratus lumborum it pierces the aponeurosis of attachment of the transversus abdominis muscle and divides, between the transversus and the internal oblique muscle, into a *lateral* and an *anterior* branch. It gives branches to the transversus abdominis, the quadratus lumborum, and the internal oblique muscles.

The **anterior branch** passes forward, between the internal oblique and the transversus abdominis, to which it supplies twigs. It enters the sheath of the rectus, turns forward through that muscle, and terminates in branches which become cutaneous midway between the umbilicus and the symphysis. Before it becomes cutaneous it supplies twigs to the transversus abdominis, the internal oblique, the rectus abdominis, and the pyramidalis muscles.

The **lateral branch** pierces the internal oblique; it supplies the lowest digitation of the external oblique, and then pierces the latter muscle from 2.5 to 8 cm. (1 to 3 in.) above the iliac crest, and descends in the superficial fascia of the anterior part of the gluteal region, crossing the iliac crest about 2.5 cm. (1 in.) behind its anterior extremity, reaching as far down as the level of the great trochanter. Occasionally this branch is absent and its place is taken by the iliac branch of the iliohypogastric. In such cases, however, the branch from the last thoracic to the first lumbar nerve is larger than usual.

THE LUMBOSACRAL PLEXUS

The lumbosacral plexus (fig. 795) is formed by the union of the *anterior primary divisions* of the lumbar, sacral, and coccygeal nerves. In about 50 per cent. of cases it receives a branch from the twelfth thoracic nerve. Its components are distributed to the lower extremity in a manner homologous and similar to the distribution of the parts of the brachial plexus to the upper extremity; the lumbar nerves are distributed similarly to the nerves formed from the anterior (medial and lateral) cords of the brachial plexus, and the sacral nerves are distributed in a manner similar to the distribution of the nerves from the posterior cord of the brachial plexus.

Partly for convenience of description and partly on account of the differences in position and course of some of the nerves arising from it, this plexus is subdivided into four parts—the lumbar, sacral, pudendal, and coccygeal plexuses. These plexuses overlap so that there is no definite line of demarcation between them in origin and distribution. However, they will be considered separately.

3. THE LUMBAR NERVES

The anterior primary divisions of the five lumbar nerves increase in size from the first to the last. Each lumbar nerve is connected by one or two long, slender rami with a lumbar sympathetic ganglion. The first three nerves and the greater part of the fourth enter into the formation of the lumbar plexus, and the smaller part of the fourth and the fifth nerve commonly unite to form the lumbosacral trunk which takes part in the formation of the sacral plexus (figs. 795, 796). When the fourth nerve enters into the formation of both lumbar and sacral plexuses, it may be called the *furcal nerve*, but this name is also applied to any of the nerves that enter into the formation of both plexuses, so there may be one or more furcal nerves.

THE LUMBAR PLEXUS

Although the **lumbar plexus** is ordinarily formed by the anterior primary divisions of the first three lumbar nerves and a part of the fourth, yet it is subject to considerable variation in the manner of its formation.

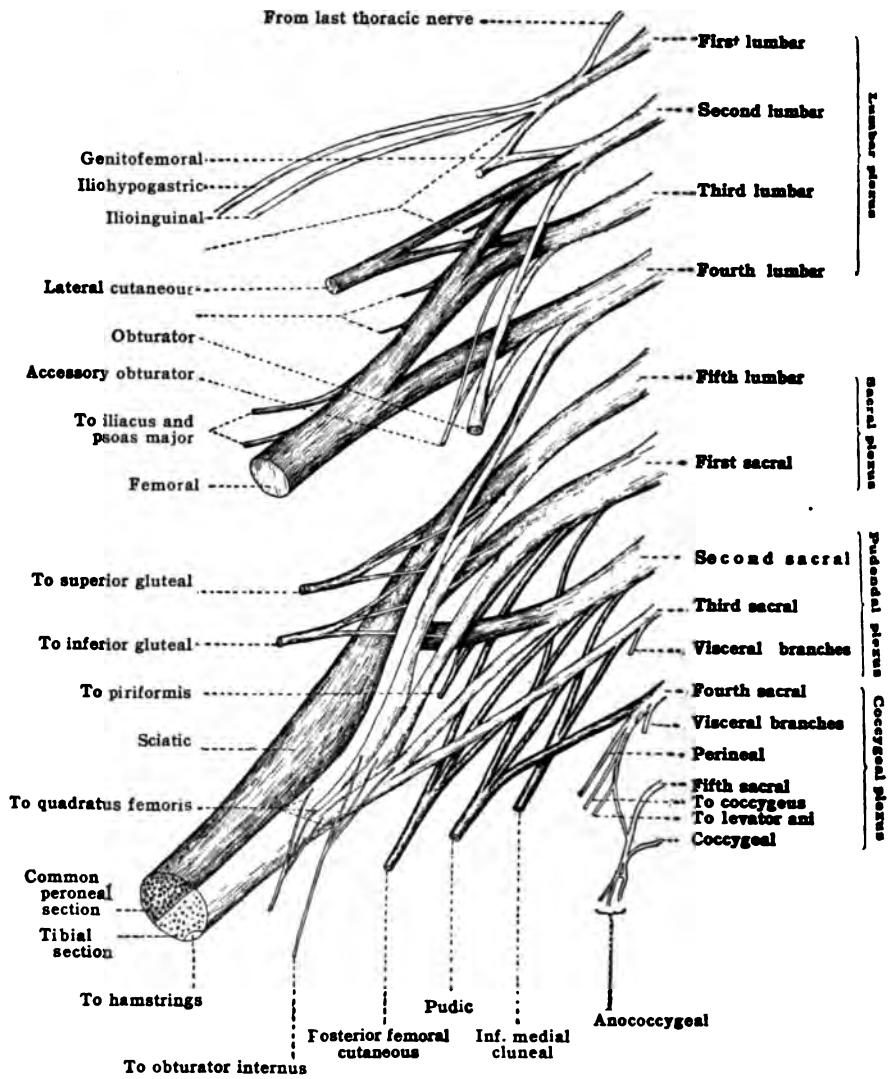
Owing to this variation three general classes of plexuses may be found, **prefixed** (proximal), **ordinary**, and **postfixed** (distal). The basis of classification is the relation of the nerves of the limb to the spinal nerves which enter into their formation. The intermediate or slighter degrees of variation may consist only of changes in the size of the portions contributed by the different spinal nerves to a given peripheral nerve, for a given nerve may receive a larger share of its fibers from a spinal nerve more anterior (cephalad) in position, and a smaller share from a more posterior nerve, or *vice versa*. However, in the more marked degrees of variation the origin of a given peripheral nerve may vary in either direction to the extent of one spinal nerve. The

more extreme types of the plexuses are sometimes associated with abnormal conditions of the vertebral column. It has been suggested that when the prefixed condition occurs, it indicates that the lower limb is placed a segment more cephalad than in the ordinary cases, and when the postfixed condition is present, that the limb is arranged a segment more caudad. Three types each of the prefixed classes and one type of the ordinary class have been described by Bardeen. His statistics are made use of in the compilation of the following tables, in which are shown the common composition and the range of variation of each class of plexus:—

COMMON COMPOSITION (RANGE IN PARENTHESIS)

NERVE	PREFIXED	ORDINARY	POSTFIXED
Lateral (external) cutaneous	1, 2 L (12T–3L)	1, 2, 3 L (1–4L)	2, 3 L (1–4L)
Femoral (anteror crural)....	1, 2, 3, 4 L (12T–4L)	2, 3, 4 L (1–4L)	2, 3, 4, 5 L (1–5L)
Obturator.....	1, 2, 3, 4 L	2, 3, 4 L (1–4L)	2, 3, 4 L (2–5L)
Furcal.....	4 L (3–4L)	4 L	4 L (4–5L)

FIG. 795.—DIAGRAM OF A COMMON FORM OF LUMBOSACRAL PLEXUS. (Modified from Paterson.)



The lumbar plexus lies in the posterior part of the psoas muscle (figs. 7[illegible] 796, 800), in front of the transverse processes of the lumbar vertebræ and t medial border of the quadratus lumborum, and its terminal branches are d tributed to the lower part of the abdominal wall, the front and medial part of t thigh, the external genital organs, the front of the knee, the medial side of the l and the medial side of the foot.

The first and second of the lumbar nerves give collateral *muscular branches* to the quadratus lumborum muscle, and the second the third nerves give similar branches to the psoas. The remaining branches of the plexus are *terminal branches*. The first lumbar nerve, after it has been joined by the branch from the last thoracic nerve, divides into three terminal branches, the iliohypogastric nerve, the ilioinguinal nerve, and a branch which joins the second nerve. The fibers of this latter branch pass mainly into the genitofemoral (genitocrural) nerve, but occasionally some of them enter the femoral (anterior crural) and obturator nerves. The remaining nerves divide into anterior or ventral and posterior or dorsal divisions. The **anterior divisions** form a portion of the genitofemoral (genitocrural) nerve and the obturator nerve, and the **posterior divisions** enter the lateral (external) cutaneous and femoral (anterior crural) nerves.

All the terminal branches of the plexus are formed in the substance of the psoas muscle; four of them, the iliohypogastric, the ilioinguinal, the lateral (external) cutaneous, and the femoral (anterior crural), leave the muscle at its lateral border. The genitofemoral (genitocrural) passes through its anterior surface, and the obturator through its medial border.

Terminal branches.—The **iliohypogastric nerve** springs from the first lumbar nerve, after the latter has been joined by the communicating branch from the last thoracic nerve, as it is in about 50 per cent. of the cases, and it thus contains fibers of both the last thoracic and the first lumbar nerves. It pierces the lateral border of the psoas and crosses in front of the quadratus lumborum (fig. 796), and behind the kidney and the colon. At the lateral border of the quadratus it pierces the aponeurosis of origin of the transversus abdominis and enters the areolar tissue between the transversus and the internal oblique, where it frequently communicates with the last thoracic and with the ilioinguinal nerve, and it divides into an iliac and a hypogastric branch, which correspond, respectively, with the lateral and anterior branches of a typical spinal nerve.

The **anterior cutaneous (hypogastric) branch** passes forward and downward, between the transversus abdominis and the internal oblique muscles, giving branches to both; it communicates with the ilioinguinal nerve, and, near the anterior superior spine of the ilium, it pierces the internal oblique muscle and continues forward beneath the external oblique aponeurosis toward the middle line. About 2.5 cm. above the subcutaneous inguinal ring it pierces the aponeurosis of the external oblique, becomes subcutaneous, and supplies the skin above the symphysis.

The **lateral cutaneous (iliac) branch** pierces the internal and external oblique muscles, emerging through the latter above the iliac crest at the junction of its anterior and middle thirds (fig. 800). It is distributed to the integument of the upper and lateral part of the thigh, in the neighborhood of the gluteus medius and tensor fasciæ latæ muscles (fig. 799).

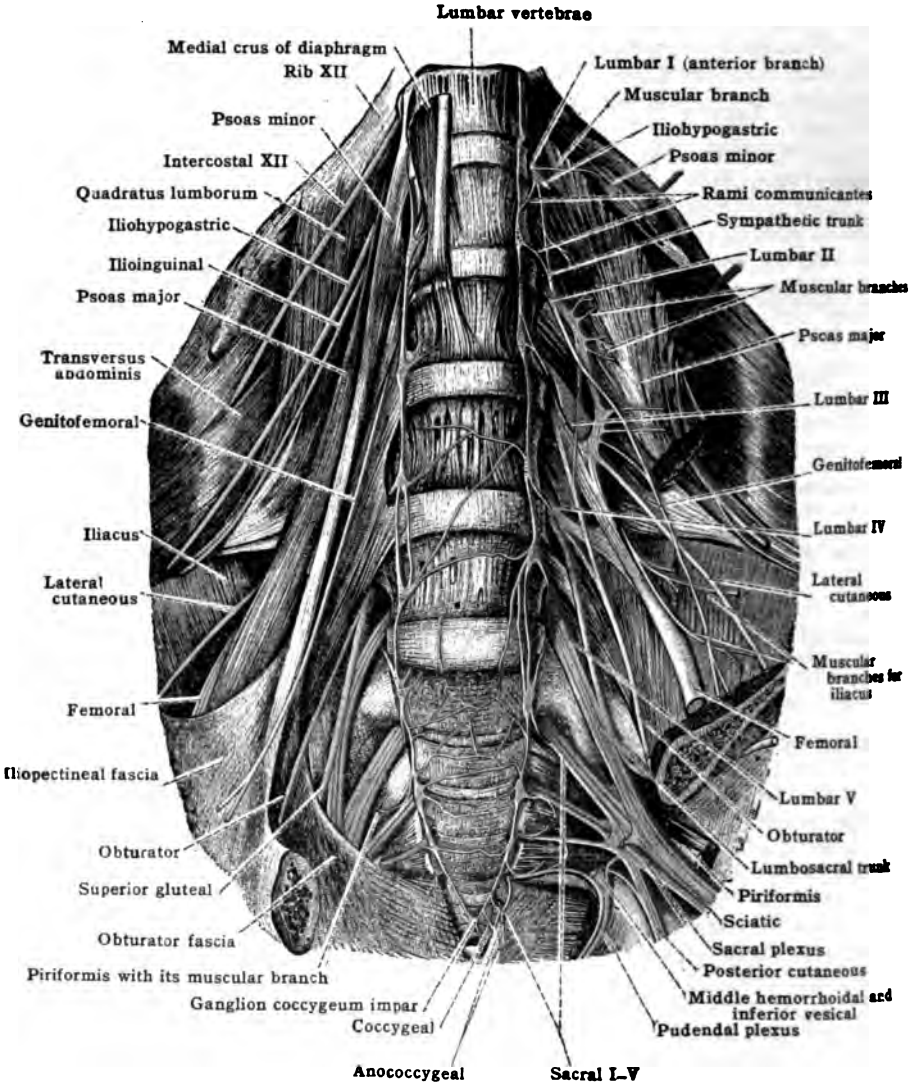
The **ilioinguinal nerve** arises principally from the first lumbar nerve, but it frequently contains fibers of the last thoracic nerve. It emerges from the lateral border of the psoas, at a lower level than the iliohypogastric nerve, and passes across the quadratus lumborum (figs. 796, 797). As a rule, it is below the level of the inferior end of the kidney, but it passes dorsal to the ascending or the descending colon according to the side considered, and crosses the posterior part of the inner lip of the iliac crest; it then runs forward on the upper part of the iliacus, pierces the transversus abdominis near the anterior part of the crest, and communicates with the anterior cutaneous (hypogastric) branch of the iliohypogastric nerve. A short distance below the anterior superior spine it passes through the internal oblique muscle, and then descends in the inguinal canal to the subcutaneous inguinal (external abdominal) ring, through which it emerges into the thigh on the lateral side of the spermatic cord (fig. 794). It is distributed to the skin of the upper and medial part of the thigh, in the male to the root of the penis and to the skin of the root of the scrotum through the **anterior scrotal nerves** (fig. 799), and in the female to the mons veneris and labium majus through the **anterior labial nerves.**

Not uncommonly the ilioinguinal nerve is blended with the iliohypogastric nerve and separates from the latter between the transversus abdominis and the internal oblique muscles. It may be replaced by branches of the genitofemoral (genitocrural) nerve, or it may replace that nerve or the lateral femoral cutaneous nerve.

The **genitofemoral (genitocrural) nerve** is connected with the first and second lumbar nerves, but the majority of its fibers are derived from the second nerve. It passes obliquely forward and downward through the psoas and emerges from

the anterior surface of that muscle, close to its medial border, at the level of the lower border of the third lumbar vertebra. After emerging from the substance of the psoas it runs downward on the anterior surface of the muscle (fig. 796), to the lateral side of the aorta and the common iliac artery, passes behind the ureter and divides into two branches, an external spermatic and a lumboinguinal (fig. 797). Occasionally it divides in the substance of the psoas, and then the two branches issue separately through the anterior surface of the muscle.

FIG. 796.—LUMBOSACRAL PLEXUS. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)

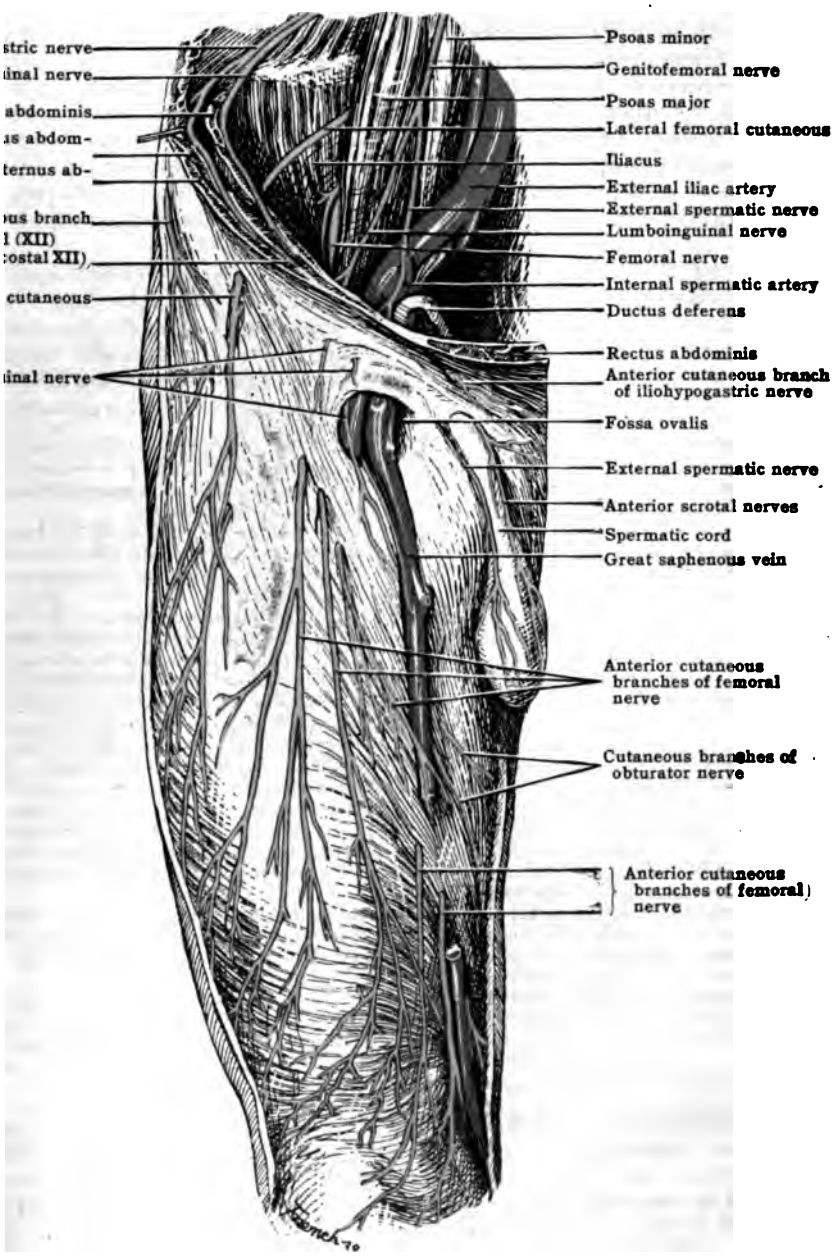


The **external spermatic** (genital) branch runs downward on the psoas muscle, external t the external iliac artery; it gives a branch to the psoas, and at Poupart's ligament it turn around the inferior epigastric artery and enters the inguinal canal, accompanying the spermat cord in the male or the round ligament in the female. It supplies the cremaster muscle, an gives twigs to the integument of the scrotum (fig. 797) or the labium majus.

The **lumboinguinal** (crural) branch passes downward along the external iliac artery an beneath Poupart's ligament into the thigh, which it enters to the lateral side of the femor artery. A short distance below Poupart's ligament it pierces the fascia lata or passes throu the fossa ovalis (saphenous opening) and supplies the skin in the middle of the upper part of t thigh. A short distance below Poupart's ligament it sometimes sends branches to the anteri branch of the lateral cutaneous nerve, and about the middle of the thigh it often joins with t cutaneous branches of the femoral (anterior crural) nerve.

ral femoral cutaneous nerve receives fibers from the dorsal branches of r primary divisions of the second and third lumbar nerves, and fre- ne fibers from the first lumbar (fig. 800). It emerges from the lateral e psoas and passes obliquely across the iliacus, dorsal to the iliac fascia o the cecum on the right side and the sigmoid colon on the left side, to

797.—Cutaneous Nerves of the Right Thigh. (After Spalteholz.)
(The iliac fascia has been removed, the fascia lata retained.)



ediately below the anterior superior spine of the ilium, where it passes art's ligament into the lateral angle of the femoral trigone (Scarpa's eaving the trigone at once it passes through, behind, or in front of s and divides into two branches, anterior and posterior, which enter cia (figs. 797, 799).

rior branch of the lateral cutaneous nerve breaks up into several secondary h become subcutaneous, and they supply the integument of the lateral part of the

thigh, from the great trochanter to the level of the middle of the femur. The anterior branch runs downward in a canal in the deep fascia, for three or four inches, before it becomes subcutaneous. It usually divides into two branches, a lateral and a medial. The *lateral branch* supplies the skin of the lower half of the lateral side of the thigh, and the *medial branch* is distributed to the skin of the lateral side of the front of the thigh as far as the knee (fig. 797). Its lower filaments frequently unite with the cutaneous branches of the femoral and with the patellar branch of the saphenous nerve in front of the patella, forming with them the **patellar plexus.**

The **femoral** (anterior crural) **nerve** is the largest terminal branch of the lumbar plexus. It is formed chiefly by fibers of the dorsal branches of the anterior primary divisions of the second, third, and fourth lumbar nerves, but it sometimes receives fibers from the first nerve also (figs. 796 and 800). It emerges from the lateral border of the psoas a short distance above Poupart's ligament, and descends in the groove between the psoas and the iliacus, behind Poupart's ligament, into the femoral trigone (Scarpa's triangle), where it lies to the lateral side of the femoral artery (figs. 798, 1142), from which it is separated by some of the fibers of the psoas. In this situation it is flattened out and it divides into two series of terminal branches, the superficial and the deep. In general, they supply the muscles and skin on the anterior aspect of the thigh.

Branches.—The branches of the femoral nerve are collateral and terminal.

The **collateral branches** are twigs of supply to the iliacus, and a branch to the femoral artery; they are given off before the nerve enters the femoral trigone.

The **terminal branches** form two groups, the superficial and the deep.

The **superficial terminal branches** are two muscular branches, the nerve to the pectineus, and the nerve to the sartorius, and two anterior cutaneous branches.

The **nerve to the pectineus** passes medially and downward behind the femoral sheath and in front of the psoas to the anterior surface of the pectineus, in which it terminates.

The **nerve to the sartorius** accompanies the middle cutaneous nerve; it leaves the latter nerve above the sartorius and ends in the upper part of the muscle.

The **anterior (middle and internal) cutaneous nerves** (branches of the femoral) are best described separately. The **middle cutaneous nerve** soon divides into two branches, medial and lateral. The lateral branch pierces the sartorius and both branches become cutaneous about the junction of the upper and middle thirds of the thigh (figs. 797, 799). They descend along the medial part of the front of the thigh to the knee, supplying the skin in the lower two-thirds of the medial part of the front of the thigh, and their terminal filaments take part in the formation of the patellar plexus. About the middle of the thigh the middle cutaneous is often joined by a twig with the lumboinguinal nerve (crural branch of the genitocrural nerve). The **medial (or internal) cutaneous nerve** runs downward and medialward along the lateral side of the femoral artery, to the apex of the femoral trigone (Scarpa's triangle), where it crosses in front of the artery and divides into an anterior and a posterior terminal branch. Before this division takes place, however, two or three collateral branches are given off from the trunk. The highest of these passes through the fossa ovalis (saphenous opening), or it pierces the deep fascia immediately below the opening, and supplies the skin as low as the middle of the thigh. The lowest pierces the deep fascia at the middle of the thigh and it descends in the subcutaneous tissue, supplying the skin on the medial side of the thigh from the middle of the thigh to the knee (figs. 799, 800). This nerve frequently varies in size inversely with the cutaneous branches of the obturator and saphenous nerves.

The **anterior branch** of the medial cutaneous nerve passes vertically downward to the junction of the middle and lower thirds of the thigh, where it pierces the deep fascia. It still continues downward for a short distance, then it turns lateralward and passes to the front of the knee, where it enters into the patellar plexus.

The **posterior branch** descends along the dorsal border of the sartorius, and it gives off a branch which passes beneath that muscle to unite with twigs from the saphenous and from the superficial division of the obturator nerve, forming with them the **subsartorial plexus** which lies on the roof of the adductor (Hunter's) canal. At the medial side of the knee the nerve pierces the deep fascia and it descends to the middle of the calf (figs. 797, 799).

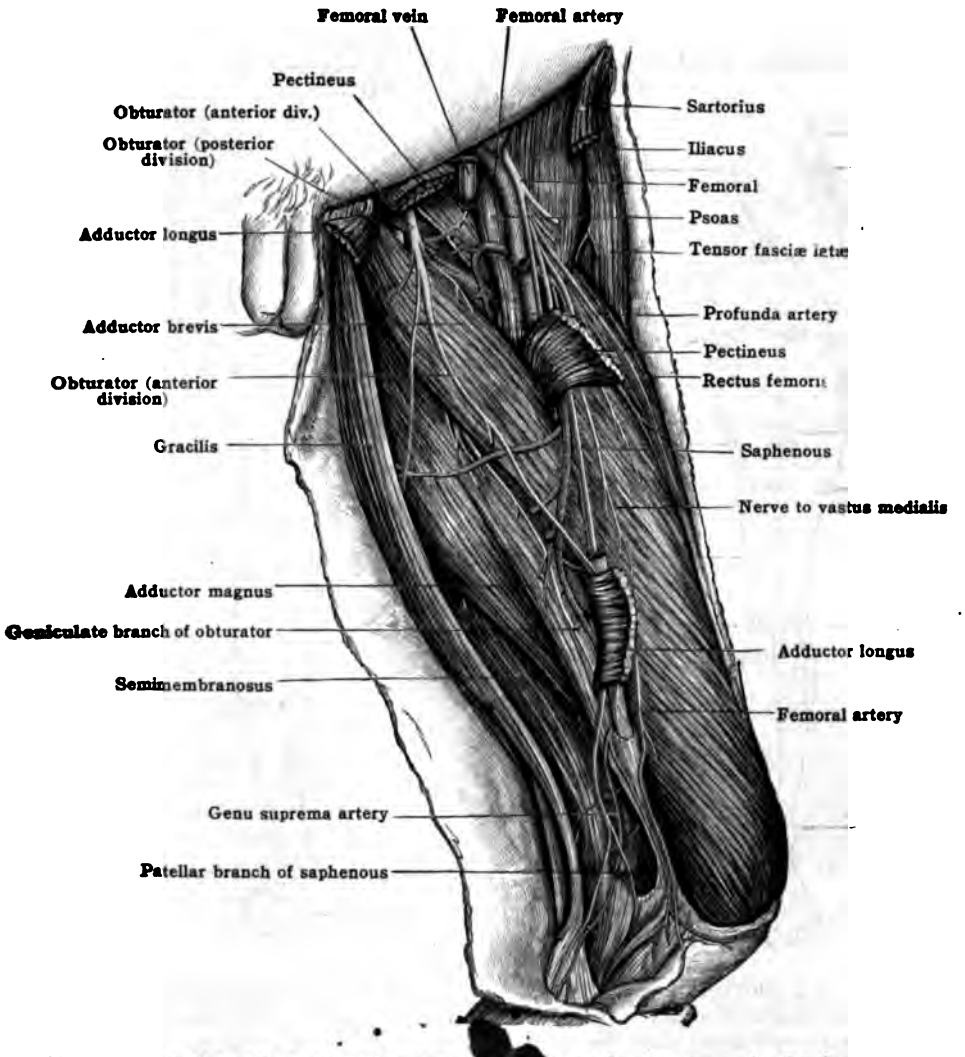
The **deep terminal branches** of the femoral nerve are six in number, one cutaneous branch, the *saphenous*, and five *muscular branches*. The branches radiate from the termination of the trunk of the femoral nerve, and they are arranged in the following order from medial to lateral:—the saphenous nerve, the nerve to the vastus medialis, the nerve to the articularis genu (subcrureus), the nerve to the vastus intermedius (crureus), the nerve to the vastus lateralis, and the nerve to the rectus femoris.

The **saphenous nerve** passes down through Scarpa's triangle along the lateral side of the femoral artery. At the apex of the triangle it enters the adductor (Hunter's) canal and descends through it, lying first to the lateral side, then in front, and finally to the medial side of the artery (fig. 798). After emerging from the lower end of the canal, accompanied by the superficial branch of the genu suprema (anastomotic) artery, it passes between the dorsal border of the sartorius and the anterior border of the tendon of the gracilis, and, becoming superficial, it

[redacted]rs into relationship with the great saphenous vein and descends with it along the inner bor-[redacted] of the upper two-thirds of the tibia (fig. 799). It crosses the medial surface of the lower [redacted]d of the tibia, passes in front of the internal malleolus, and runs forward along the medial [redacted]der of the foot to the ball of the great toe.

While it is in the adductor (Hunter's) canal it gives off a twig to the subsartorial plexus. [redacted]fore it passes from under cover of the sartorius it gives off an infrapatellar branch, which [redacted]rces the sartorius just above the knee and passes outward to the patellar plexus. After it [redacted]comes superficial it supplies the integument on the medial side of the leg and foot, and it [redacted]stomoses, in the foot, with the medial dorsal cutaneous branch of the superficial peroneal [redacted]usculocutaneous) nerve.

FIG. 798.—FEMORAL AND OBTURATOR NERVES. (Ellis.)



The **nerve to the vastus medialis** accompanies the saphenous nerve in the femoral trigone (**Scarpa's triangle**), lying to its outer side. At the upper end of the adductor canal it passes beneath the sartorius, external to the roof of the canal, and enters the medial surface of the vastus medialis. It sends a twig down to the knee-joint.

The **nerve to the articularis genu** (subcrureus), usually a terminal branch of the femoral, frequently arises from the nerve to the vastus intermedius. It passes between the vastus medialis and the vastus intermedius to the lower third of the thigh, where it supplies the articularis genu and sends a branch to the knee-joint.

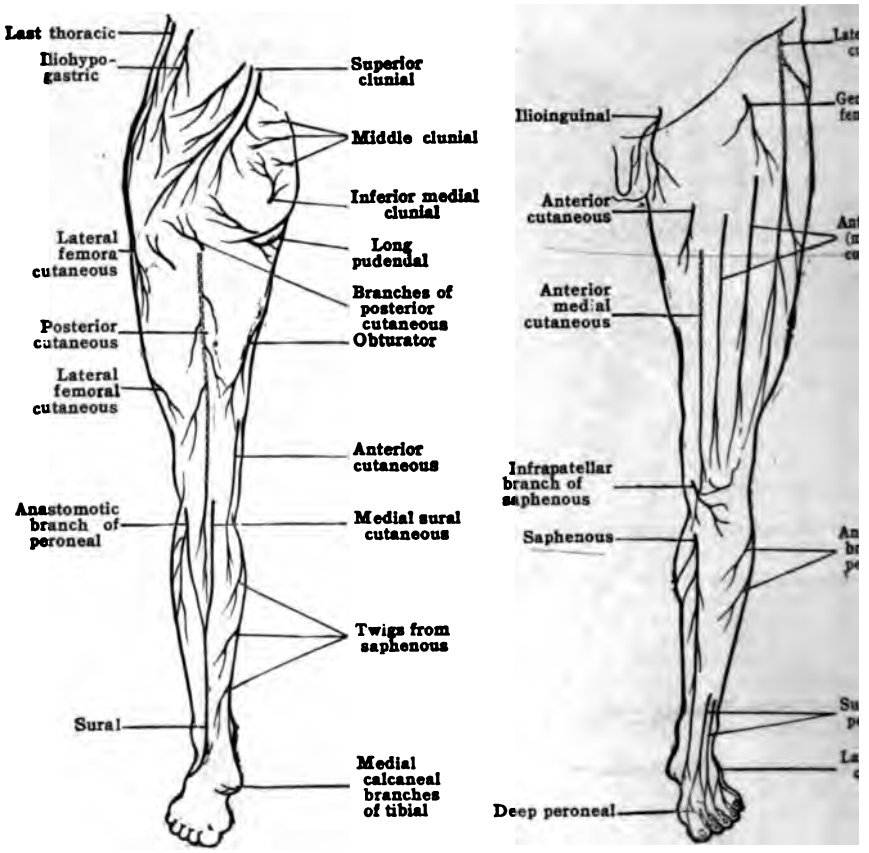
The **nerve to the vastus intermedius** (crureus) is represented by two or three branches which enter the upper part of the muscle. One of them frequently sends a twig to the knee-joint.

The **nerve to the vastus lateralis** passes downward behind the rectus and along the anterior border of the vastus lateralis accompanied by the descending branch of the lateral circumflex artery. It also sends a branch to the knee-joint.

The **nerve to the rectus femoris** (fig. 798) enters the deep surface of that muscle, having previously given off a twig to the hip-joint which accompanies the ascending branch of the external circumflex artery.

The **obturator nerve** contains fibers from the anterior primary division second, third, and fourth lumbar nerves, but its largest root is derived fr third nerve (figs. 796, 800). It sometimes receives fibers from the first nerve. It emerges from the medial border of the psoas at the dorsal part brim of the pelvis, where it lies in close relation with the lumbosacral trunk plexus, from which it is separated by the iliolumbar artery. Immediatel its exit from the psoas it pierces the pelvic fascia, crosses the lateral side internal iliac vessels and the ureter, and runs forward in the extraperiton below the obliterated hypogastric artery and along the upper part of the surface of the obturator internus to the upper part of the obturator fo where it passes through the obturator canal below the so-called horizonta

FIG. 799.—DISTRIBUTION OF CUTANEOUS NERVES ON THE POSTERIOR AND ANTERIOR OF THE INFERIOR EXTREMITY.



of the pubis and above the obturator membrane, into the upper part of t It is accompanied in the pelvis and the obturator canal by the obturato which lies at a lower level than the nerve and it divides in the obturator c two branches, an anterior and a posterior, which supply the adductor muscles, the hip and knee-joints, and the skin on the medial aspect of

The **anterior branch** of the obturator has a twig joining it with the a obturator nerve, if that nerve is present, and then descends behind the p and adductor longus and in front of the obturator externus and adducto muscles (fig. 798). Its branches are:-

1. A **twig** to the accessory obturator nerve if the latter is present.
2. An **articular branch** to the hip-joint.
3. **Muscular branches** to the gracilis, adductor longus, and, usually, to the addue
4. Two **terminal branches**, of which one is distributed to the femoral artery and communicates with the subsartorial plexus. The *subsartorial branch* is occasions than usual, and it then descends, along the dorsal border of the sartorius, to the me the knee, where it enters the subcutaneous tissue, and supplies the skin on the medial leg as far as the middle of the calf. Twigs join it with the saphenous nerve.

The **posterior branch** of the obturator (fig. 798) pierces the upper part of the obturator externus and passes downward between the adductor brevis and adductor magnus. Its branches are:—

1. **Muscular branches** to the obturator externus, to the oblique fibers of the adductor magnus and to the adductor brevis when the latter is not entirely supplied by the anterior branch. The branch to the obturator externus is given off in the obturator canal.

2. An **articular branch** to the knee-joint which appears in some cases to be the continuation of the trunk of the posterior branch (fig. 798). It either pierces the lower part of the adductor magnus, or it passes through the opening for the femoral artery. In the popliteal space it descends on the popliteal artery to the back of the joint, where it pierces the posterior ligament, and its terminal filaments are distributed to the crucial ligaments and the structures in their immediate neighborhood. This branch is not uncommonly absent. Occasionally the posterior branch of the obturator nerve also supplies a twig to the hip-joint.

The **accessory obturator nerve** arises from the third or fourth or from the third and fourth lumbar nerves, in the angles between the roots of the femoral (anterior crural) and obturator nerves. It is present in about 29 per cent. of all cases (Eisler). It is often closely associated with the obturator nerve to the level of the brim of the pelvis, but instead of passing through the obturator foramen, it descends along the medial border of the psoas, crosses the anterior part of the brim of the pelvis, passes beneath the pectineus, and terminates in three main branches. One of these branches joins the anterior division of the obturator nerve, another supplies the pectineus, and the third is distributed to the hip-joint.

The Lumbosacral Trunk

The trunk of the plexus usually formed by the union of the smaller part of the fourth and the entire fifth lumbar nerves is called the **lumbosacral trunk** (figs. 796, 800). Sometimes the larger part of the fourth nerve may help to form the trunk. It may receive fibers from the third lumbar nerve or be formed entirely from the fifth. At its formation it is situated on the ala of the sacrum under cover of the psoas. It descends into the pelvis, and, as it crosses the anterior border of the ala of the sacrum, it emerges from beneath the psoas at the medial side of the obturator nerve, from which it is separated by the iliolumbar artery. It passes behind the common iliac vessels and unites with the first and second sacral nerves, forming with them the upper trunk of the sacral plexus.

4. SACRAL NERVES

The anterior primary divisions of the upper four sacral nerves enter the pelvis through the anterior sacral foramina and they diminish in size progressively from above downward. The first sacral is the largest of the spinal nerves, the second is slightly smaller than the first, while the third and fourth are relatively small. The fifth sacral nerve is still smaller than the fourth; it enters the pelvis between the sacrum and the coccyx. The anterior divisions of these nerves enter into the formation of three parts of the lumbosacral plexus, the sacral, pudendal, and coccygeal parts (figs. 795, 796).

Sacral Plexus

The **sacral plexus** shows in its formation variations similar to those of the lumbar plexus; hence there are also seven types of this plexus, three of them belonging to the prefixed (proximal) class, three to the postfixed (distal) class, and one to the ordinary class. The following tables show the range of variation and the common arrangement in these classes:—

Composition of the Nerves of the Sacral Plexus

Common Composition

Nerve	Prefixed	Ordinary	Postfixed
Lumbosacral trunk	4L.	4L.	4L.
Common peroneal	4, 5 L. 1, 2 S.	4, 5 L. 1, 2 S.	4, 5 L. 1, 2 S.
Tibial (internal popliteal)	3,4, 5 L. 1, 2 S.	4, 5 L. 1, 2, S.	4, 5 L. 1, 2, 3, 4 S.
Posterior femoral cutaneous (small sciatic)	1, 2, 3 S.	1, 2, 3 S.	2, 3 S.

RANGE OF VARIATION

NERVE	PREFIXED	ORDINARY	POSTFIXED
Lumbosacral trunk.....	3 or 3, 4 L.	4 L.	4, 5 or 5 L.
Common peroneal.....	3, 4, 5 L. 1, 2 S.	4, 5 L. 1, 2 S.	4, 5 L. 1, 2, 3 S.
Tibial (internal popliteal)	3, 4, 5 L. 1, 2 S.	4, 5 L. 1, 2, 3 S.	4, 5 L. 1, 2, 3, 4 S.
Posterior femoral cutaneous (small sciatic).....	5 L. 1, 2, 3 S.	5 L. 1, 2, 3, 4 S.	5 L. 1, 2, 3, 4 S.

The ordinary type of sacral plexus is commonly formed by the smaller part of the anterior division of the fourth lumbar nerve and the entire anterior division of the fifth lumbar nerve, together with the first and parts of the second and third sacral nerves.

The plexus lies in the pelvis on the anterior surface of the piriformis (fig. 796) and behind the pelvic fascia and the branches of the hypogastric (internal iliac) artery. It is also dorsal to the coils of intestine, the sigmoid colon lying in front of the left plexus, and the lower part of the ileum in front of the right plexus.

The branches given off by this plexus are:—visceral, cutaneous, and muscular.

Visceral branches are given off from the second, third, and fourth sacral nerves to the pelvic viscera.

The visceral branches correspond to white rami communicantes, though not joining the sympathetic trunk. The branches from the second and fourth sacral nerves are inconstant.

Cutaneous branches.—The **posterior femoral cutaneous** (small sciatic) nerve arises partly from the anterior and partly from the posterior branches of the anterior primary divisions of the first, second, and third sacral nerves. It lies on the back of the plexus (figs. 796, 800), leaves the pelvis at the lower border of the piriformis, and descends in the buttock between the gluteus maximus and the posterior surface of the sciatic nerve (fig. 801). At the lower border of the gluteus maximus it passes behind the long head of the biceps femoris, and descends, immediately beneath the deep fascia, through the thigh and the upper part of the popliteal space. At the lower part of the popliteal region it perforates the deep fascia, and it terminates in branches which are distributed to the skin of the calf.

Branches of the posterior femoral cutaneous.—1. **Perineal branches** go in part to the skin of the upper and medial sides of the thigh on its dorsal aspect. One of the branches, known as the **long pudendal nerve** (fig. 801), runs forward and medialward in front of the tuberosity of the ischium to the lateral margin of the anterior part of the perineum, where it perforates the fascia lata and Colles' fascia and enters the anterior compartment of the perineum. In the perineum twigs join it with the superficial perineal nerves, and its terminal filaments are distributed to the skin of the scrotum in the male, and to the labium majus in the female.

2. **Inferior clunial** (gluteal) **branches,** two or three in number, are given off beneath the gluteus maximus; they turn around the lower border of this muscle and are distributed to the skin of the lower and lateral part of the gluteal region.

3. **Femoral cutaneous branches** are given off as the nerve descends through the thigh. They perforate the deep fascia and are distributed to the skin of the back of the thigh, especially toward the medial side.

In case of the separate origin of the tibial (internal popliteal) and common peroneal (external popliteal) nerves, the posterior femoral cutaneous (small sciatic) also arises from the sacral plexus in two parts. The *ventral portion* descends with the tibial nerve below the piriformis and gives off the perineal branches and medial femoral branches, while the *dorsal portion* passes through that muscle with the common peroneal nerve, and furnishes the gluteal and lateral femoral branches.

The **inferior medial clunial (perforating cutaneous) nerve** arises from the posterior portion of the second and third sacral nerves (figs. 795, 799, 800). It perforates the lower part of the sacrotuberous (great sciatic) ligament, turns around the inferior border of the gluteus maximus, and is distributed to the skin over the lower and medial part of that muscle. It is sometimes associated at its origin with the pudic nerve. It is not always present. Its place is sometimes taken by a small nerve (the *greater coccygeal perforating nerve* of Eisler), arising from the third and fourth or fourth and fifth sacral nerves, and sometimes it is represented by a branch of the posterior femoral cutaneous.

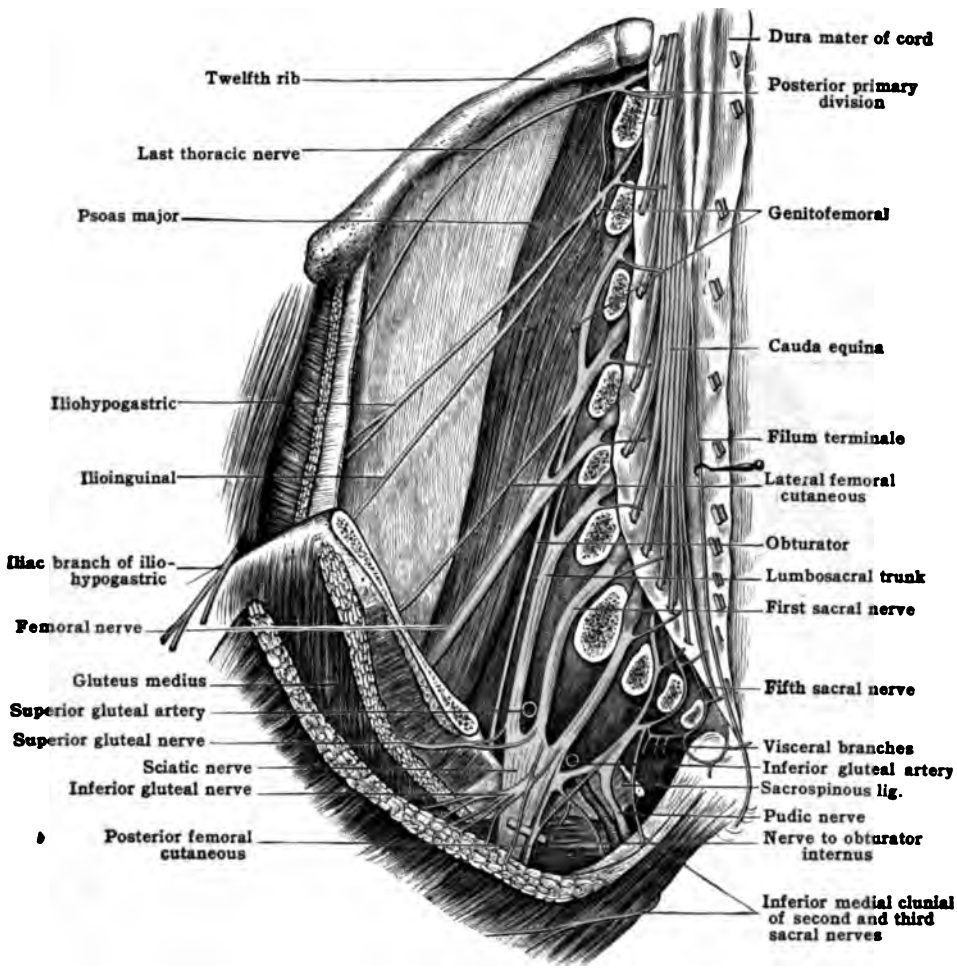
Muscular branches of the sacral plexus.—(*a*) One or two small **nerves to the piriformis** pass from the posterior branches of the first and second sacral nerves.

(*b*) The **superior gluteal nerve** receives fibers from the posterior branches of the fourth and fifth lumbar, and the first sacral nerves. It passes out of the pelvis through the great sciatic foramen, above the upper border of the piriformis, and it is accompanied by the superior gluteal artery. As soon as it enters the buttock it divides into two branches, an upper and a lower.

1. The **upper branch** is the smaller. It accompanies the upper branch of the deep division the superior gluteal artery below the middle curved line of the ilium, and it ends entirely the gluteus medius (fig. 801).
2. The **lower branch,** larger than the upper, passes forward across the middle of the gluteus minimus, with the lower branch of the gluteal artery; it supplies the gluteus medius and the gluteus minimus, and it ends in the medial and posterior part of the tensor fasciæ latæ.

(*c*) The **inferior gluteal nerve** is formed by fibers from the posterior branches of the fifth lumbar, and the first and second sacral nerves. It passes through the great sciatic foramen, below the piriformis, and divides into a number of branches which end in the gluteus maximus (figs. 796, 800).

FIG. 800.—A DISSECTION OF THE LUMBAR AND SACRAL PLEXUSES, FROM BEHIND.



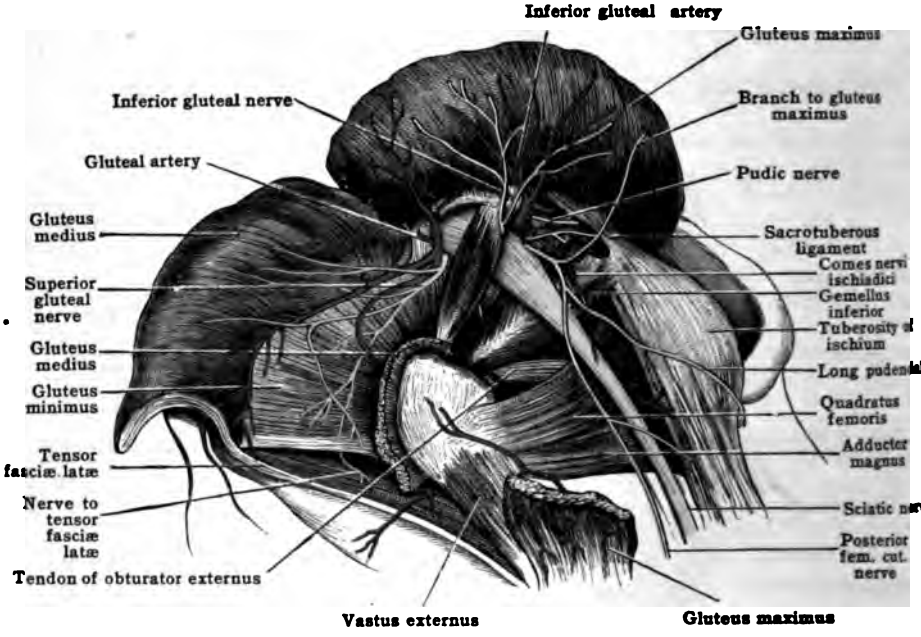
(*d*) The **nerve of the quadratus femoris** is formed by the anterior branches of the fourth and fifth lumbar and the first and second sacral nerves. It lies on the front of the plexus and issues from the pelvis below the piriformis. In the buttock it lies at first between the sciatic nerve and the back of the ischium, and, at a lower level, between the obturator internus with the gemelli and the ischium. It terminates in the anterior surface of the quadratus femoris, having previously given off a branch to the hip-joint and another to the inferior gemellus.

(*e*) The **nerve of the obturator internus** is formed by the anterior branches of the fifth lumbar, and the first and second sacral nerves (figs. 795, 800). It leaves the pelvis below the piriformis, and crosses the spine of the ischium on the lateral side of the internal pudic artery and on the medial side of the sciatic nerve. It gives a branch to the gemellus superior, and turns forward through the small

sciatic foramen into the perineum, where it terminates in the inner surface of the obturator internus.

The **sciatic nerve** [n. ischiadicus].—The sciatic is not only the largest nerve of the sacral plexus, but it is also the largest nerve in the body. Its terminal branches are chiefly muscular, though some of its fibers are cutaneous. Although it is referred to as one trunk, it consists in reality of peroneal (lateral) and tibial (medial popliteal) portions (fig. 795), which are bound together by a sheath of fibrous tissue as far as the upper end of the popliteal space. In about 10 per cent. of the cases the two parts remain separate, and in such cases the peroneal (lateral popliteal) part usually pierces the piriformis. The peroneal portion of the nerve consists of fibers derived from the dorsal branches of the anterior primary divisions of the fourth and fifth lumbar and the first and second sacral nerves, while the tibial part is formed by the fibers from the anterior branches of

FIG. 801.—A DISSECTION OF THE NERVES IN THE GLUTEAL REGION.
(The gluteus maximus and gluteus medius have been divided near their insertions, and thrown upward.)



the fourth and fifth lumbar, and the first, second, and third sacral nerves (figs. 796, 800). The common trunk leaves the pelvis by passing through the great sciatic foramen, usually below the piriformis, and descends through the buttock, running midway between the tuber ischii and the great trochanter (fig. 801). Passing down the thigh, the trunk terminates at the upper angle of the popliteal space by dividing into the common peroneal (external popliteal) and the tibial (internal popliteal) nerves (fig. 802).

The relation of the trunk to the piriformis muscle is more or less unique. It may pass either above or below the muscle, it may split and pass around the muscle, or the muscle may be split and surround the nerve. Again, there may be a splitting of both the muscle and the nerve, in which case any possible combination of the four parts may occur; a portion of the nerve may be above and a portion between the parts of the muscle, or a portion may be below and a portion between. The trunk of the nerve lies deeply in the thigh, and it is covered posteriorly by the skin and fascia, the gluteus maximus and the long head of the biceps femoris. Anteriorly it is in relation, from above downward, with the following structures:—the posterior surface of the ischium and the nerve to the quadratus femoris, the gemellus superior, obturator internus, gemellus inferior, quadratus femoris, and adductor magnus muscles.

Muscular branches of the sciatic are given off at the upper part of the thigh to the semitendinosus, to the long head of the biceps femoris, to the semimembranosus, and to the adductor magnus, and, about the middle of the thigh, a branch is furnished to the short head of the biceps.

The branch to the **short head of the biceps femoris** is derived from the peroneal (lateral popliteal) portion of the nerve, while all the other muscular branches are given off by the tibial (medial popliteal) part. The **semitendinosus** receives two branches, one which enters it above and another which passes into it below its tendinous intersection. The nerve to the **long head of the biceps** descends along the sciatic trunk and enters the middle of the deep surface of the muscle. The nerves to the **semimembranosus** and **adductor magnus** arise by a common trunk which divides into three or four branches. One branch ends in the adductor, and the others are distributed to the semimembranosus. The branch to the adductor magnus supplies only those fibers of the muscle which begin from the tuberosity of the ischium and descend vertically to the medial condyle of the femur.

At the popliteal space the two component parts of the common trunk of the sciatic are always distinct, forming (*A*) the tibial and (*B*) the common peroneal nerve.

(*A*) The **tibial nerve** (internal popliteal), formed by fibers from the anterior branches of the fourth and fifth lumbar and first, second, and third sacral nerves, passes vertically through the popliteal space, descends through the leg to a point midway between the medial malleolus and the most prominent part of the medial tubercle of the calcaneus, where it divides into its terminal branches, the *lateral plantar* and the *medial plantar* nerves.

The part of the nerve from the point of bifurcation to the lower border of the popliteus muscle was formerly called the *internal popliteal;* the part of the nerve in the dorsum of the leg being then designated the *posterior tibial nerve.*

In the upper part of the popliteal space the tibial nerve lies relatively superficially, being covered dorsally by the skin and fascia, while in the lower part of the space it is overlapped by the heads of the gastrocnemius and is crossed by the plantaris. In the upper part of the space it lies in front of the posterior femoral cutaneous (small sciatic) nerve and to the lateral side of the vein and artery; at the middle of the space it is dorsal, and in the lower part of the space it is medial to both of them.

The **branches** given off by the tibial nerve *in the popliteal space* are articular, cutaneous, and muscular.

The **articular branches** are usually three in number, a superior and an inferior internal articular and an azygos articular. They accompany the corresponding arteries, and, after piercing the ligaments, are distributed in the interior of the joint. The superior branch is often wanting.

The **medial sural cutaneous** (tibial communicating) nerve, descends between the heads of the gastrocnemius, beneath the deep fascia, to the middle of the calf, where it pierces the fascia and unites with the peroneal anastomotic branch of the lateral sural cutaneous nerve to form the **sural** (external saphenous) nerve, through which its fibers are distributed to the skin of the lower and dorsal part of the leg and the lateral side of the foot (fig. 802).

The **muscular branches** are distributed to both heads of the gastrocnemius, to the plantaris, soleus, and popliteus.

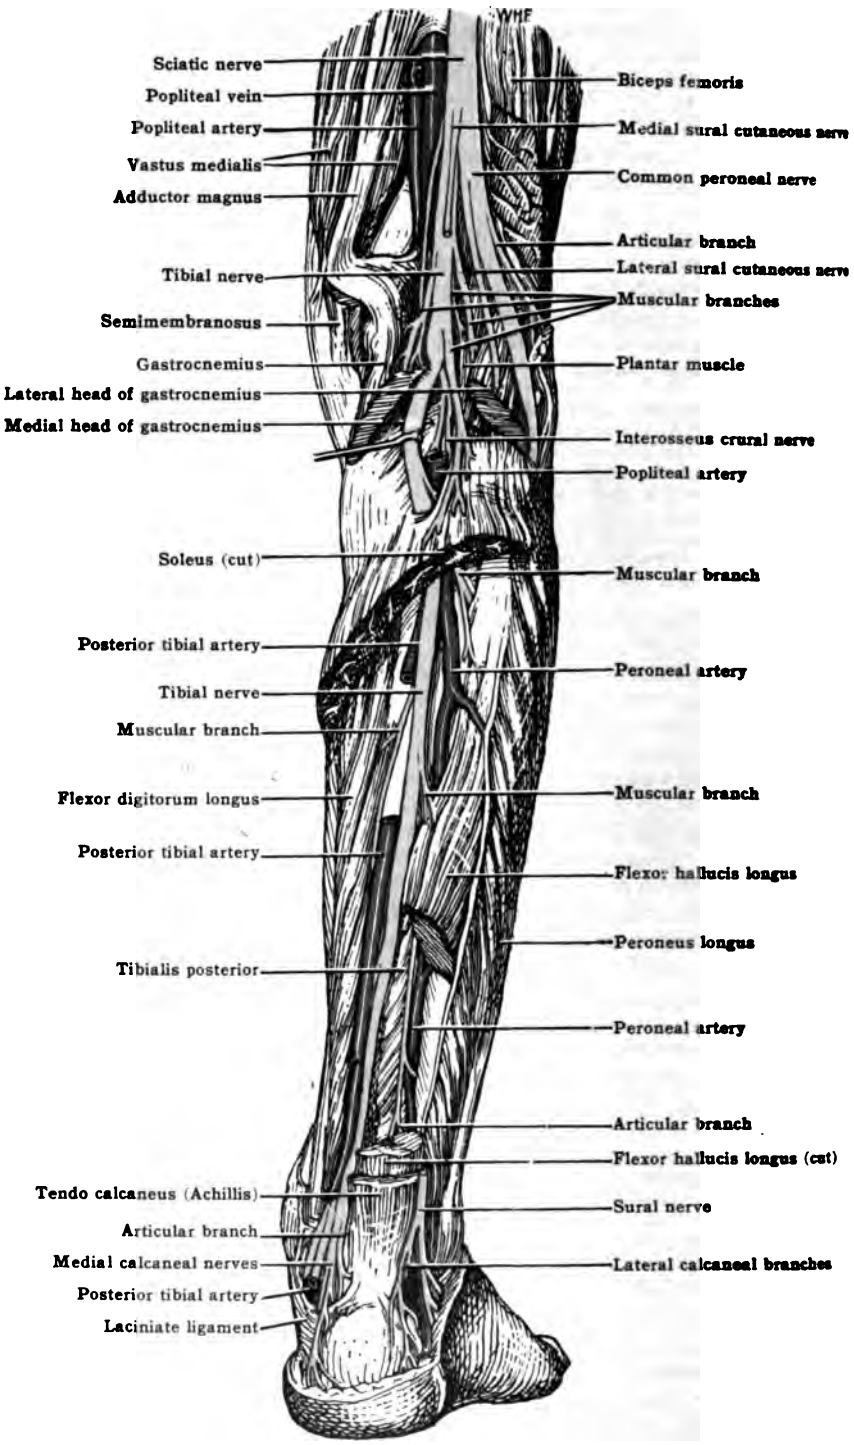
The *nerve to the soleus* is relatively large, and passes between the lateral head of the gastrocnemius and the plantaris before it reaches its termination (fig. 802). The *nerve to the popliteus* descends on the posterior surface of the muscle, turns around its lower border, and is distributed on its anterior aspect. In addition to supplying the popliteus, it gives articular branches to the knee and superior tibiofibular joints, a branch to the tibia which accompanies the medullary artery, and a long, slender twig which gives filaments to the anterior and posterior tibial arteries, and it descends as the **interosseous crural** nerve on the interosseous membrane to the inferior tibiofibular joint. It also gives branches to the interosseous membrane and to the periosteum of the lower part of the tibia.

Relations.—In the upper part of the leg the tibial nerve is placed deeply, under the gastrocnemius and soleus, but in the lower half it is merely covered by the deep fascia, which is thickened between the medial malleolus and the calcaneus to form the lacinate (internal annular) ligament, and the termination of the nerve lies either under cover of this ligament, or under the attachment of the abductor hallucis. The anterior relations of the nerve are, from above downward, the tibialis posterior, the flexor digitorum longus, the lower part of the tibia, and the posterior ligament of the ankle-joint. For a short distance after its commencement the nerve lies to the medial side of the posterior tibial artery; then it crosses behind the artery and runs downward along its lateral aspect.

The **branches of the lower part** of the tibial nerve (below the popliteal space) are likewise muscular, cutaneous, and articular. They are supplied to the deep muscles of the dorsum of the leg, to the fibula, to the skin of the heel and foot, and to the ankle-joint. Several of the terminal branches are important enough to receive special names and special treatment.

The **muscular branches** pass from the upper part of the nerve to the tibialis posterior, flexor digitorum longus, soleus, and flexor hallucis longus. The **fibular branch** arises with the

FIG. 802.—MUSCLE-NERVES OF THE RIGHT LEG, VIEWED FROM BEHIND. (After Spalteholz.) The semitendinosus, semimembranosus, biceps femoris, gastrocnemius, plantaris, soleus, and flexor hallucis longus have been wholly or in part removed.



nerve to the flexor hallucis longus, and accompanies the peroneal artery. It supplies periosteum and gives filaments which accompany the medullary artery.

The articular branches arise from the lower part of the nerve, immediately above its minal branches, and they pass into the ankle-joint through the deltoid ligament.

The medial calcaneal (calcaneoplantar cutaneous) nerves arise from the trunk of tibial nerve in the lower part of the leg. They pierce the laciniate (internal annular) ligan

l are distributed to the integument of the medial side and plantar surface of the heel and adjoining part of the sole of the foot (figs. 802, 803).

Terminal branches of tibial nerve.—Between the medial malleolus and the lcaneus the tibial nerve divides into (1) the medial plantar and (2) the lateral antar nerve.

1. The **medial plantar nerve** is the larger of the two terminal branches of the ıial nerve. It commences under cover of the lower border of the laciniate ıternal annular) ligament, or under the posterior border of the abductor hallucis, ıd passes forward, accompanied by the small medial plantar artery, in the

ıtermuscular septum between the abductor hallucis and the flexor digitorum revis. At the middle of the length of the foot it becomes superficial, in the ıterval between the two muscles, and divides into four sets of terminal branches ig. 803):—

(*a*) **Muscular branches** pass from the trunk of the nerve to the abductor allucis and the flexor digitorum brevis.

(*b*) **Articular branches** are distributed to the talonavicular and the navicular-ıneiform joints.

(*c*) **Plantar cutaneous branches** are supplied to the skin of the medial part of ıe sole.

(*d*) The **digital branches** are four in number, the first, a **proper plantar digital**, the second, third, and fourth, the **common plantar digitals.** Near the bases of the metatarsal bones, the second, third and fourth common plantar digitals divide into **proper plantar digital nerves.**

The first proper plantar digital nerve becomes subcutaneous farther back than the others, and, after sending a branch to the flexor hallucis brevis, passes to the medial side of the great toe. The second (common digital) nerve gives a twig to the first lumbrical and bifurcates to supply the adjacent sides of the first and second toes. The third supplies the adjacent sides of the second and third toes, and the fourth, after connecting with the superficial branch of the lateral plantar nerve, divides to supply the adjacent sides of the third and fourth toes. All the proper digital nerves run along the sides of the toes and lie below the corresponding arteries: they supply the joints of the toes, and each give off a dorsal branch to the skin over the second and terminal phalanges and to the bed of the nail. All of them give fibers terminating in numerous Pacinian corpuscles in the subcutaneous connective tissue.

2. The **lateral plantar nerve** is the smaller of the two terminal branches of the tibial nerve. It commences at the lower border of the laciniate (internal annular) ligament, or under cover of the origin of the abductor hallucis, and passes forward and lateralward to the base of the fifth metatarsal bone, where it divides into a superficial and a deep branch (fig. 803). As it runs forward and lateralward it is superficial to the tendon of the flexor hallucis longus and to the quadratus plantæ (flexor accessorius), and deep to the flexor digitorum brevis. At its termination it lies in the interval between the flexor digitorum brevis and abductor digiti quinti.

Branches.—From the trunk of the lateral plantar nerve muscular, superficial and deep, and articular branches are given off.

The **muscular branches** arise from the commencement of the nerve and are distributed to the abductor digiti quinti and quadratus plantæ.

The **articular branches** supply the calcaneocuboid joint.

The **superficial branch** supplies muscular filaments to the flexor digiti quinti brevis, the opponens, the third plantar and fourth dorsal interosseous muscles, and divides into two **common plantar digital nerves,** each of which subdivides to form **proper plantar digital nerves.**

The lateral of the two common branches supplies the lateral side of the fifth digit; the medial connects with the lateral digital branch of the medial plantar nerve (fig. 803) and divides into proper plantar digital nerves for the adjacent sides of the fourth and fifth digits. The digital branches of the superficial division of the lateral plantar, like those of the medial plantar, supply the skin of the toes and the beds of the nails, and their fibers terminate in numerous Pacinian corpuscles.

The **deep branch** passes forward and medialward into the deep part of the sole with the plantar arterial arch. It runs deep to the quadratus plantæ, the long flexor tendons and the lumbricals, and the oblique adductor of the great toe. It lies, therefore, immediately beneath the bases of the metatarsal bones and it supplies the following muscular and articular branches:—

Muscular branches to the lateral three lumbricals, the interossei of the medial three intermetatarsal spaces, and the transverse and oblique adductor muscles of the great toe.

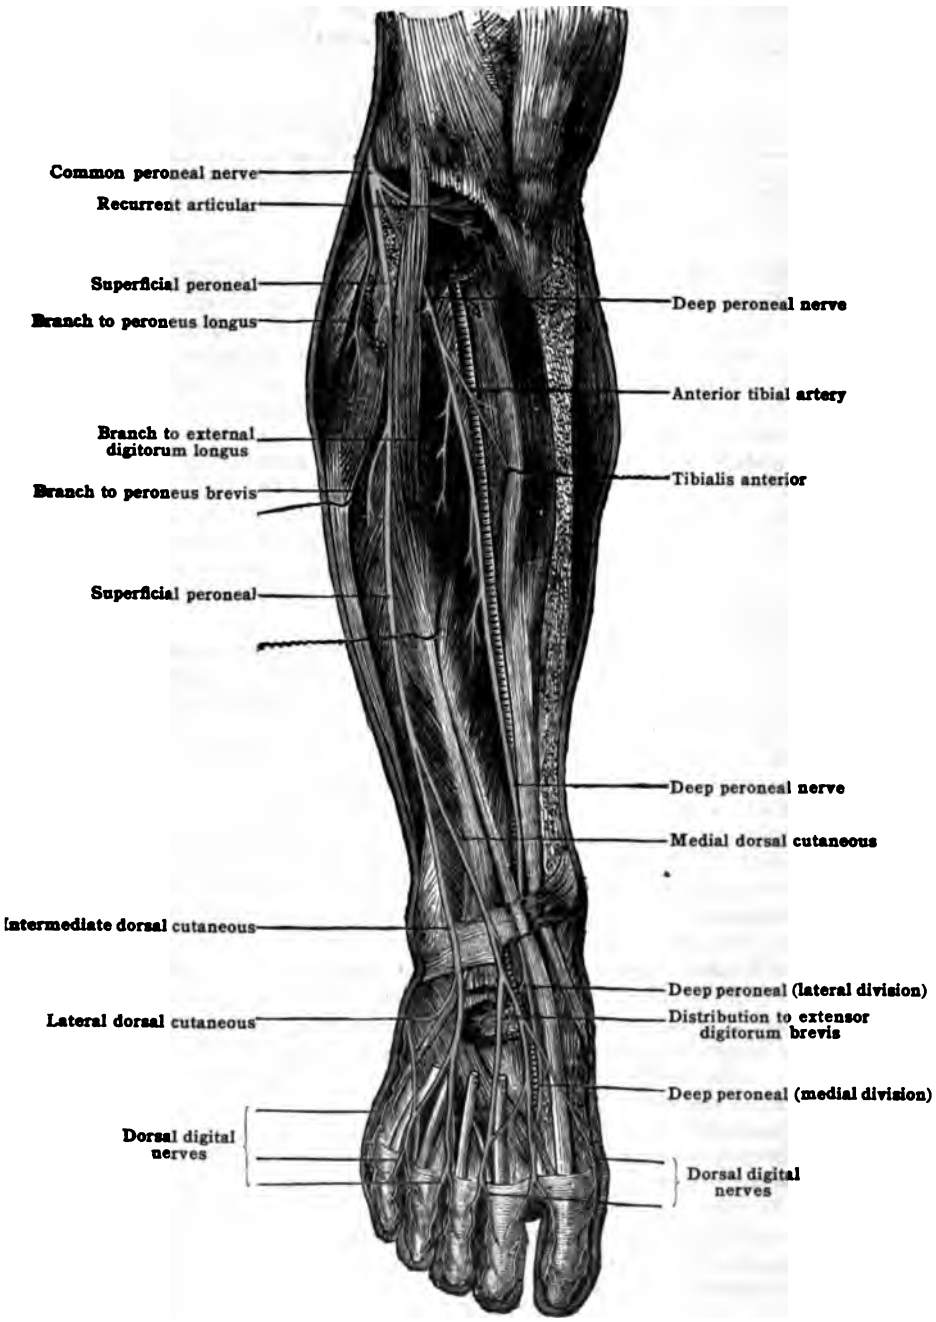
Articular branches to the intertarsal and to the tarsometatarsal joints and not uncommonly to the metatarsophalangeal joints also. Filaments from the deep branch frequently pass through the interosseous spaces and join with the interosseous branches of the deep peroneal (anterior tibial) nerve.

(B) The **common peroneal** (external popliteal) **nerve.**—At the apex of the popliteal space, where the two component parts of the sciatic trunk usually become distinct, the lateral portion receives the name *common peroneal nerve.* It descends along the posterior border of the biceps femoris, which forms the upper part of the lateral boundary of the space (fig. 802). It leaves the space at the lateral angle, crosses the plantaris, the lateral head of the gastrocnemius, the popliteus, and the inferior external artery, and descends behind the upper part of the soleus, to the neck of the fibula, where it turns forward between the peroneus longus and the bone, and breaks up into its three terminal branches, the recurrent articular, the superficial peroneal (musculocutaneous), and the deep peroneal (anterior tibial) nerves (fig. 804).

Upper branches.—While it is in the popliteal space the common peroneal nerve gives off two articular branches and a cutaneous branch.

The superior articular branch accompanies the superior external articular artery. The **inferior articular branch** passes down with the trunk of the nerve, across the plantaris and the lateral head of the gastrocnemius, and it joins the inferior-lateral articular artery behind the tendon of the biceps femoris. Both the upper and lower articular branches pierce the ligaments and are distributed in the interior of the knee joint.

FIG. 804.—DISTRIBUTION AND DEEP PERONEAL NERVES ON THE ANTERIOR ASPECT OF THE LEG AND ON THE DORSUM OF THE FOOT. (Hirschfeld and Leveillé.)



The **cutaneous branch** (*communicans fibularis*), the **lateral sural cutaneous,** is extremely variable both as to the number of its branches and as to the place of its anastomosis with the medial sural cutaneous. Leaving the common peroneal (external popliteal) in the popliteal space, it descends between the deep fascia and the lateral head of the gastrocnemius to the middle of the calf, where it pierces the fascia and unites with the medial sural cutaneous to form the **sural** (external saphenous) nerve. In its course it may give off no branches; or it may give

off several, some of which supply the skin of the dorsum of the leg, while one of them the peroneal anastomotic branch, unites with the medial sural cutaneous to form the sural (short saphenous) nerve. The junction of the peroneal anastomotic branch with the medial sural cutaneous may take place at any point between the popliteal space and the lower third of the leg.

The **sural** (external or short saphenous) **nerve** is formed by the union of the lateral sural cutaneous nerve either directly, or through a connecting branch, the peroneal anastomotic, with the medial sural cutaneous. It descends along the lateral border of the tendo Achillis, (figs. 799, 802), giving branches to the lower and lateral part of the leg, and **lateral calcaneal** branches to the lateral side of the heel.

It passes dorsal to the lateral malleolus, turns forward across the lateral surface of the cruciate (external annular) ligament, and becomes the **lateral dorsal cutaneous nerve.** Continuing along the lateral side of the foot it divides into two branches, the **dorsal digitals,** one of which supplies the lateral side of the fifth digit, while the other anastomoses with or takes the place of a branch of the superficial peroneal (musculocutaneous) nerve, which is distributed to the adjacent sides of the fourth and fifth digits (fig. 804).

The terminal branches of the common peroneal.—(1) The **recurrent articular nerve** (fig. 804) passes medialward, around the neck of the fibula, and through the upper part of the attachment of the extensor digitorum longus. At the medial border of the fibula it becomes associated with the anterior tibial recurrent artery, with which it ascends through the upper part of the tibialis anterior to the head of the tibia and the knee-joint. It supplies the tibialis anterior, the superior tibiofibular joint, and the knee-joint.

(2) The **superficial peroneal** (musculocutaneous) **nerve** (fig. 804) arises from the common peroneal between the peroneus longus and the neck of the fibula and descends in the intermuscular septum between the long and short peronei on the *lateral* side, and the extensor digitorum longus on the medial side. It gives off muscular and cutaneous branches in its descent, and at the junction of the middle and lower thirds of the leg it pierces the deep fascia and divides into a *medial dorsal* and a *lateral branch* (fig. 804).

Muscular branches are given off from the superficial peroneal to the peroneus longus and peroneus brevis before the nerve pierces the deep fascia.

Cutaneous branches pass from the trunk of the superficial peroneal to the skin of the lower part of the front of the leg.

The **medial dorsal cutaneous nerve** passes downward and medialward across the transverse and the cruciate (anterior annular) ligament of the ankle and subdivides into two branches. The *medial branch* passes to the medial side of the great toe; it also supplies twigs to the skin of the medial side of the foot, and it anastomoses with the deep saphenous nerve and with the medial terminal branch of the deep peroneal (anterior tibial) nerve. The *lateral branch* passes to the base of the cleft between the second and third toes and divides into two dorsal digital branches which supply the adjacent sides of the cleft.

The **lateral branch** (**intermediate dorsal cutaneous**) of the superficial peroneal, in separating from the medial, crosses in front of the cruciate ligament and divides into two dorsal digital branches, which pass beneath the dorsal venous arch. The medial of these branches supplies the adjacent sides of the third and fourth toes (fig. 804). The lateral branch communicates with the sural (external saphenous) nerve and is distributed to the adjacent sides of the fourth and fifth toes. This latter branch is frequently replaced by the sural nerve.

(3) The **deep peroneal** (**anterior tibial**) **nerve** springs from the end of the common peroneal (external popliteal) nerve between the peroneus longus muscle and the neck of the fibula. It passes forward and medialward through the upper part of the origin of the extensor digitorum longus, to the interval between that muscle and the tibialis anterior; then it descends, in the anterior compartment of the leg, to the ankle, where it divides into a medial and a lateral terminal branch (fig. 804).

In the upper part of the leg the deep peroneal nerve lies between the extensor digitorum longus and tibialis anterior and lateral to the anterior tibial artery. In the middle of the leg it is in front of the artery and between the extensor hallucis longus and tibialis anterior; then it crosses beneath the extensor hallucis, and in the lower third of the leg it is again to the lateral side of the artery, but between the extensor hallucis longus and the extensor digitorum longus.

Branches furnished from the trunk of the deep peroneal are muscular, articular, and terminal.

The **muscular branches** supply the tibialis anterior, extensor digitorum longus, extensor hallucis longus, and peroneus tertius.

Articular filaments are given to the ankle-joint and the inferior tibiofibular articulation.

Terminal branches.—The **medial terminal branch** passes downward along the side of the dorsalis pedis artery and divides into two dorsal digital branches which supply the adjacent sides of the first and second toes. It also gives filaments to the periosteum of the adjacent bones, to the metatarsophalangeal and interphalangeal articulations, a twig to the dorsal interosseous muscle of the first space, and a perforating twig which connects with the lateral plantar nerve. The **lateral terminal branch** passes lateralward, beneath the extensor digitorum brevis, and it ends in a gangliform enlargement from which branches are distributed to the extensor digitorum brevis, the tarsal joints, and to the three lateral intermetatarsal spaces. The latter branches supply the neighboring bones, periosteum, and joints. They give off perforating twigs, which pass through the spaces and anastomose with branches of the lateral plantar nerve, and the most medial also gives a twig to the second dorsal interosseous muscle.

THE PUDENDAL PLEXUS

The **pudendal plexus,** like the parts of the lumbosacral plexus alread scribed, varies in its formation. The following table shows the extreme ra variation and the common method of formation of the largest nerve (puden pudic) of this plexus in each of the three classes previously referred to.

Common Composition

Nerve	Prefixed	Ordinary	Post
Pudic nerve	2, 3 S.	2, 3, 4 S.	3, 4

Range of Variation

Nerve	Prefixed	Ordinary	Post
Pudic nerve	1, 2, 3, 4, 5 S.	1, 2, 3, 4 S.	2, 3, 4

The pudendal plexus is commonly formed by parts of the anterior divisi the second, third, and fourth sacral nerves (fig. 795). It lies in the lower p the back of the pelvis, and gives off visceral, muscular, and terminal bran

Visceral branches (pelvic splanchnics) arise from the third and fourth nerves especially, and enter branches of the sympathetic plexus. Th distributed both directly by their afferent or sensory fibers terminating pelvic viscera and indirectly by their visceral efferent fibers terminating ganglia of the sympathetic plexus or upon ganglion cells in the walls of the viscera (figs. 795, 818). The **middle hemorrhoidal nerves** pass to the rectu **inferior vesical nerves** to the bladder, and, in the female, the **vaginal nerves** vagina (see Sympathetic System).

Muscular branches are given by the fourth sacral nerve to the cocc levator ani, and sphincter ani externus (fig. 795).

The nerves to the two former muscles pass into the pelvic surfaces of the muscles, t to the last-named muscle, called the **perineal branch,** passes backward between the ani and the coccygeus, or through the posterior fibers of the latter muscle, into the p part of the ischiorectal fossa, and, in addition to supplying the sphincter ani, it gives cu filaments to the skin between the anus and the coccyx.

Terminal branches.—The **pudendal (pudic) nerve** [n. pudendus] rises i from the anterior primary divisions of the second, third, and fourth sacral (figs. 795, 796). It emerges from the pelvis below the piriformis, crosses th of the ischium, lying to the medial side of the internal pudic artery (figs. 80(and accompanies the artery, through the small sciatic foramen, into Alcock' in the obturator fascia on the lateral wall of the ischiorectal fossa, where it nates by dividing into three branches, the inferior hemorrhoidal, the perine the dorsal nerve of the penis.

The inferior hemorrhoidal nerves frequently arise independently from the third and fourth sacral nerves, pierce the medial wall of Alcock's canal, and pass forward and medialward through the ischiorectal fat to supply the sphincter ani externus and adjacent skin. They anastomose with branches of the perineal nerve.

The perineal nerve (fig. 1100) runs forward for a short distance in Alcock's canal and divides into a deep and a superficial branch. The *deep branch* breaks up into filaments, one or two of which pierce the medial wall of the canal and pass medialward to the anterior fibers of the sphincter and levator ani. The remaining part of the nerve pierces the base of the urogenital diaphragm, and enters the superficial pouch of the urethral triangle, where it is distributed to the bulb of the urethra, and to the transversus perinei, bulbocavernosus, and ischiocavernosus. It also sends some sensory filaments to the mucous membrane of the urethra. The *superficial branch* almost at once divides into medial and lateral branches, the *posterior scrotal* (*labial*) nerves.

Both branches pass through the wall of Alcock's canal into the anterior part of the ischiorectal fossa, then they pierce the base of the urogenital diaphragm, and enter the superficial pouch of the urethral triangle. The lateral branch usually passes below the transversus perinei, and the medial branch above the muscle or through its fibers. The lateral branch connects with the long pudendal nerve, and with the inferior hemorrhoidal nerve, and both branches end in terminal filaments which anastomose and which are distributed to the skin of the scrotum and the anterior part of the perineum in the male, and to the labium majus in the female.

The dorsal nerve of the penis runs forward in Alcock's canal above the internal pudic artery. It pierces the base of the urogenital diaphragm, continues forward between its layers, embedded in the fibers of the constrictor urethræ, and it gradually passes to the lateral side of the internal pudic artery. A short distance below the pudic arch it pierces the anterior layer of the urogenital diaphragm, gives a branch to the corpus cavernosum penis, passes forward between that structure and the bone, and turns downward on the dorsum of the penis, passing between the layers of the suspensory ligament and along the outer side of the dorsal artery of the penis. It supplies the skin of the dorsum of the penis, and, having given branches to the prepuce, it breaks up into terminal filaments which are distributed to the glans penis.

The dorsal nerve of the clitoris is much smaller than the dorsal nerve of the penis to which it corresponds. It is distributed to the clitories.

THE COCCYGEAL PLEXUS

This plexus is frequently, and with reason, considered as a subdivision of the pudendal plexus, and sometimes it is described with the coccygeal nerves. It is formed chiefly by the anterior division of the fifth sacral nerve and the coccygeal nerve, but it receives a small filament from the anterior division of the fourth sacral nerve (figs. 795, 796, 800). These constituents unite to form plexiform cords lying on either side of the coccyx. From these cords arise the **anococcygeal nerves,** which pierce the sacrotuberous (great sacro-sciatic) ligament and supply the skin in the neighborhood of the coccyx.

III. THE DISTRIBUTION OF THE CUTANEOUS BRANCHES OF THE SENSORY AND MIXED CRANIAL AND SPINAL NERVES.

The cutaneous filaments of the sensory and mixed nerves are distributed to definite regions of the surface of the body which are known as 'cutaneous areas.' Each cutaneous area has one special nerve of supply and the central part of the area receives that nerve alone, but wherever the borders of two areas meet they reciprocally overlap, therefore each margin of every cutaneous area has two nerves of supply, its own nerve and that of an adjacent area, and of these, sometimes one and sometimes the other preponderates.

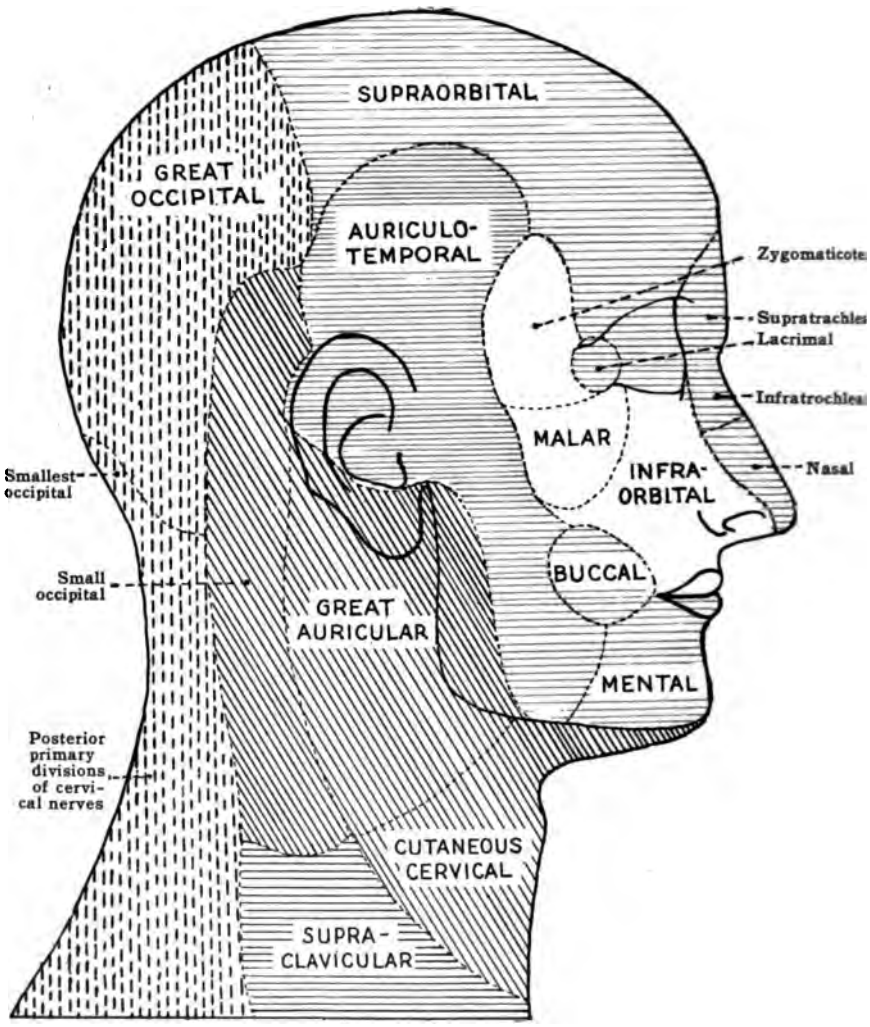
The Cutaneous Areas of the Scalp

The limits of the cutaneous areas in the scalp region are indicated in figs. 805, 807, but in general terms it may be said that the skin of the scalp in front of the auricle is supplied by

four cutaneous nerves, viz., the medial part by the supratrochlear and the supraorbital bra of the ophthalmic division of the trigeminus, and the lateral part by the temporal branch maxillary division, and the auriculotemporal branch of the mandibular division of the nerve.

The portion of the scalp behind the auricle also receives four cutaneous nerves; later is supplied by the great auricular and small occipital branches of the cervical plexus contain filaments from the second and third cervical nerves, and medially it receives the and smallest occipital nerves which are derived from the medial branches of the pos primary divisions of the second and third cervical nerves respectively.

FIG. 805.—DIAGRAM OF THE CUTANEOUS NERVE-AREAS OF THE HEAD AND NECK
Red—ophthalmic division of trigeminus. White—maxillary division of trige
Blue—mandibular division of trigeminus.
Vertical broken line shading—Posterior primary divisions of cervical nerves.
Oblique shading—Ascending and transverse superficial branches of cervical plexus.
Transverse shading—Descending superficial branches of cervical plexus.
It must be remembered that the boundaries of each area are not distinct; wherev areas meet they overlap.



THE CUTANEOUS AREAS OF THE FACE

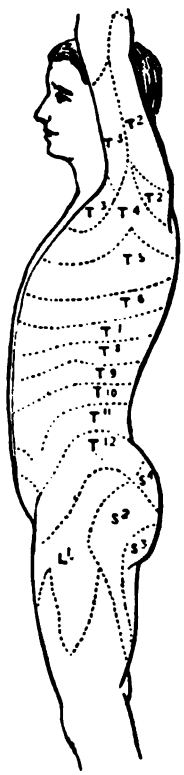
With the exception of the skin over the posterior part of the masseter muscle, th of the skin of the face is supplied by the branches of the trigeminus (figs. 805, 807). Th supplied medially by the supratrochlear, the infratrochlear, and the nasal branches ophthalmic division, and laterally by the infraorbital branch of the maxillary division upper eyelid is supplied by the supratrochlear, the supraorbital, and the lacrimal b of the ophthalmic division; the lower eyelid by the infratrochlear branch of the o mic division andby the infraorbital and the zygomaticofacial (malar) branches of the m division. The skin over the upper jaw and the zygomaticofacial (malar) bone is supp

infraorbital and zygomaticofacial branches of the maxillary division, that over the buccinator by the buccal branch of the mandibular division, and that over the lower jaw, from in front backward, by the mental, buccal, and auriculotemporal branches of the mandibular division, except a small part near the posterior border which receives its supply from the great auricular nerve.

The Cutaneous Areas of the Auricle

The upper two-thirds of the outer surface of the auricle (pinna) are supplied by the auriculotemporal branch of the mandibular division of the trigeminus, and the lower third by twigs of the great auricular nerve (fig. 805). The lower three-fourths of the cranial surface of the auricle are supplied by the great auricular nerve, and the upper fourth by the small occipital nerve. The posterior surface of the external auditory meatus receives filaments from the auricular branch of the vagus.

Fig. 806.—Diagram of the Cutaneous Areas of the Side of the Body and Part of the Limb. (After Head.)



The Cutaneous Areas of the Neck

The skin over the anterior part of the neck (figs. 805, 807) is supplied by the superficial cervical branch of the cervical plexus, which contains fibers from the second and third cervical nerves, and in the lower part of its extent, by the anterior supraclavicular nerves (suprasternal branches), which convey twigs of the third and fourth cervical nerves. The lateral part of the neck receives filaments from the second, third, and fourth cervical nerves by way of the great auricular, small occipital, and middle supraclavicular (supraclavicular) branches of the cervical plexus, and posteriorly the skin of the neck is supplied by the smallest occipital nerve and by the medial branches of the posterior primary divisions of the cervical nerves from the second to the sixth inclusive.

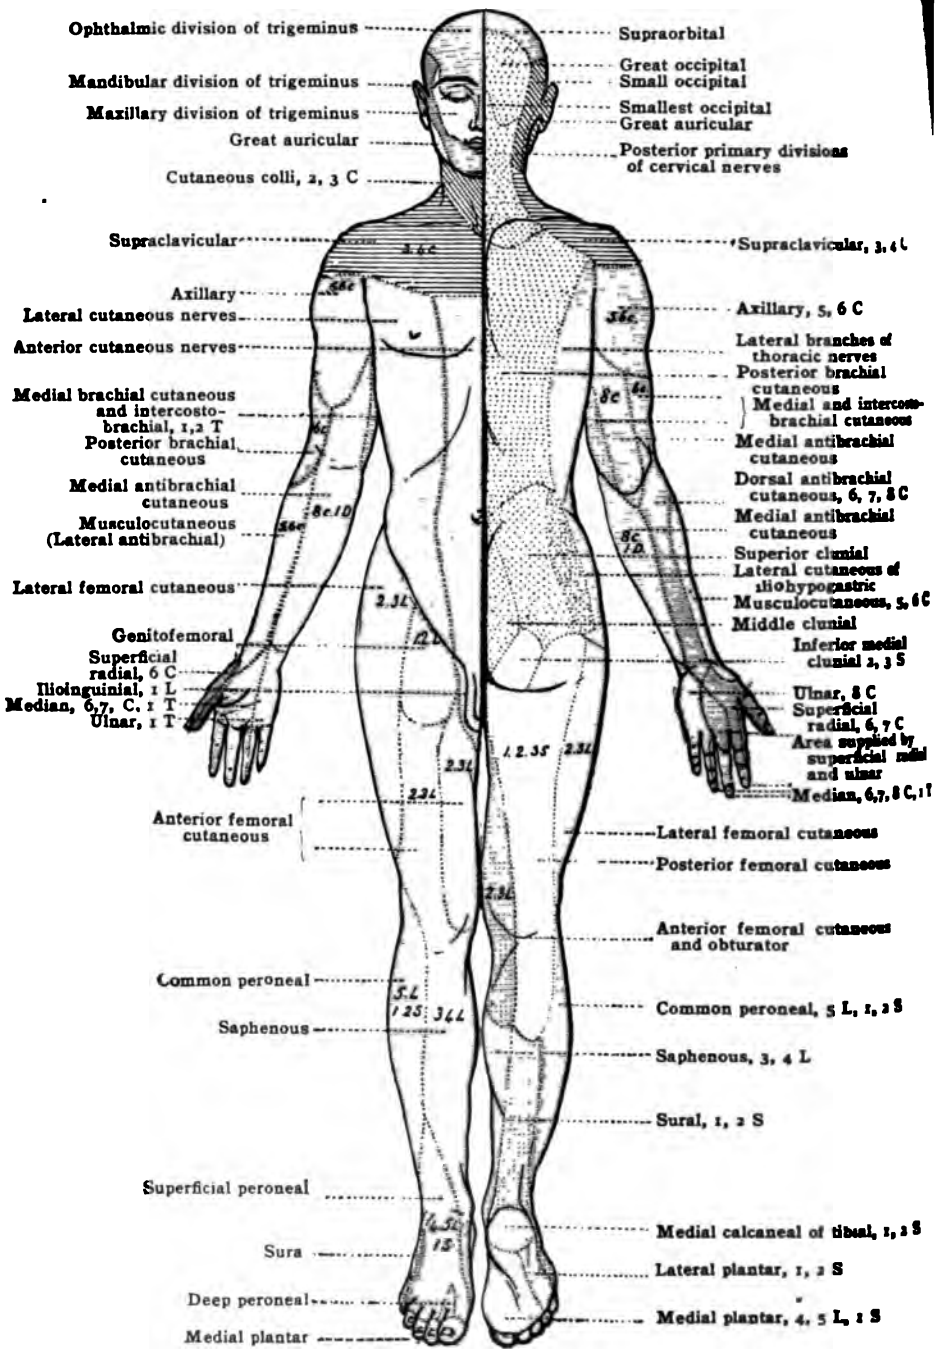
The Cutaneous Areas of the Trunk

The skin over the ventral aspect of the trunk as far down as the third rib is supplied by the anterior supraclavicular (suprasternal) and middle supraclavicular (supraclavicular) branches of the cervical plexus, which contain filaments from the third and fourth cervical nerves (fig. 807). From the third rib to the lower part of the abdominal wall the skin receives the anterior cutaneous branches, and the anterior divisions of the lateral cutaneous branches of the thoracic nerves except the first, second, and twelfth. The skin over the lower and anterior part of the abdominal wall is supplied by the ilio-hypogastric branch of the first lumbar nerve.

FIG. 807.—DIAGRAM SHOWING AREAS OF DISTRIBUTION OF CUTANEOUS NERVES.

HEAD:—RED—Ophthalmic division of trigeminus. White—maxillary division of trigeminus. Blue—mandibular division of trigeminus. Dotted area—Posterior primary divisions of cervical nerves. Oblique and transverse shading—Branches of cervical plexus.

BODY AND LIMBS:—RED—Anterior branches of anterior primary divisions. Blue—Posterior branches of anterior primary divisions. Two colors in one area indicate that the area is supplied by two sets of nerves, and it should be remembered that wherever two nerve areas approach each other they overlap. The dotted blue area of the posterior femoral cutaneous (small sciatic) indicates that the nerve comes from the posterior as well as from the anterior parts of the anterior primary divisions of the sacral nerves, but it supplies a flexor area. The area of the inferior medial cluneal nerve is left uncolored, because its true nature is uncertain. Dotted shading—posterior primary divisions. The numbers and initial letters refer to the respective spinal nerves from which the nerve-supplies are derived.



The cutaneous supply of the lateral aspects of the body (fig. 806) is derived from the lateral branches of the anterior primary divisions of the thoracic nerves from the second to the eleventh, and the skin over the dorsal aspect of the body is supplied laterally by the posterior divisions of the lateral branches of the thoracic nerves from the third to the eleventh, and medially by the posterior primary divisions of the thoracic nerves, in the upper half by their medial branches and in the lower half principally by their lateral branches.

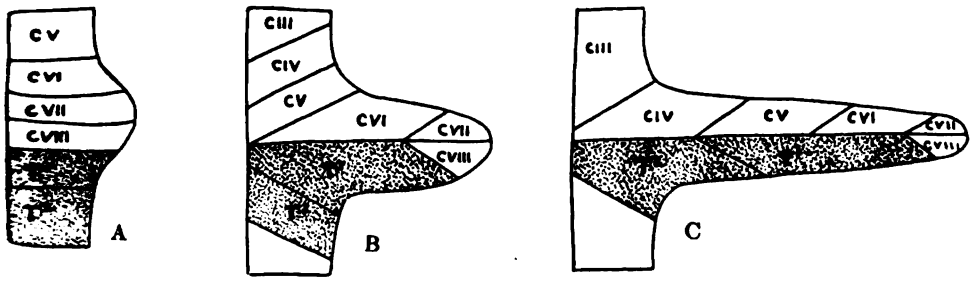
THE CUTANEOUS AREAS OF THE LIMBS

The areas of skin of the upper and lower limbs which are supplied by the branches of the brachial, lumbar, and sacral plexuses are indicated in fig. 807, and the spinal nerves which contribute to each nerve area are noted. The question of the skin areas supplied by any given spinal nerve is one of great clinical importance, in connection with the diagnosis of injuries of nerves and of pathological conditions affecting them. Therefore, considerable attention has been directed to the matter and it has been found that the areas which become hypersensitive when certain spinal nerve-roots are irritated, or anesthetic when the roots are destroyed, do not correspond exactly with the regions to which the fibers of the roots can apparently be traced by dissection.

Moreover, it has been discovered, partly by clinical observations on the human subject and partly by experiment on monkeys, that the nerves of the limbs have a more or less definite *segmental distribution*. To understand clearly this segmental arrangement the reader must remember that in the embryonic stage when no limbs are present the body is formed of a series of similar segments, each of which is provided with its own nerve. At a later stage when the limbs grow outward, each limb is formed by portions of a definite number of segments which fuse

FIG. 808.—DIAGRAMS A, B, AND C, ILLUSTRATING STAGES IN THE PROJECTION OF THE LIMB-BUDS FOR THE UPPER EXTREMITY, AND THE DRAWING OUT OF THE NERVES OF THE CORRESPONDING BODY SEGMENTS FOR THE CUTANEOUS AREAS OF THE PREAXIAL AND POSTAXIAL BORDER OF THE LIMB.

Postaxial border shaded.

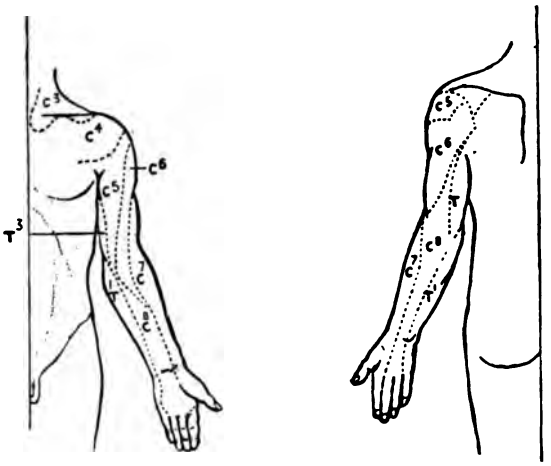


together into a common mass of somewhat wedge-like outline. Each rudimentary limb possesses a dorsal and a ventral surface. The dorsal surfaces of both the upper and the lower limbs are originally the extensor surfaces, and the ventral surfaces the flexor surfaces, but, as the upper limb rotates lateralward and the lower limb rotates medianward as development proceeds, in the adult, the extensor surface of the upper limb becomes the posterior surface, and the extensor surface of the lower limb, the anterior surface. The preaxial border of the upper limb is the radial or thumb border, and the postaxial border, the ulnar or little finger border. The preaxial border of the lower limb is the tibial or great toe border, and the postaxial border, the fibular or little toe border. As projections of the segments of the body grow out to form the limb-buds and limbs each projection carries with it the whole or part of the nerve of the segment to which it belongs, and therefore the number of body segments which take part in a limb is indicated by the number of spinal nerves which pass into it. If these facts are remembered it will naturally be expected (1) that the highest spinal nerves passing into a limb will be associated with its preaxial portion and the lowest with its post-axial portion; (2) that only the nerves of those segments forming middle or central portions of the limbs will extend to the tips of the limbs; (3) that the highest and lowest segments in each limb area will take a smaller part in the formation of the limb that the middle segments; and (4) that, consequently, the highest and lowest nerves will pass outward into the limb for a shorter distance than the middle nerves. Observers are not yet in perfect agreement as to the exact distribution of each nerve, but the diagrams in figs. 806 to 812 show the embryonic derivation of the cutaneous areas and the adult dorsoventral segmental arrangement in the projected portions of both the upper and lower limbs as assumed from clinical observations. In the upper parts of the lower limbs, the original segmental distribution appears to be masked. This may be due (1) partly to the fact that the areas recognizable by clinical phenomena do not correspond exactly with the areas to which definite dorsal root-fibers are distributed, but rather to definite segments of the gray substance of the spinal cord with which the root-fibers are connected; (2) partly to the overlapping of segments and the acquired preponderance of one nerve over another in the overlapping areas, and (3) partly to the fact that in the lower limb there has been a greater amount of shifting of parts to result in the fixed flat position of the sole of the foot; (4) and partly to the incompleteness of the data which are at our disposal in the case of the human subject. Sherrington has proved that in the monkey the sensory areas of the limbs are arranged in serial correspondence

with the spinal nerves, the middle nerves of each limb series passing to the distal par extremity while the higher and lower nerves are limited to the proximal regions. Th observations, which differ from Head's, are, especially as regards the upper limb, conformity with the results obtained by Sherrington's experiments on monkeys.

Each limb may be divided into its preaxial and postaxial borders by a line dra tudinally along the middle of both its anterior and posterior surfaces (compare figs. 808

FIG. 809.—DIAGRAM OF THE CUTANEOUS AREAS OF THE UPPER EXTREMIT (Modified from Head.)

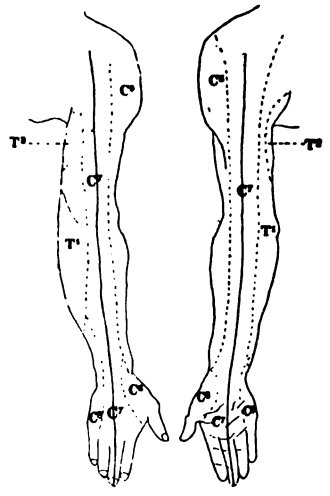


The cutaneous nerves to the preaxial border are from the cephalic portion of the li and those to the postaxial are from the caudal components of the plexus. Thus t and index finger are cephalad.

THE CUTANEOUS AREAS OF THE UPPER LIMB

A line passing along the middle of both the anterior and posterior surfaces of the tremity to the tip of the middle finger (fig. 810) separates the preaxial from the border and passes longitudinally along the area of the cutaneous fibers derived from t cervical nerve.

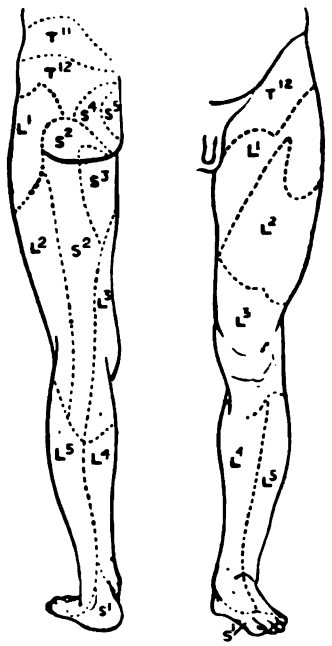
FIG. 810.—DIAGRAM OF THE CUTANEOUS AREAS OF THE UPPER EXTREMI The solid middle lines are drawn to separate preaxial (radial) borders from postaxi (After Thorburn, modified.)



The skin over the upper third of the deltoid muscle is supplied by the poste clavicular (supra-acromial) and middle supraclavicular (supraclavicular) nerves, branches of the cervical plexus containing fibers of the third and fourth cervical that over the lower two-thirds by the axillary (circumflex) nerve which conveys f fifth and sixth cervical nerves (fig. 807).

The skin over the lateral surface of the upper arm is supplied externally by the axillary (circumflex) nerve above, and below by the superior branch of the dorsal antibrachial cutaneous, the external cutaneous branch of the radial (musculospiral) nerve. The former contains filaments of both the fifth and sixth cervical nerves, and the latter filaments of the sixth alone. The skin of the medial side of the upper arm is supplied by the medial antibrachial cutaneous (internal cutaneous) nerve with fibers of the eighth cervical and first thoracic nerves, and by the medial brachial cutaneous (lesser internal cutaneous) and intercostobrachial (intercostohumeral) nerves which are derived from the first and second thoracic nerves. The dorsal side of the upper arm is supplied, laterally, by the fifth and sixth cervical nerves through the axillary (circumflex) nerve and by the dorsal antibrachial cutaneous; the middle portion, by the seventh cervical nerve through the posterior brachial cutaneous, the internal cutaneous branch of the radial (musculospiral) nerve; and the medial portion by the first and second thoracic nerves through the medial brachial cutaneous (lesser internal cutaneous) nerve, and the intercostobrachial (intercostohumeral) nerve (fig. 807).

FIG. 811.—DIAGRAM OF THE CUTANEOUS AREAS OF THE LOWER EXTREMITY. (After Head.)



The front of the forearm is divided into three areas, a lateral which is supplied by the fifth, sixth, and possibly the seventh cervical nerves, through the musculocutaneous branch of the brachial plexus; a middle which is supplied by the seventh cervical nerve as above, and a medial area supplied by the eighth cervical and first thoracic nerve through the medial antibrachial cutaneous (internal cutaneous) nerve. On the dorsal side of the forearm there are three areas: —(1) a lateral supplied by fibers of the fifth and sixth cervical nerves through the musculocutaneous nerve; (2) a middle, which receives fibers of the seventh, and probably some from the sixth and eighth cervical nerves through the lower branch of the dorsal antibrachial cutaneous branch of the radial (inferior external cutaneous branch of the musculospiral nerve), and (3) a medial which receives fibers from the eighth cervical and first thoracic nerves through the medial antibrachial cutaneous (figs. 807, 810).

The palm of the hand is supplied by the sixth, seventh, and eighth cervical nerves through the superficial radial (radial) nerve, and through the median and ulnar nerves. The superficial radial supplies the radial side of the thumb by its palmar cutaneous branch. The remainder of the palm and the palmar aspects of the fingers are supplied by the median and ulnar nerves through their palmar cutaneous and digital branches, the median supplying three and a half digits and the ulnar the remaining one and a half (figs. 791, 807 and 810).

The dorsal aspect of the hand is supplied by the sixth, seventh, and eighth cervical nerves, which reach it through the superficial radial (radial) and through the median and ulnar nerves. The superficial radial supplies the lateral part of the dorsum and the lateral three and a half digits, except the lower portions of the second, third, and half of the fourth digits, which receive twigs from the median nerve; the ulnar nerve supplies the ulnar half of the dorsum of the hand, including the medial one and a half digits. The areas supplied by definite spinal nerves according to the observations of Head and Thorburn, are shown in figures 809 and 810 respectively.

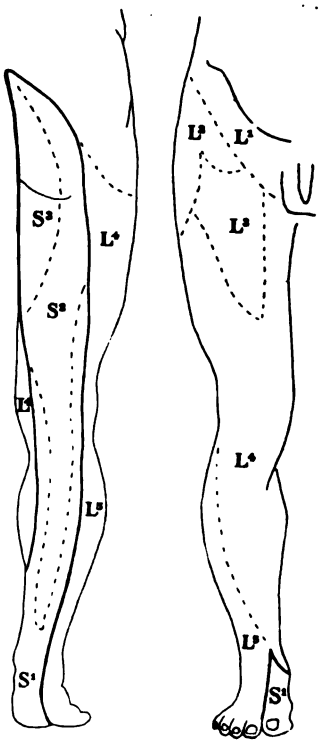
THE CUTANEOUS AREAS OF THE LOWER EXTREMITY

The segmental arrangement of the cutaneous areas of the lower extremity is not so well retained as in the upper, due largely to a greater amount of developmental shifting of the parts.

Both of the lines separating the areas of the lumbar (cephalic) and the sacral (caud of the lumbosacral plexus lie on the dorsal aspect of the limb. The nerves from the part of the plexus are distributed to the entire anterior and the medial and lateral su the limb and to the muscles of the anterior and medial portions of the thigh and the portion of the leg, whereas the cutaneous nerves from the sacral part of the plexus fined to a narrow strip along the dorsal aspect of the limb (fig. 812). However, the n distribution of the sacral part is as much expanded as its cutaneous area is contracted; it the muscles in the dorsal portions of the hip, thigh and knee, the whole of the dorsa the leg and ankle and the plantar muscles of the foot.

There are six cutaneous areas in the region of the buttock, three upper and thr Of the upper areas the lateral is supplied by the anterior primary divisions of the last and first lumbar nerves through the iliac branches of the last thoracic and the iliohy nerves; the middle upper area receives the lateral divisions of the posterior primary of the upper three lumbar nerves, and the medial upper area is supplied by twigs from th branches of the posterior primary divisions of the upper two or three sacral nerves (811).

FIG. 812.—DIAGRAM OF THE CUTANEOUS AREAS OF THE LOWER EXTREMIT (After Thorburn, modified.)



Of the lower three areas, the lateral receives filaments from the second and thi nerves through the lateral femoral cutaneous (external cutaneous) branch of the lumb the middle area is supplied by the first, second, and third sacral nerves through th femoral cutaneous (small sciatic) nerve; and the medial area by the second and th nerves through the medial inferior clunial (perforating cutaneous) branch of the sa (fig. 807).

On the back of the thigh there are three areas. According to Head, the medial a areas are supplied by the second and third lumbar nerves, the former through t femoral cutaneous (external cutaneous) branch of the lumbar plexus, and the latte the anterior cutaneous branches of the femoral (internal cutaneous branch of th crural) nerve. The middle area receives twigs from the first, second, and third sac through the posterior femoral cutaneous (small sciatic), a branch of the sacral plexu

The front of the thigh is supplied by the first, second, and third lumbar nerves, and, to Head, there are five cutaneous areas. The lateral area receives twigs of the second lumbar nerves through the lateral (external) cutaneous nerves. There are two me an upper and a lower. The former is supplied by the lumboinguinal (crural) branch of t femoral (genitocrural), which conveys twigs of the first and second lumbar nerves; receives fibers of the second and third lumbar nerves through one of the anterio cutaneous branches of the femoral (anterior crural) nerve. The small upper and mec supplied by the first lumbar nerve through the ilioinguinal, and the lower medial ar twigs of the second and third lumbar nerves through one of the anterior cutaneou (internal cutaneous) of the femoral (anterior crural) nerve (fig. 807).

The front of the knee is supplied by the second, third, and fourth lumbar nerves through the anterior (middle and internal) cutaneous and saphenous (long saphenous) branches of the femoral (fig. 807).

Of the skin over the region of the popliteal space, the medial portion receives fibers from the second, third, and fourth lumbar nerves through the anterior (internal) cutaneous branch of the femoral (anterior crural) nerve and through the superficial division of the obturator nerve; the middle and lateral portion receives twigs of the first three sacral nerves through the posterior cutaneous (small sciatic) nerve (fig. 807).

The skin over the front and medial side of the leg is supplied by the fourth lumbar nerve through the saphenous nerve, and the skin of the front and lateral side receives nerve-fibers from the fifth lumbar nerve through the sural cutaneous (fibular communicating) branch of the common peroneal (external popliteal) nerve.

In the skin of the back of the leg four areas can be distinguished, a medial, two middle, upper and lower, and a lateral area. The medial area is supplied by the fourth and fifth lumbar nerves through an anterior cutaneous branch (internal cutaneous) of the femoral (anterior crural) nerve and the superficial branch of the obturator nerve. The upper middle area is supplied by the second and third sacral nerves through the posterior femoral cutaneous (small sciatic) nerve, and the lower middle area by the first sacral nerve through the sural (external saphenous) nerve. The lateral area is supplied by the fifth lumbar nerve through the lateral sural cutaneous (fibular communicating) branch of the common peroneal (external popliteal) nerve (figs. 807, 811, 812).

The skin of the dorsum of the foot is supplied principally by the fifth lumbar and by the first sacral nerves; the majority of the nerve-fibers travel by the superficial peroneal (musculocutaneous) nerve, but the adjacent sides of the first and second toes are supplied by the femoral (anterior crural) nerve and the side of the dorsum of the little toe is supplied through the sural (external saphenous).

The skin of the region of the heel is supplied by the first sacral nerve, the medial surface and medial part of the under surface by the medial calcaneal branches of the tibial calcaneoplantar) nerve and the posterior, external, and lower aspects by the sural (external saphenous) nerve (fig. 807).

The sole of the foot in front of the heel receives cutaneous fibers from the fifth lumbar and the first sacral nerves; the medial area, which includes the medial three and a half digits, being supplied by the medial plantar nerve which conveys fibers of the fifth lumbar and the first sacral nerves; and the lateral area by the fifth lumbar nerve through the lateral plantar nerve.

The medial side of the foot is supplied by the first sacral and fourth lumbar nerves through the saphenous nerve and the lateral side by the fifth lumbar nerve through the sural (external saphenous) nerve.

The skin of the scrotum and penis is supplied by the first lumbar nerve through the ilioinguinal nerves, and by the second and third sacral nerves through the perineal and dorsal penile branches of the pudendal (pudic) nerve.

The cutaneous areas of the lower extremity which have been demarcated by Head and Thorburn are shown in fig. 811. These do not conform wholly with each other nor with the areas given in more detail in fig. 807, due probably to individual differences in subject and observer and to the difficulties coincident with the overlapping of the areas. Fig. 812 is more general in character and is considered more approximately correct.

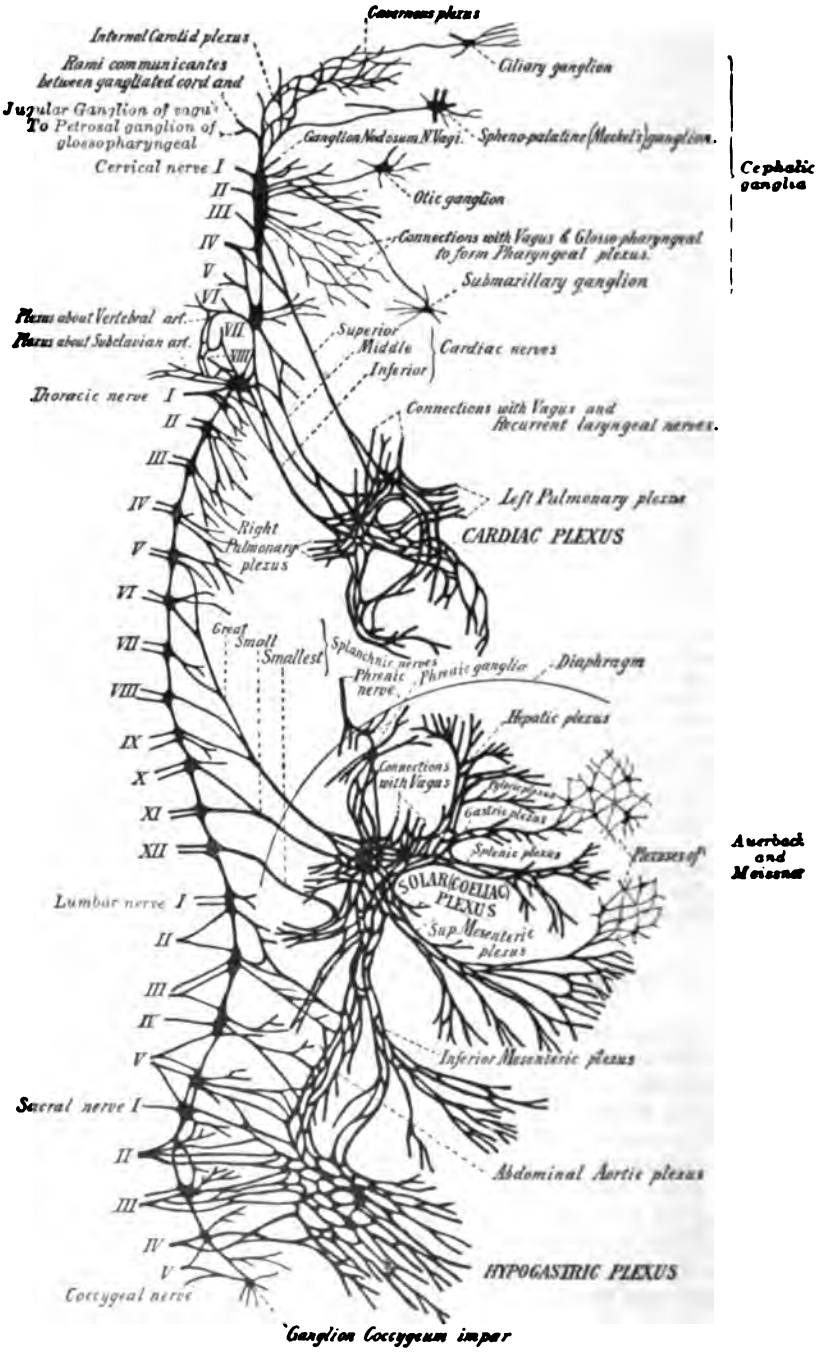
The homology of the parts of the plexuses of the upper and lower extremities is not well carried out in the distribution of the nerves. The radial and great sciatic nerves are similar to the extent that the one arises from the posterior cord of the brachial plexus and the other from the sacral plexus, and that the one is distributed to the dorsal aspect of the arm and the other to the dorsal surface of the lower extremity, but the great sciatic supplies the sole of the foot, and the plantar muscles, whereas the radial does not supply the palm of the hand and the palmar muscles.

THE SYMPATHETIC SYSTEM

The so-called sympathetic system is that collateral division of the peripheral nervous system which is especially concerned in the distribution of impulses to all glands, to the muscle of the heart, and to the plain muscular tissue of the body (including that of blood- and lymph-vessels, of the digestive, respiratory and urogenital apparatuses, integument, etc.). Since these tissues are most abundant in and largely comprise the viscera or splanchnic organs of the body, the largest and most evident of the structures comprising the sympathetic system are found either in or near the cavities containing the viscera. However, the finer divisions of the system ramify throughout the whole body, supplying vasomotor fibers to the blood-vessels throughout their course, controlling the glands of the skin, and supplying pilomotor fibers for the hairs, and forming intrinsic plexuses within the walls of the viscera. Though it seems probable that certain of the simpler reflexes of the splanchnic organs may be mediated by the sympathetic system alone, yet the sympathetic is by no means independent of the craniospinal system, but is rather, both anatomically and functionally merely a part of one continuous whole. Throughout, it shares its domain of termination with craniospinal fibers, chiefly of the sensory variety, and most of its rami and terminal branches carry a few craniospinal fibers toward their areas of distribu-

tion. Likewise the craniospinal nerves carry numerous sympathetic fibers gained by way of rami connecting the two systems.

FIG. 813.—SCHEME SHOWING GENERAL PLAN OF THE COARSER PORTIONS OF THE SYMPATHETIC NERVOUS SYSTEM AND ITS PRINCIPAL COMMUNICATIONS WITH THE CEREBROSPINAL SYSTEM (After Flower, modified.)



Like the craniospinal system, the sympathetic consists of cell-bodies, each of which gives off one axone. In addition, the cell-bodies give off numerous dichotomously branched dendrites by which their receptive surfaces are increased, and they are accumulated into ganglia large and small. The larger ganglia have more or less constant positions, shapes, and arrangements, while the smaller, some of which are microscopic, are scattered throughout the body in a seemingly more indefinite manner. The axones or fibers arising in these sympathetic ganglia

en off in trunks and rami which associate the ganglia with each other or with the cranio-
system, or which pass from the ganglia to be distributed directly upon their allotted
its.

e **sympathetic fibers** arising from the ganglia are, for the most part, either totally non-
ated or partially medullated. Some fibers are completely medullated near their cells
in, but lost their medullary sheaths before reaching their terminations. Some of them
complete medullary sheaths throughout, but in no cases are the sheaths as thick or
veloped as is the rule with the craniospinal fibers. Thus, nerve-trunks and rami in
sympathetic fibers predominate appear grayish in color and more indefinite, as dis-
hed from those of the craniospinal nerves, which always appear a glistening white, due
t being reflected from the emulsified myelin of the sheathes of their fibers.

gin of the sympathetic system.—Not only must the craniospinal and sympathetic
s be considered anatomically continuous and dependent, but also the neurones of the
stems have a common origin, namely, the ectoderm of the dorsal midline of the embryo.
lls of the ganglion crest (see p. 790) become arranged in segmental groups and soon
te into two varieties:—those which will remain near the spinal cord and develop into
nal ganglia, and those which, during the growth processes, migrate and become displaced
r into the periphery and form the sympathetic ganglia.

the development of the sympathetic system the migration from the vicinity
e central system occurs to varying extents, so that in the adult the
comprise three general groups of ganglia situated different distances away
the central nerve axis.—(1) A large portion of the cells remain near the
al system and form a linear series of ganglia which, with the trunks con-
ng them, become two gangliated *sympathetic trunks* extending along each side,
mal to and parallel with the vertebral column; (2) a still larger portion of the
migrate further toward the periphery and are accumulated into *collateral*
ia which assume an intermediate position and which, with the rami asso-
g them with each other and with other structures, form a series of great
tebral plexuses, such as the aortic, cardiac and celiac plexuses; (3) still other
wander even further away from the locality of their origin and invade the
walls of the organs innervated by the sympathetic system. The latter cells
as numerous small *terminal ganglia*, most of which are microscopic and
, with the twigs connecting them, form the most peripheral of the sympa-
plexuses. Examples of these are the intrinsic ganglia of the heart and
eas and the *plexuses of Auerbach* and *Meissner* in the walls of the digestive
. Small, straggling ganglia may be found scattered between these three
al groups. In the head, the sympathetic trunks and great prevertebral
ses are represented by the ciliary, sphenopalatine, otic and submaxillary
ia and the plexuses associated with these.

nstruction of the sympathetic system.—The sympathetic ganglia may be
lered as relays in the pathways for the transmission of impulses from the
in which they arise to the tissues in which they are distributed; the cells
osing the ganglia are the cell-bodies of the sympathetic neurones interposed
various neurone chains performing this function. A fiber arising from a
ody in a given ganglion may pass out of the ganglion and proceed directly to
mination upon a smooth muscle-fiber or gland-cell, or, fibers arising in given
ia may pass uninterrupted through other ganglia and proceed to their re-
ve destinations. Several neurones, only one being sympathetic, may be
ed in the transmission of a given impulse when sent from a region distant
the tissue to which it is distributed.

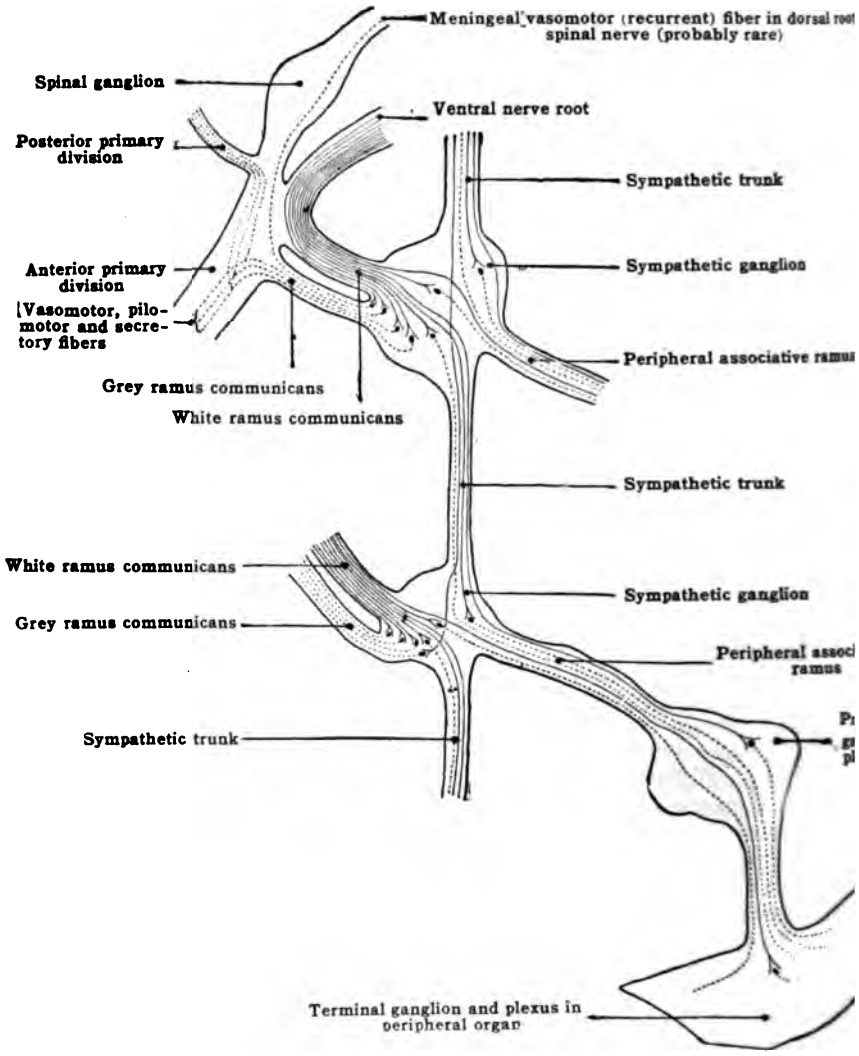
mmunication between the central nervous system and the sympathetic is
lished through both efferent and afferent fibers. In the region of the
l cord both varieties of fibers pass from one system to the other by way of the
communicantes, delicate bundles of fibers connecting the nearby sympa-
trunk with the respective spinal nerves (fig. 779). The cranial nerves are
se abundantly associated with the gangliated cephalic sympathetic plexuses.

e efferent fibers of the rami arise in the ventral horn (dorsolateral cell-group chiefly) of
nal cord, emerge through the ventral roots, enter the rami, and terminate about the cells
sympathetic ganglia. Since these fibers transmit impulses from the central to the sympa-
system, they are known as **visceral efferent** or **preganglionic fibers.** They are of smaller
an is the average for the craniospinal somatic efferent fibers of the ventral root.

ie thoracic and lumbar spinal nerves are each connected with the sympa-
trunk by two rami communicantes. Most of both the visceral efferent and
he visceral afferent fibers (which latter arise in the spinal ganglia) pass
ay of one ramus. These fibers are of craniospinal type and, being medul-

lated, they give the ramus a white appearance meriting the name, **white r communicans.** Fibers of the sympathetic type predominate in the w ramus, the **gray ramus communicans.** The latter consists of (1) fibers cen directed in the nerve and nerve roots to the blood vessels of the central ne system and (2) fibers which join the primary divisions of the nerve trun course in them to the peripheral tissues allotted to the sympathetic (fig. The cervical nerves have gray rami but no distinct white rami.

FIG. 814.—DIAGRAM SUGGESTING THE ORIGIN, COURSE AND CONNECTIONS OF SYMPATHETIC NERVE-FIBERS.



That the cervical nerves have no white rami communicantes is probably due to an ment by which at least most of the visceral efferent fibers arising in the cervical segme spinal cord pass downward in these segments and join the sympathetic through the whi the upper thoracic nerves; others enter the cervical sympathetic trunk and the va through the spinal accessory or eleventh cranial nerve, rather than through individual wh while others pass into the nerves of the brachial plexus to terminate in the minute gan plexuses upon the blood-vessels of the limb.

Vasomotor fibers to the meninges and intrinsic blood-vessels of th cord pass to the spinal nerves by way of the gray rami. Thence they m the meninges by one of three ways:—(1) through the delicate recurrent ingeal branch of the spinal nerve (fig. 779); (2) through the trunk and root of the spinal nerve; (3) probably more rarely, through the trunk an root of the spinal nerve (fig. 814).

Corresponding communications exist between the cranial nerves and the sympathetic, but the corresponding rami usually extend further toward the periphery and in not so regular a manner as the communications between the spinal nerves and the sympathetic system. The mesencephalon, for example, is chiefly connected with the ciliary ganglion of the sympathetic by fibers which are sent through the oculomotor nerve and which enter this ganglion by way of its short root and terminate about its cells. Visceral efferent fibers from the rhombencephalon pass outward to the sympathetic in the roots of the facial, glossopalatine, glossopharyngeal, vagus, and spinal accessory nerves, all of which have more or less irregularly disposed communicating rami. Likewise twigs of other cranial nerves, especially of the trigeminus, connect with (pass through) the small sympathetic ganglia of the head. The meningeal branches given by certain of the cranial nerves contain vasomotor fibers, and these correspond to the sympathetic fibers in the meningeal rami and in the roots of the spinal nerves.

It is known that spinal ganglia and certain of the ganglia of the cranial nerves contain cell-bodies of sympathetic neurones—cell-bodies which, during the period of the migration peripheralward, remained within the confines of these ganglia (fig. 779). These cell bodies receive efferent impulses from ventral root fibers and send their axones further into the periphery just as if in the sympathetic ganglion. Their relative abundance is not known. It is supposed that the ganglia of the vagus, glossopharyngeus, trigeminus and the geniculate ganglion contain a considerable proportion of such sympathetic cell-bodies.

According to the groups of sympathetic ganglia in which they make synapses, the visceral efferent fibers, or chief components of the white rami communicantes, may be described as coursing from their origin in the central system in two general streams:

(1) A *thoracolumbar stream* comprising visceral efferent fibers which pass from their origin in the spinal cord almost wholly by way of the white rami of from the first thoracic to the second lumbar spinal nerves inclusive and terminate (transfer their impulses) for the most part in the ganglia of the sympathetic trunk. Some terminate in the intermediate or collateral ganglia of the prevertebral plexuses. None are said to terminate in the terminal ganglia. Of those terminating in the ganglia of the trunk, some terminate in the nearest ganglia or those corresponding to their respective spinal nerves. Others enter the trunk and ascend or descend in it to terminate in ganglia of higher or lower levels. In general, fibers from the upper white rami of the stream run upward and those from the lower run downward. The fibers of the sympathetic trunks consist largely of these ascending and descending fibers. Fibers arising from the cells of the ganglia of the trunks pass out either by way of their peripheral branches, or, by way of the gray rami, join the spinal nerves to course to their destination in the terminal branches of these.

(2) A *sacral or pelvic stream* which arises from the inferior end of the spinal cord and passes almost wholly by way of the white rami of the second, third and fourth sacral nerves, usually, chiefly by the second and third or the third and fourth. Fibers of this stream do not terminate in the ganglia of the trunk, but pass either by them without connection or over them or through them without interruption, to terminate chiefly in the terminal ganglia. Some may terminate in the collateral ganglia.

The relations of the visceral efferent fibers of the cranial nerves to the sympathetic, when contrasted in this way, suggest the addition of a *cranial stream*. The visceral efferent fibers arising from the brain pass outward almost entirely by way of the vagus, spinal accessory, glossopharyngeal, facial, glossopalatine and oculomotor nerves. If the four pairs of the larger ganglia of the cephalic sympathetic plexus are considered as the superior extensions of the sympathetic trunks of each side, then, the cranial stream is similar to the sacral stream in part only. Most of the visceral efferent fibers of the oculomotor, glossopalatine and facial nerves, and some of those in the glossopharyngeal and probably the vagus terminate in these larger cephalic ganglia, while a very large proportion of those in the vagus and spinal accessory are not concerned at all with the cephalic ganglia, large or small, but pass to terminate in collateral and terminal ganglia below and removed from the region of the head. If, on the other hand, the sympathetic trunk be considered as terminating above with the superior cervical sympathetic ganglion and its branches of distribution to the head, then all the ganglia, large and small, of the cephalic sympathetic plexus must be considered as collateral and terminal ganglia of the sympathetic. Such analogy makes all the visceral efferent fibers of the cranial nerves similar to those of the sacral stream and thus makes possible reference to the two general streams of the body as a *thoracolumbar* and a *craniosacral stream*.

In general, these two streams of visceral efferent fibers are antagonistic in function. By way of them, the visceral organs receive a double innervation, one producing contractions of smooth and cardiac muscle, such as vasoconstrictor, pilomotor and peristaltic activities, the other inhibiting these; or, one exciting muscular contractions antagonistic to the contractions excited by the other. For example, the pupil is contracted by way of the cranial stream while its dilation is accomplished by way of the thoracolumbar stream. Inhibitory impulses are not confined to either stream. The craniosacral stream carries fibers inhibitory to the heart (the vagus proper) and fibers which excite peristalses in the stomach and intestine, while the thoracolumbar stream carries accelerator fibers for the heart and fibers inhibiting peristalses in the stomach and intestine.

For purposes of distinction, some physiologists refer to the neurones of the sacral (or craniosacral) visceral efferent stream, taken together with the sympathetic ganglion neurones with which the former make synapses, as the *parasympathetic system*, and reserve the name, *sympathetic system*, for the thoracolumbar stream, together with the sympathetic neurones with which they are chained. Further, the English physiologists (Langley especially) have suggested

the name, 'Autonomic nervous system,' to include the sum total of all the craniospinal visceral efferent neurones (preganglionic fibers, craniosacral and thoracolumbar) and all the sympathetic ganglion neurones (postganglionic fibers) in the body. This name includes those fibers which arise in sympathetic ganglia and enter and course to their destination in the trunks and branches of the craniospinal nerves; it includes the entire efferent innervation of all gland and cardiac and smooth muscle. As to function implied, the name is as misleading as the old term, 'Sympathetic system,' though it is anatomically more comprehensive. In microscopic anatomy, the visceral efferent preganglionic fibers, included in the name, are considered craniospinal fibers instead of part of the sympathetic system.

Visceral afferent fibers.—The sensory innervation of the visceral organs (enteroceptive) is accomplished by the peripheral processes of spinal ganglion neurones, and those of the ganglia of cranial nerves, which course outward in the nerve trunks to join the sympathetic either by way of the terminal branches of these trunks or by way of the white rami communicantes and thence through the sympathetic nerves and their terminal branches. They are merely craniospinal sensory fibers which collect impulses in the domain of the sympathetic and convey them to the central system by way of the sympathetic rami and the trunks and dorsal roots of the cranial and spinal nerves. Naturally, they pass through sympathetic ganglia without interruption. They serve chiefly to give rise to visceral reflexes. The sensations aroused by the impulses they carry to the central system are usually vague and indefinite, and most of the impulses do not enter consciousness at all. The cranial nerves carrying most visceral afferent fibers are the vagus, glossopharyngeus and trigeminus. There is no satisfactory evidence, once claimed, of afferent or sensory fibers arising from the cells of sympathetic ganglia.

Myenteric visceral reflexes.—There is evidence that purely local reflexes are possible within the walls of the digestive canal. Contractions of reflex character may be induced in the stomach and intestine after all the nerves leading to them have been cut—contractions different from the myogenic contractions which occur upon direct mechanical stimulation of the muscle and much different from the automatic contractions of excised cardiac muscle. They suggest the existence of complete reflex arcs within the wall of the gut. If so, the terminal ganglionated plexuses (of Auerbach and Meissner) within the wall must be concerned in them. They must depend upon an anatomical mechanism different from that of all other reflex arcs, but the mechanism is unknown. All other visceral reflexes involve at least three neurones: a visceral afferent neurone, a craniospinal visceral efferent or preganglionic neurone, and a sympathetic or postganglionic neurone. *Local enteric reflexes* would be a more expressive name for them than myenteric visceral reflexes.

From the above it may be seen that the ganglia and connecting trunks and rami of the sympathetic system may be divided as follows:—(1) The two gangliated **sympathetic trunks** lying adjacent to and parallel with the vertebral column; (2) the **great prevertebral plexuses,** containing the intermediate or collateral ganglia, of which plexuses there are roughly four, one in the head, one in the thorax, one in the abdomen, and one in the pelvic cavity (**fig. 813**), each of which is subdivided; (3) the numerous **terminal ganglia and plexuses** situated either within or close to the walls of the various organs; (4) the **trunks** and **rami** connecting the ganglia with each other and thus contributing to the plexuses, or connecting the ganglia with other nerves or with organs with whose innervation they are concerned. The trunks and rami may be divided into—(*a*) the *rami communicantes,* or *central branches,* connecting the sympathetic with the craniospinal and central systems; (*b*) *communicating trunks,* best considered as those which connect sympathetic ganglia situated on the same side of the body; (*c*) *commissural branches,* or those which pass between ganglia situated on opposite sides of the midline of the body, such as the transverse connecting branches between the sympathetic trunks in the lumbosacral region (**fig. 815**), or all the trunks between the ganglia of plexuses occupying the midregion of the body: (*d*) *terminal* or *peripheral branches,* or those which pass from the ganglia to their final distribution in the tissues they innervate, apparently uninterrupted by other ganglia.

THE SYMPATHETIC TRUNKS

The **sympathetic trunks,** or gangliated cords, of the sympathetic system are two symmetrical trunks with ganglia interposed in them at intervals of varying regularity, and extending vertically, one on each side of the ventral aspect of the vertebral column, from the second cervical vertebra to the first piece of the coccyx (figs. 813, 815). Upon the coccyx the two trunks unite and terminate in a single median ganglion, the **ganglion coccygeum impar.** The various ganglia are connected with the craniospinal nerves by the rami communicantes. Morphologically, each trunk might be expected to possess thirty-one ganglia, one for each spinal nerve, but, owing to the fusion of adjacent ganglia in certain regions, especially in the cervical, there are in the adult only twenty-one or twenty-two ganglia in each trunk. These occur as *three cervical ganglia, ten or eleven thoracic*

glia, four lumbar and four sacral ganglia, and the *ganglion coccygeum impar,* which is common to both trunks.

In the cervical region the sympathetic trunks lie in front of the transverse processes of the vertebræ, from which they are separated by the longus capitis and longus colli; in the thoracic region they lie at the sides of the bodies of the vertebræ and on the heads of the ribs; in the lumbar region they are placed more ventrally with reference to the spinal nerves and more in front of the bodies of the vertebræ and along the anterior borders of the psoas muscles; in the pelvis the ganglia lie between and ventral to the openings of the sacral foramina. In the lower lumbar and sacral region one ganglion may send rami communicantes to two spinal nerves and one spinal nerve may be connected with two ganglia. The ganglia of the trunks throughout give off communicating branches to the ganglia of the prevertebral plexuses and branches to the nearby viscera and blood-vessels. These branches may appear either white or gray according to the predominance of medullated or non-medullated fibers in them. In the lumbosacral region commissural or transverse branches between the ganglia of the two trunks are especially abundant. In trunks having a whiter appearance, the greater part of the medullated fibers producing it are sensory and visceral efferent fibers from the spinal nerves which have passed through the sympathetic ganglia without termination. The nerve trunks connecting the ganglia of the sympathetic trunks all contain three varieties of fibers:—(1) visceral efferent fibers which have entered them in the white rami communicantes from the spinal nerves of higher or lower levels, and which are coursing in them to terminate in other ganglia, either in the trunks above or below or in ganglia not belonging to the trunks; (2) fibers arising in sympathetic ganglia of a higher or lower level and passing upward or downward to issue from the trunk and proceed to the tissues they supply; (3) visceral afferent fibers or sensory fibers arising in the spinal ganglia.

THE CEPHALIC AND CERVICAL PORTIONS OF THE SYMPATHETIC TRUNK

The cephalic portion of the sympathetic system consists of numerous small ganglia and of numerous plexuses connected with the internal carotid nerve, the ascending branch given off by the superior cervical sympathetic ganglion. The cephalic ganglia are all relatively small. There are four considered in the ordinary macroscopic dissections, namely, the ciliary (ophthalmic), the sphenopalatine (Meckel's ganglion), the otic, and the submaxillary. To these may be added a portion of the superior cervical sympathetic ganglion, the sympathetic portions of the nodosal, petrous, geniculate and semilunar ganglia, and the various small ganglia dispersed in the plexuses. These ganglia with their roots or communicating branches have been described in their relations with the divisions of the trigeminus and with the oculomotor, glossopalatine, vagus and facial nerves. (See GANGLIATED CEPHALIC PLEXUS.)

The internal carotid nerve, the **ascending branch** from the superior cervical sympathetic ganglion, may be regarded as an upward prolongation of the primitive sympathetic trunk.

It arises from the upper end of the superior cervical ganglion and passes through the carotid canal into the cranial cavity. It divides into two branches which subdivide to form a coarse plexus, the *internal carotid plexus,* which partly surrounds the internal carotid artery before the latter enters the cavernous sinus (fig. 771 and 815). It passes with the artery to the cavernous sinus, where it forms the finer meshed *cavernous plexus.*

The internal carotid plexus supplies offsets to the artery and receives branches from the tympanic plexus through the inferior caroticotympanic nerve and from the sphenopalatine ganglion through the great deep petrosal nerve. It also communicates by fine branches with the semilunar (Gasserian) ganglion and with the abducens nerve.

The **cavernous plexus** gives branches of communication to the oculomotor and trochlear nerves and to the ophthalmic division of the trigeminus. According to Toldt and Spalteholz, it communicates with the **tympanic plexus** through the superior caroticotympanic (small deep petrosal) nerve. It also communicates with the ciliary ganglion through the *long root of the ciliary ganglion* and usually through a separate *sympathetic root* of this ganglion. These branches may pass through the superior orbital (sphenoidal) fissure either separately or with the nasociliary (nasal) nerve.

The cavernous plexus also give branches to the carotid artery and filaments of the plexus accompany small branches of the artery to the hypophysis (pituitary body) and to the dura mater on the sphenoid bone.

The *terminal branches* of the cavernous plexus consist of delicate filaments that anastomose freely, forming fine plexuses, and pass from the cavernous plexus along the terminal divisions

of the internal cartoid artery and their branches. These fine plexuses take the name of the artery on which they lie. The four larger of them are the plexuses of the anterior and middle cerebral arteries, the plexus of the choroid artery, and the ophthalmic plexus.

The cervical portion of the sympathetic trunk extends upward along the great vessels of the neck (fig. 815). No white rami communicantes connect it directly with the spinal cord, but instead it receives visceral efferent fibers from the upper thoracic spinal nerves through the sympathetic trunk, and probably also from the cervical spinal cord through the spinal acessory nerve and the connections with the vagus. . It sends **gray rami communicantes** to each of the cervical nerves. It extends from the subclavian artery to the base of the skull, lying dorsal to the sheath of the great vessels and in front of the longus capitis and longus colli, which separate is from the transverse processes of the cervical vertebræ. It usually has but three **ganglia,** one at each end, the superior and inferior, and one between these two, called the middle ganglion. The latter varies somewhat in position and is sometimes absent.

1. Superior Cervical Ganglion

The superior cervical ganglion (figs. 771, 813, 815) is usually fusiform in shape and is sometimes marked by one or more constrictions. There is ground for the belief that it is formed by the coalescence of four ganglia corresponding to the first four cervical nerves. It varies from 2.5 to 3.7 cm. in length, lying dorsal to the upper part of the sheath of the great vessels of the neck and in front of the transverse processes of the second and third cervical vertebræ. It occasionally extends upward as high as the transverse process of the first vertebra. It is connected with the middle cervical ganglion by the intervening trunk, and it gives off a large number of communicating branches.

Rarely, the ganglion may be double or split with a ventral portion lying superficial to the carotid sheath and a dorsal portion dorsal to the sheath, connected by sympathetic filaments near the superior and inferior extremities of the ganglion.

Communications:—(1) **Four gray rami communicantes** associate the ganglion with the anterior primary divisions of the first four cervical nerves.

(2) **Communicating branches to the cranial nerves.**—An irregular number of small twigs pass between the superior cervical ganglion and the hypoglossal nerve and to the ganglion nodosum of the vagus. A named branch, the *jugular nerve,* runs upward to the base of the skull and divides into two branches, one of which enters the jugular foramen and joins the jugular ganglion of the vagus, and the other passes through or over the petrous ganglion of the glossopharyngeus and contributes to the tympanic nerve and plexus. (See fig. 771.)

(3) Four or five **laryngopharyngeal branches** come from the superior ganglion and the plexus extending downward from it, and pass forward and medialward, lateral to the carotid vessels, to the wall of the pharynx, where they unite on the middle constrictor with the pharyngeal branches of the glossopharyngeus and vagus, forming with them the *pharyngeal plexus,* from which branches are distributed to the walls of the pharynx and to the superior and external laryngeal nerves (fig. 815).

(4) The **superior cervical cardiac nerve** springs from the lower part of the ganglion or from the trunk immediately below it. It passes downward behind the carotid sheath, either in front of or dorsal to the inferior thyroid artery, and in front of the longus colli, and establishes communications with the upper cervical cardiac branch of the vagus, the middle cervical cardiac branch of the sympathetic, and with the inferior and external laryngeal nerves. At the root of the neck the nerve of the *right side* passes in front of or behind the first part of the right subclavian artery, and is continued along the innominate artery to the front of the bifurcation of the trachea, where it joins the deep part of the cardiac plexus. The *left nerve* passes into the thorax along the front of the left common carotid artery, crosses the front of the arch of the aorta immediately anterior to the vagus, and joins the superficial part of the cardiac plexus (fig. 816). Filaments from both the right and left nerves pass to the inferior thyroid plexus.

(5) The **external carotid nerves** (fig. 815) pass forward from the superior cervical ganglion to the external carotid artery, where they divide into branches which anastomose freely to form around the artery the **external carotid plexus.** This plexus extends to the beginning of the artery, and is continued upon the common carotid artery as the **common carotid plexus.** From the external carotid plexus, filaments pass to form secondary plexuses around each of the branches of the external carotid artery. These plexuses take the names of the arteries which they follow, namely, the **superior thyroid plexus, lingual plexus,** etc. Filaments pass from the external carotid plexus to the *glomus caroticum* (the carotid gland), and from the superior thyroid plexus to the thyroid gland.

From the **external maxillary** (facial) **plexus** passes the *sympathetic root of the submaxillary ganglion.*

A part of the **internal maxillary plexus** is continued upon the middle meningeal artery as the **meningeal plexus.** From this plexus filaments pass to the otic ganglion, and sometimes a branch, called by British anatomists the **external superficial petrosal nerve,** passes to the geniculate ganglion.

(6) Small branches to the ligaments and bones of the upper part of the vertebral column.

(7) The internal carotid nerve (ascending branch) and plexus have been described with the cephalic portion of the sympathetic system.

2. The Middle Cervical Ganglion

The middle cervical ganglion is small and somewhat triangular in outline. It is sometimes absent. Its position is variable, but it commonly lies about the level of the cricoid cartilage, in front of the bend of the inferior thyroid artery (fig. 815), and it is associated with the superior cervical ganglion and with the inferior cervical ganglion by the intervening portions of the sympathetic trunk. From the lower part of the middle ganglion some filaments pass dorsal to the subclavian artery, while others pass in front of and beneath that artery and anastomose with the first-mentioned filaments to form a loop, the ansa subclavia (*ansa Vieussenii*) (figs. 782, 815). Filaments from this loop to the inferior cervical ganglion thus form another communication between the middle and inferior cervical ganglia.

Connections.—The middle cervical ganglion gives off four or more rami.

Two (*a* and *b*) are gray rami communicantes which connect the middle ganglion with the anterior primary divisions of the fifth and sixth cervical nerves.

(*c*) One or more peripheral branches pass along the inferior thyroid artery and anastomose with branches from the superior and middle cardiac nerves and from the inferior cervical ganglion, thus taking part in the formation of the inferior thyroid plexus, from which branches pass to the thyroid gland.

(*d*) The middle cardiac nerve arises by one or more branches from the ganglion, or from the trunk, and passes downward dorsal to the common carotid artery and, on the right side, either in front of or dorsal to the subclavian artery, and then along the innominate artery to the deep part of the cardiac plexus (figs. 815 and 816). It is frequently larger than the superior cardiac nerve. On the left side the nerve runs between the subclavian and common carotid arteries. On both sides the nerve communicates with the inferior laryngeal nerve and external laryngeal nerve.

The middle cervical ganglion also gives branches to the common carotid plexus.

3. The Inferior Cervical Ganglion

The inferior cervical ganglion is irregular in form. It is larger than the middle cervical ganglion, and it lies deeply in the root of the neck dorsal to the vertebral artery or the first part of the subclavian artery, and ventral to the interval between the transverse processes of the last cervical and the first thoracic vertebræ (figs. 782, 815). It is connected with the middle cervical ganglion by the sympathetic trunk, and by filaments passing to the ansa subclavia, and it is either blended directly with the first thoracic ganglion or connected with it by a short stout portion of the trunk. It gives rami to the last two cervical nerves and peripheral branches to the vertebral and internal mammary arteries, to the heart, and to the inferior thyroid plexus.

Connections.—(1) The rami to the seventh and eighth cervical nerves are gray rami communicantes.

(2) The branches to the vertebral artery are large and they unite with similar branches from the first thoracic ganglion to form a plexus, the vertebral plexus (fig. 815), which accompanies the artery into the posterior fossa of the cranium, where it is continued on the basilar artery. The plexus communicates in the neck by delicate threads with the cervical spinal nerves. These are probably meningeal rami.

(3) The branches to the internal mammary artery form the internal mammary plexus.

(4) The inferior cardiac nerve may arise from the inferior cervical ganglion, from the first thoracic ganglion, or by filaments from both these ganglia (figs. 815, 816). It communicates with the recurrent laryngeal nerve and with the middle cardiac nerve, and passes to the deep part of the cardiac plexus. On the left side it frequently joins the middle cardiac nerve to form a common trunk.

Construction of the cervical portion of the sympathetic trunk.—This portion of the trunk contains both medullated and non-medullated fibers, and a large part of the former are of craniospinal origin. In the absence of white rami communicantes to this portion of the sympathetic trunk, it is evident that few if any of the craniospinal visceral efferent fibers are contributed to it below the superior ganglion by the cervical region of the spinal cord. Instead, such fibers are known to enter by way of the white rami from the upper thoracic nerves, and to ascend to this portion of the sympathetic trunk. Most of these fibers terminate about the cells of the superior, middle, and inferior cervical ganglia, and these cells in their turn give off sympathetic fibers which pass by way of the branches mentioned above for the cephalic and cervical portions, to their distribution in the structures of the head, neck, and thorax. The visceral efferent fibers which terminate in the superior ganglion especially are among those which mediate—(1) vasomotor impulses for the head; (2) secretory impulses for the submaxil-

lary gland; (3) pilomotor impulses for the hairs of the face and neck; (4) motor impulses for the smooth muscle of the eyelids and orbit, and (5) dilator impulses for the pupil. The sympathetic or gray fibers in the cervical portion of the sympathetic trunk arise from the cells of the upper thoracic and the cervical ganglia, and are passing to enter the peripheral branches and proceed to their terminal distribution.

THE THORACIC PORTION OF THE SYMPATHETIC TRUNK

The thoracic part of the gangliated trunk (figs. 813, 815) is extended on the heads of the ribs from the first to the tenth, and then passes a little ventralward on the sides of the bodies of the lower two thoracic vertebræ. Above it is continuous with the cervical portion at the root of the neck, dorsal to the vertebral artery. Below it leaves the thorax dorsal to the medial lumbocostal arch (arcuate ligament), or sometimes dorsal to the lateral lumbocostal arch, and continues into the lumbar portion of the trunk. It lies behind the costal pleura and crosses over the aortic intercostal arteries.

The number of ganglia in this part of the trunk is variable. There are usually ten or eleven, but the first is sometimes fused with the inferior cervical ganglion (fig. 782) and occasionally other ganglia fuse. The ganglia are irregularly angular or fusiform in shape, and lie on the head of the ribs, on the costovertebral articulations, or on the bodies of the vertebræ. The portions of the trunk connecting the ganglia usually are single, but sometimes they are composed of two or three small cords in juxtaposition. Each ganglion, with the rare exception of the first, receives a *white ramus communicans* from a thoracic nerve and all give off *gray rami communicantes* to these nerves.

The **white rami communicantes,** as they approach the sympathetic trunk, quite often appear double, due to the separation of a large portion of their fibers into two main directions, one passing upward in the sympathetic trunk, and one passing downward. Of the white rami from the upper five thoracic nerves, the upward stream of fibers is much larger than the downward, due to the fact that a greater part of the visceral efferent fibers from these nerves are distributed through the cervical portion of the sympathetic trunk, as noted above in the construction of that portion.

Usually the white rami from the spinal nerves pass directly to the corresponding ganglia of the trunk, and thus lie in company with the corresponding gray rami. Sometimes, however, they may join the intermediate portions of the trunk, and in the lower thoracic region especially a ramus may pass from a nerve to the ganglion corresponding to the nerve above or below. The fibers of the white rami from the lower thoracic nerves are in greater part directed downward in the sympathetic trunk, and also downward in its peripheral branches, to be distributed to the ganglia of the abdominal viscera. In all cases, however, some of the fibers of the thoracic white rami terminate in the ganglia nearest their junction with the trunk, while others pass to the ganglia above or below or into the nearest peripheral branches. In this way the white rami from the thoracic spinal nerves, are directly concerned in the innervation of both the thoracic viscera and also (chiefly through the splanchnic nerves) the abdominal viscera.

The **first thoracic ganglion** is larger than the other ganglia of this region and is irregular in form. It may be narrowly ovoid or semilunar. It lies in front of the neck of the first rib, behind the pleura, and on the medial side of the costocervical trunk (superior intercostal artery), which vessel separates it from the prolongation of the portion of the first thoracic nerve which passes to the brachial plexus. It sometimes fuses with the inferior cervical ganglion, and, on the other hand, sometimes extends to the upper part of the second rib to fuse with the second thoracic ganglion. The result of the latter fusion resembles the stellate ganglion of the carnivora, and when it occurs, is sometimes referred to as the **stellate ganglion.** When well developed, the first ganglion sends a branch to the cardiac plexus, forming the fourth cardiac nerve of Valentin.

The **second thoracic ganglion,** triangular in shape and almost as large as the preceding, is sometimes placed on the costovertebral articulation, and is sometimes partly concealed by the first rib.

The **third to the ninth thoracic ganglia** are usually placed opposite the heads of the corresponding ribs, but the **tenth** and **eleventh** may lie on the bodies of the vertebræ.

The fibers passing from the ganglia form two groups of branches, the *central* and the *peripheral.*

The **central** branches are the **gray rami communicantes,** which pass from the ganglia to the corresponding spinal nerves. After they have joined with the anterior primary divisions of the nerves, the fibers of these rami divide into three

groups:—(1) Fibers which pass medialward along the roots of the nerves to supply vessels of the membranes of the spinal cord, or enter a meningeal or recurrent branch for the same purpose; (2) fibers which pass dorsalward into the posterior primary divisions of the nerves; (3) fibers which pass lateralward in the anterior primary divisions of the nerves. The last two groups of fibers are distributed chiefly to the muscle of the blood-vessels of the body-walls, to the skin-glands, and to the muscles of the hairs of the body.

The **peripheral branches** of the ganglia form two series, an upper and a lower.

Those of the *upper series* pass from the upper four or five ganglia ventralward to be distributed as follows (figs. 813, 816):—

(1) **Pulmonary branches** which accompany the intercostal arteries toward their aortic origin without forming plexuses around them, and pass to the posterior pulmonary plexus.

(2) **Aortic branches,** some of which arise directly from the ganglia and some from the pulmonary branches, and unite with branches from the cardiac plexus and from the splanchnic nerves to surround the aorta as the **thoracic aortic plexus.** This plexus accompanies the aorta into the abdomen and there joins with the celiac (solar) plexus.

(3) **Esophageal branches** join with the esophageal plexus of the vagus.

(4) **Vertebral branches,** some of which pass with the nutrient arteries into the bodies of the vertebræ and some of which pass to the median line and there anastomose with similar branches from the opposite side (commissural branches).

The peripheral ganglionic branches forming the *lower series* consist largely of visceral efferent and afferent fibers from the spinal nerves, which pass through the ganglia and reinforce the sympathetic filaments proper. Thus composed, these branches run ventralward and medialward on the sides of the bodies of the vertebræ and unite to form the *splanchnic nerves* concerned with the abdominal organs. (figs. 640, 813). The visceral afferent fibers serve to collect sensory impulses in this domain of the sympathetic.

(1) The **great splanchnic nerve** is usually formed by branches from all the thoracic ganglia from the fifth to the tenth inclusive, or it may receive fibers from only two or three of these ganglia (figs. 813, 815). The superior branch, usually the largest, receives smaller inferior branches from the lower ganglia as it passes downward on the sides of the bodies of the vertebræ in the posterior mediastinum. The nerve enters the abdominal cavity by passing through the crus of the diaphragm, and joins the upper end of the celiac (semilunar) ganglion of the celiac (solar) plexus. Near the disk between the eleventh and the twelfth thoracic vertebra there is formed on the nerve the **splanchnic ganglion.** Filaments from the nerve and from this ganglion pass along the intercostal arteries to the aorta, esophagus, and the thoracic duct, and some fibers from the right side pass to the vena azygos (major). Sometimes this nerve divides into two cords, giving off numerous branches which anastomose with each other and with the lesser splanchnic nerve to form a plexus, in the meshes of which are found some small ganglia.

(2) **The lesser splanchnic nerve** receives fibers from the ninth and tenth ganglia. Its course is similar to that of the great splanchnic nerve (figs. 813, 815), but on a more dorsal plane, and it joins the celiac (solar) and renal plexuses.

(3) **The least splanchnic nerve,** not always present, arises from the last thoracic ganglion or sometimes from the lesser splanchnic nerve. It passes through the crus of the diaphragm and joins the renal plexus.

Construction of the thoracic portion of the trunk.—Being part of the general *thoracolumbar stream,* the majority of the visceral efferent fibers which pass from the central nervous system enter the thoracic portion of the sympathetic trunk and terminate there in synapsis with the cells of its ganglia, while others merely pass through on their way to terminate in the collateral ganglia. With regard to those which terminate in the ganglia of the trunk, it has been shown that in the dog and cat many end in the ganglion stellatum which corresponds with the last cervical and the upper three or four thoracic ganglia in man. Among these are the fibers conveying secretory impulses to the sweat-glands of the upper limb, which emerge from the spinal cord in the thoracic nerves from the sixth to the ninth, and, in the dog, those which convey and transfer vasoconstrictor impulses to the sympathetic neurones supplying the pulmonary blood-vessels. These visceral efferent fibers leave the spinal cord in the second to the seventh thoracic nerves. Other fibers which terminate upon the thoracic sympathetic ganglion-cells in the dog and cat are the vasoconstrictor fibers for the upper limbs and some of the vasoconstrictor fibers for the lower limbs.

Of the fibers which traverse the thoracic portion of the sympathetic trunk to gain more distant terminations, some ascend to the cervical region (p. 1069), others descend to the lumbar region, and some pass by the immediate peripheral branches to the splanchnic nerves and terminate in the ganglia of the abdominal plexuses.

Among those visceral efferent (preganglionic) fibers which descend to the lumbar region are pilomotor fibers, vasomotor fibers, and secretory fibers to the lower limb, some vasoconstrictor fibers to the abdominal blood-vessels, motor fibers to the circular, and inhibitory fibers to the longitudinal muscle of the rectum. The latter enter the sympathetic trunk by the lower thoracic nerves and pass in the lumbar peripheral branches to the aortic plexus, and terminate around the cells of the inferior mesenteric ganglion.

The visceral efferent fibers which pass through the thoracic ganglia to the splanchnic nerves are

mainly vasomotor fibers to the abdominal blood-vessels; the majority of them probably terminate around the cells of the ganglia in the celic (solar) plexus, but those for the renal blood-vessels no doubt end in the ganglia of the renal plexus. In addition to all the above-mentioned fibers there are in the thoracic part of the sympathetic trunk afferent fibers of the spinal ganglia which pass into the dorsal roots of the thoracic spinal nerves.

THE LUMBAR PORTION OF THE SYMPATHETIC TRUNK

The lumbar portion of each trunk lies on the fronts of the bodies of the vertebræ along the anterior border of the psoas muscle, and nearer to the median line than the thoracic portion. It is connected with the thoracic portion of the sympathetic trunk by a slender intermediate portion of the trunk that may pass through the diaphragm or dorsal to it (figs. 813, 815). The continuation of the lumbar into the sacral portion is also slender, and descends dorsal to the common iliac artery. The right trunk is partly covered by the vena cava inferior and the left by the aorta.

The **ganglia**, which are small and oval, vary in number from three to eight, but are usually four. Rarely they are so fused as to form one continuous ganglion.

White rami communicantes pass to the ganglia from the first two to four lumbar nerves only. This portion of the sympathetic trunk also receives visceral efferent and afferent fibers which are derived from the white rami communicantes of the lower thoracic nerves and continue downward in the trunk.

Branches.—As in the thoracic region, the branches from the ganglia are central and peripheral. The central are **gray rami communicantes.** There may be two rami to a nerve or one ramus may divide so as to join two adjacent spinal nerves. Sometimes a spinal nerve may receive as many as five gray rami from the sympathetic trunk.

The peripheral branches (sympathetic and visceral afferent and efferent fibers) include:—(*a*) Branches passing to the aorta and taking part in the formation of the aortic plexus; (*b*) branches which descend in front of the common iliac artery to the hypogastric plexus; and (*c*) branches to the vertebræ and ligaments.

THE SACRAL PORTION OF THE SYMPATHETIC TRUNK

The sacral part of each trunk passes downward in front of the sacrum, immediately lateral to the medial borders of the anterior sacral foramina. It is continuous above with the lumbar portion of the trunk, and below it anastomoses freely in front of the coccyx with the trunk of the other side to form a plexus in the terminus of which is the **coccygeal ganglion** (*ganglion coccygeum impar*) (fig. 815). Like the cervical and lower lumbar portions of the sympathetic trunk, the sacral part receives no white rami communicantes from the spinal nerves. The visceral efferent fibers arising from this portion of the spinal cord form the sacral part of the general *craniosacral stream.* They pass by the ganglia of the trunk to terminate in the terminal ganglia of the visceral organs, and to some extent in the collateral ganglia.

The sacral **ganglia** are small in size, and usually four in number. The variation both in size and number is more marked in this portion of the trunk than in the two parts above.

Branches.—The branches of the sacral ganglia include:—

(1) Gray rami communicantes to the sacral nerves.

(2) Branches to the front of the sacrum which anastomose with their fellows of the opposite side (commissural branches).

(3) Branches which enter into the formation of the plexus on the middle sacral artery.

(4) Branches which join the pelvic plexuses.

(5) Branches given off by the ganglion coccygeum impar to the coccyx and its ligaments and to the *glomus coccygeum* (coccygeal gland).

Construction of the lumbar and sacral portions of the gangliated trunk.—The ganglia of both these portions of the trunk are very variable in shape, size, position, and number. There are usually four ganglia belonging to each portion, but sometimes as many as eight may be distinguished in the lumbar and at other times there may be as many as six in the sacral portion. In the majority of cases, especially in the sacral region, these masses of cells are so fused that their number is less than the number of the spinal nerves with which they are associated. As noted above, only the first two to four lumbar spinal nerves send white rami which enter these ganglia directly as such. However, visceral efferent fibers descend this entire stretch of the trunk, through both the lumbar and sacral portions, from the white rami of the lower thoracic and the upper lumbar nerves above. These fibers terminate in the various ganglia of the trunk here; a few pass uninterrupted to the more distant sympathetic cell-bodies which are concerned in impulses that are vasomotor to the genital organs, motor for the uterus, the ductus deferens, and the muscular coats (circular coat especially) of the bladder. Also, some of them convey secre-

tory, pilomotor, and vasomotor impulses for the glands, skin, and vessels of the lower extremity in addition to the similar impulses conveyed in the peripheral branches from the lower part of the thoracic portion of the sympathetic trunk. The motor impulses for the uterus or ductus deferens and for the bladder pass, in most part probably, by way of the peripheral branches from the lumbar portion of the trunk, through the aortic plexus to the inferior mesenteric ganglion; others, the vasomotor impulses to the genital organs especially, pass by way of the sacral ganglia and the peripheral branches from them to the hypogastric or pelvic plexus and the appropriate subplexuses of this region. Of the vasomotor fibers for the penis, some of the constrictor fibers pass down the sacral portion of the sympathetic trunk and terminate about the cells of the sacral ganglia, and these cells send out sympathetic fibers which join and course in the pudic nerve (n. pudendus).

All of both the lumbar and sacral spinal nerves receive gray rami from the gangliated trunk. These, just as those from the other portions of the trunk, consist of—(1) vasomotor fibers to vessels of the meninges and the vertebral canal; and (2) those which reach their destination via the branches of the trunks of the spinal nerves.

In addition to the visceral efferent fibers, the branches of the lumbosacral portion of the sympathetic trunk carry visceral afferent fibers—sensory fibers arising in the spinal ganglia of this and the lower thoracic region.

There are no white rami proper passing from the sacral spinal nerves to course or terminate in the sympathetic trunk. Visceral efferent fibers are given off by these nerves in abundance, but, instead of entering the trunk and its ganglia, they form bundles which pass over the trunk and directly into its peripheral branches and to end for the most part upon the cells of the terminal ganglia. The bundles passing from the second, third, and fourth sacral nerves are large and especially definite. While homologous to white rami, such bundles are better known as the *visceral branches* of the sacral nerves or the **plevic splanchnics.** They contain some spinal sensory fibers, but consist for the most part of visceral efferent, conveying impulses, vasomotor (vasodilator, chiefly) to the genital organs, both motor and inhibitory for the rectum, uterus, and bladder (longitudinal coat especially), and secretory for the prostate gland. These fibers contribute to the hypogastric plexus and its subplexuses, named according to the various urogenital organs concerned.

THE GREAT PREVERTEBRAL PLEXUSES

The great prevertebral plexuses, in the body cavities, are three in number—the cardiac, the celiac (solar or epigastric), and the hypogastric or pelvic (fig. 813). Their ganglia belong to the intermediate or collateral group. The cardiac plexus lies behind and below the arch of the aorta, and the celiac and hypogastric plexuses are situated in front of the lumbar vertebræ. Each plexus receives not only sympathetic fibers which have passed from the ganglia of the sympathetic trunks of either side, but also both visceral afferent and efferent nerve-fibers derived directly from the spinal nerves. In addition the cardiac and celiac plexuses receive both visceral efferent and visceral afferent fibers from both vagus nerves.

1. The Cardiac Plexus

The cardiac plexus is formed by the cardiac branches from both vagus nerves and from both sympathetic trunks. It lies beneath and dorsal to the arch of the aorta, in front of the bifurcation of the trachea, and extends a short distance upward on the sides of the trachea. It is composed of a superficial and a deep part (fig. 816).

The **superficial part of the cardiac plexus** is much smaller than the deep part, and lies beneath the arch of the aorta in front of the right pulmonary artery. It is formed chiefly by the cardiac branches of the left vagus and by the left superior cardiac nerve, but sometimes receives filaments from the deep cardiac plexus. The **cardiac ganglion (ganglion of Wrisberg,)** usually found connected with this plexus, lies on the right side of the ligamentum arteriosum.

Branches.—From this plexus some branches pass to the left half of the deep cardiac plexus, and others accompany the left pulmonary artery to the *left anterior pulmonary plexus.* It also sends branches to the *right anterior coronary plexus.*

The **deep portion of the cardiac plexus** lies dorsal to the arch of the aorta at the sides of the lower part of the trachea and in front of its bifurcation. It consists of two lateral parts, more or less distinct, connected by numerous branches, which pass around the lower part of the trachea. It is formed by the superior, middle, and inferior cervical cardiac branches from the right sympathetic trunk, the middle and inferior cervical cardiac branches from the left trunk, and all the cervical and thoracic cardiac branches of the vagus except the superior cervical cardiac branch of the left vagus. It also receives branches from the superficial cardiac plexus.

The *left part of the deep cardiac plexus* gives branches to the left atrium (auricle) of the heart, to the left anterior pulmonary plexus, to the left coronary plexus, and sometimes to the superficial part of the cardiac plexus.

The *right part of the deep cardiac plexus* gives branches to the right atrium, to the right anterior pulmonary plexus, and to the right and the left coronary plexuses (fig. 816). The branches to the left coronary plexus pass behind the pulmonary artery. Some of those to the right coronary plexus pass anterior and some posterior to the right pulmonary artery.

The **coronary plexuses** are formed by branches given off by the cardiac plexus. They accompany the coronary arteries and are right and left.

The *right (anterior) coronary plexus* receives filaments from the superficial part of the cardiac plexus, but is formed chiefly by filaments from the right portion of the deep cardiac plexus (fig. 816). Its distribution to the heart follows that of the right coronary artery.

The *left (posterior) coronary plexus* is larger than the right plexus, and is formed for the most part by filaments from the left portion of the deep cardiac plexus, but it receives some filaments from the right portion of the deep cardiac plexus (fig. 816). Its distribution to the heart follows that of the left coronary artery.

The cardiac plexus and the network of nervous structures in the walls of the atria are the remains of the primitive plexuses found in the embryo, which are called the *bulbar*, the *intermediate*, and the *atrial* plexuses, terms which sufficiently indicate their relative positions. The bulbar plexus gives off the coronary nerves and is transformed into the superficial part of the deep cardiac plexus; the remainder of the deep cardiac plexus is formed by the intermediate plexus, and the atrial plexus becomes the network of the atrium.

The fibers which pass to the cardiac plexus are medullated and non-medullated; the former are the so-called inhibitory, the latter motor. The inhibitory impulses leave the central nervous system by the vagus and spinal accessory nerves and are transferred by synapses to the nerve cells of the intrinsic terminal ganglia of the heart. The accelerator fibers leave the spinal cord by the ventral roots and white rami communicantes of the thoracic nerves and terminate about the cells of the ganglia of the sympathetic trunk; some probably about cells in the ganglia of the intervening plexuses. From the cells of these ganglia arise the non-medullated (gray) fibers of the plexus and these are thought to terminate directly upon the fibers of cardiac muscle.

2. The Pulmonary Plexuses

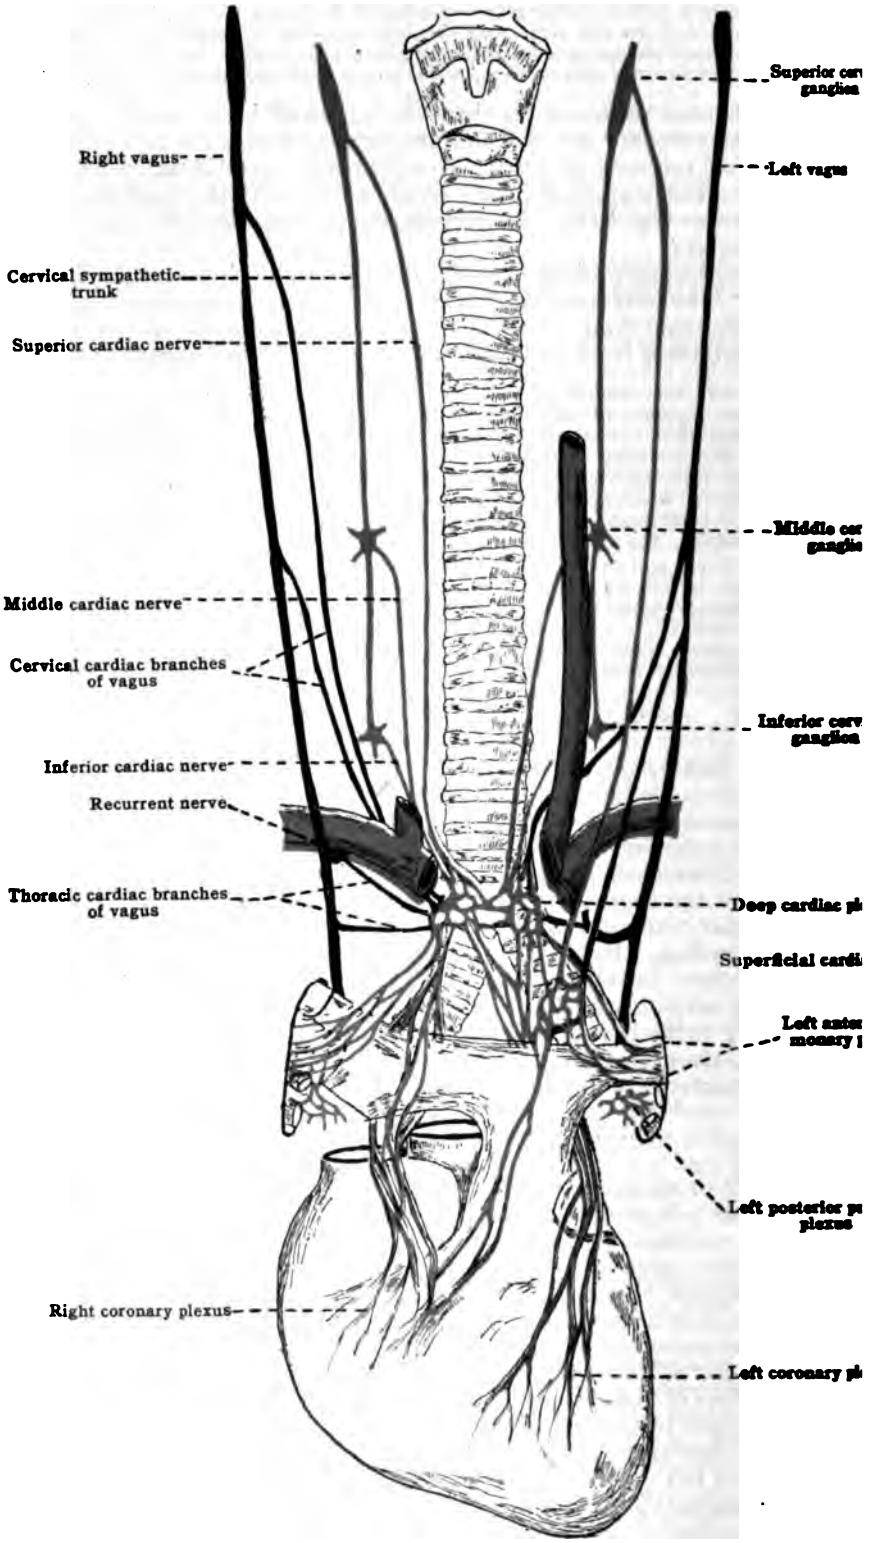
The **pulmonary plexuses** are a continuation of the cardiac plexuses. The two are so intimately joined that it is difficult to distinguish them as separate plexuses. The pulmonary are formed by fibers from both the vagus and sympathetic nerves. The anterior and posterior pulmonary branches of the vagus unite, dorsal to the bifurcation of the trachea, with fibers from the second, third and fourth ganglia of the thoracic portion of the sympathetic trunk to form the anterior and posterior pulmonary plexuses that lie ventral and dorsal to the bifurcation of the trachea. Here the pulmonary plexuses of both sides connect with each other freely. Leaving the trachea, the plexuses pass into the lungs along the pulmonary arteries (figs. 774, 816). The parts of the plexus of each side are named according to their position anterior or posterior to the right and left pulmonary arteries; thus, there is a **right anterior** and a **right posterior**, a **left anterior** and a **left posterior pulmonary plexus.**

3. The Celiac Plexus

The **celiac** (solar or epigastric) **plexus** [plexus cœliacus] is the largest of the prevertebral plexuses. It is unpaired, and is continuous above with the aortic plexus of the thorax and below with the abdominal aortic and superior mesenteric plexuses. It lies in the epigastric region of the abdomen behind the bursa omentalis (lesser sac) and the pancreas, upon the crura of the diaphragm and over the abdominal aorta, and around the origin of the celiac and the superior mesenteric arteries. It occupies the interval between the suprarenal glands and extends downward as far as the renal arteries. It is joined by the great and the lesser splanchnic nerves of both sides, by celiac branches of the right vagus, and by filaments from the upper lumbar ganglia of the sympathetic trunk. It sometimes receives celiac branches from the left vagus. It contains two large collateral ganglia, the right and left celiac (semilunar) ganglia (fig. 817).

The **celiac (semilunar) ganglia** are two large, flat, irregularly shaped masses, separable into a varying number of ganglia. These two masses, or rather the smaller ganglia which compose them, are connected by a varying number of communicating branches. Each mass, right and left, lies upon the corresponding crus

FIG. 816.—CARDIAC, PULMONARY, AND CORONARY PLEXUSES. (Schematic.)
(Modified from Cunningham.)



of the diaphragm, at the medial border of the corresponding suprarenal gland, being sometimes overlapped by this body. The right mass lies behind the inferior vena cava. Each celiac ganglion receives at its upper border the greater splanchnic nerve, and, near its lower border, lying over the origin of the renal artery, is a more or less detached part, known as the **aorticorenal ganglion.** This ganglion receives the lesser splanchnic nerve and may seemingly give origin to the greater part of the renal plexus. Another part of the celiac ganglion, often found dorsal to the origin of the superior mesenteric artery, is known as the **superior mesenteric ganglion** (fig. 817).

From the celiac plexus and its ganglia subordinate plexuses are continued upon the aorta and its branches. These comprise both paired and unpaired plexuses. The paired plexuses are the phrenic, suprarenal and renal, the spermatic in the male, and, in the female, the ovarian plexuses. The unpaired plexuses are the aortic, hepatic, splenic, superior gastric, inferior gastric, superior mesenteric, and inferior mesenteric.

That part of the celiac plexus surrounding the celiac artery was formerly described as the *celiac plexus*. It is better considered as an unnamed part of the larger celiac (solar) plexus. This part of the plexus receives fibers from both vagus nerves, and gives filaments that form plexuses around the branches of the celiac artery and their ramifications.

The paired subordinate plexuses of the celiac.—(1) The **phrenic (diaphragmatic) plexuses** consist of fibers from the upper part of the celiac ganglia, which follow the inferior phrenic arteries and their branches on the under surface of the diaphragm (fig. 817). Filaments are given off by the roots of the plexuses to the suprarenal bodies, and others unite with the terminal branches of the phrenic nerves. The point of junction with the right phrenic nerve is marked by the **phrenic ganglion,** from which branches are distributed to the inferior vena cava, to the right suprarenal body, and to the hepatic plexus.

(2) The **suprarenal plexuses** are comparatively large plexuses, formed mainly by branches from the celiac (semilunar) ganglia. However, fibers come to them from the celiac plexus along the suprarenal arteries, from the phrenic plexus along the inferior phrenic arteries, and from the renal plexus along the inferior suprarenal arteries. They are distributed to the substance of the suprarenal glands. Cell-bodies of sympathetic neurones are enclosed within the suprarenal gland forming intrinsic ganglia. The medulla of the suprarenal is of ectodermal origin and considered as derived from embyronic components of the sympathetic nervous system.

(3) The **renal plexuses** (fig. 817) receive fibers from the lower part of the celiac ganglia and from the celiac and aortic plexuses. They also receive filaments from the least splanchnic nerves, when these nerves are present, and sometimes filaments from the lesser splanchnic nerves and from the first lumbar ganglion of the sympathetic trunk. These plexuses pass along the renal arteries into the substance of the kidneys. Most of the fibers of each renal plexus are gray or postganglionic fibers, and as they pass to the kidneys small *renal ganglia* are present upon them. Both renal plexuses give branches to the corresponding spermatic plexuses and to the ureter, and the right renal plexus gives filaments also to the inferior vena cava.

(4a) The **spermatic plexuses** (fig. 817) are formed by fibers from the renal and aortic plexuses. They accompany the spermatic arteries and are joined at the abdominal inguinal (internal abdominal) ring by fibers that have passed along the ductus deferens from the pelvic plexuses. Their terminal filaments (chiefly postganglionic fibers) are distributed to the testis and the epididymis.

(4b) The **ovarian plexuses** are formed in the female like the spermatic plexuses in the male. They accompany the ovarian arteries and, in the broad ligament, receive fibers from the uterovaginal plexus. They supply the ovaries, the broad ligaments, and the Fallopian tubes, and send some fibers to the fundus of the uterus, where they become continuous with the uterovaginal plexus.

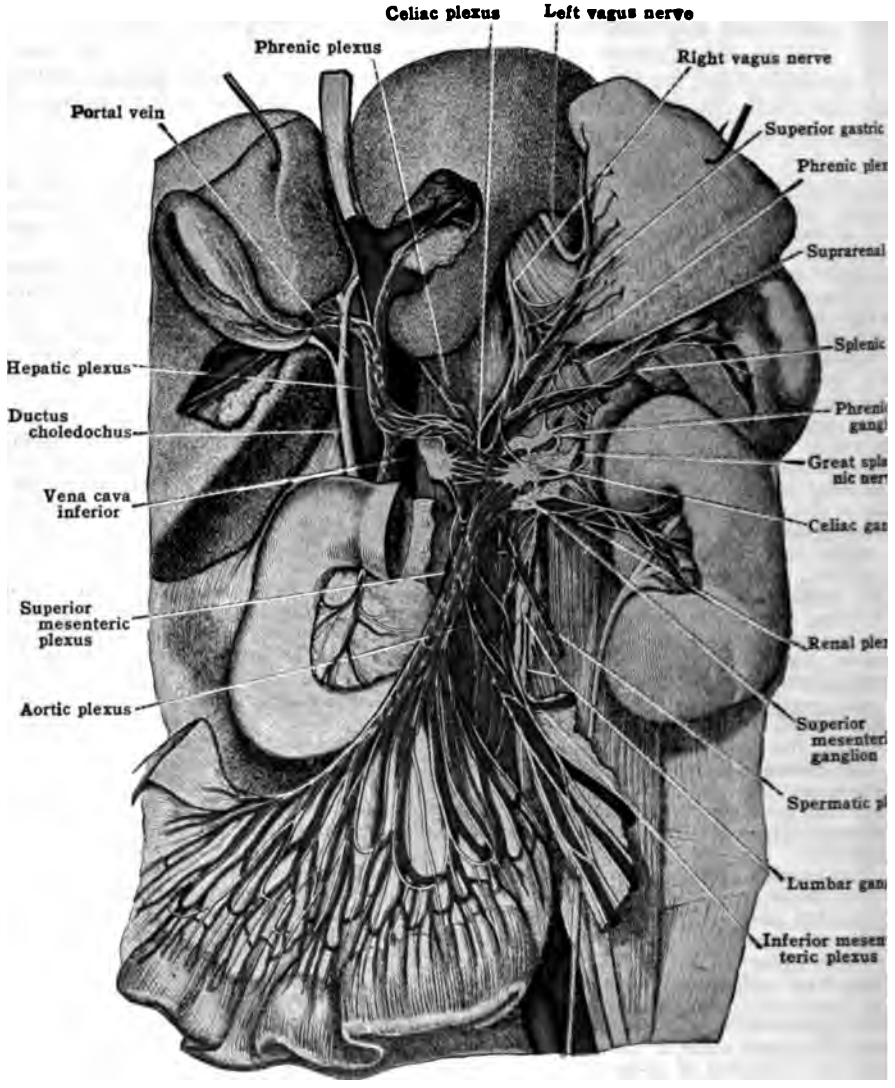
The unpaired subordinate plexuses:—(1) The **abdominal aortic plexus** is formed by two strands of fibers which descend along the sides of the aorta and communicate with each other across its ventral aspect. It is connected above with the renal plexuses, and it receives peripheral branches from some of the lumbar ganglia of the sympathetic trunk on each side. It often contains a number of ganglia, which are situated at the points where the peripheral branches join the plexus, and it terminates below, chiefly by anastomoses with the hypogastric plexus (figs. 817 and 818). Besides giving filaments to the inferior vena cava, it also gives fibers that form plexuses along each of the branches of the aorta. The fibers that pass from the lower end of the aortic plexus upon the common iliac artery form the **iliac plexus,** which is continued along the femoral artery as the **femoral plexus,** and still further along the popliteal artery as the **popliteal plexus.**

(2) The **superior gastric (coronary) plexus,** receiving filaments from the celiac plexus, accompanies the left gastric (coronary) artery along the lesser curvature of the stomach. Its filaments anastomose with filaments of the vagus nerves and with the plexus that accompanies the right gastric (pyloric) artery (fig. 817), and it gives three varieties of fibers to the walls of the stomach:—(1) visceral afferent fibers, derived chiefly from the vagi; (2) sympathetic or postganglionic fibers, and (3) visceral efferent fibers (craniosacral, chiefly exciting peristalses), which terminate within the walls, about the cell-bodies of the delicate gangliated plexus myentericus and plexus submucosus (plexuses of Auerbach and Meissner). These fibers innervate the glandular epithelium and the smooth muscle of the stomach walls and its vessels.

(3) The **inferior gastric plexus** receives from the splenic plexus filaments that accom the left gastroepiploic artery. It gives filaments to the walls of the stomach, which term as in the superior gastric plexus. It receives filaments from the vagus nerves and from plexus that accompanies the right gastroepiploic artery.

(4) The **hepatic plexus** receives filaments from the celiac plexus and from the left v It accompanies the hepatic artery and gives fibers that form plexuses on the branches artery and on their ramifications within the liver and gives secretory fibers to the liver It also gives filaments to the portal vein (fig. 817).

FIG. 817.—ABDOMINAL PLEXUSES OF THE SYMPATHETIC. (After Toldt, 'Atlas of H Anatomy,' Rebman, London and New York.)



The **splenic** or **lienal plexus** is formed by filaments from the celiac plexus, the lef (semilunar) ganglion, and from the right vagus. It accompanies the splenic artery ar filaments which form plexuses on the branches of this artery, and which pass with the b to supply fibers to the stomach and the pancreas (fig. 817).

(5) The **superior mesenteric plexus** is formed chiefly by filaments from the low of the celiac plexus, but it also receives fibers from the right vagus and fibers direct fr celiac (semilunar) ganglia. At the origin of this plexus, dorsal to the superior me artery, lies the *superior mesenteric ganglion* (fig. 817). The filaments of the plexus, wl white and firm, accompany the superior mesenteric artery and, following its branches a ramifications, are distributed to the walls of the small intestine, the cecum, and the as and transverse colon. From the *secondary plexuses* that accompany the branches of th fibers pass to form still other plexuses that lie near the wall of the intestine, between the b of the artery and between the layers of the mesentery. Filaments pass with the bran the arteries and from plexuses between them into the intestinal wall, and there join, l

the longitudinal and circular muscle-layers of the intestine the fine gangliated **plexus myentericus** (plexus of Auerbach), and filaments from this plexus join, in the submucosa, the delicate **plexus submucosus** or plexus of Meissner. From these latter plexuses fibers arise which terminate upon the gland cells and smooth muscle-fibers of the intestinal wall and its vessels. The white appearance of the filaments of the superior mesenteric plexus is due to the large number of visceral efferent and afferent fibers (from the vagi and sacral nerves, especially) in it.

(6) The **inferior mesenteric plexus** is derived chiefly from the left side of the aortic plexus. It descends upon the inferior mesenteric artery and gives off filaments which accompany the branches of the artery and are distributed to the descending colon and to the sigmoid colon (figs. 817 and 818). The filaments which accompany the left colic branch of the inferior mesenteric artery anastomose with the filaments of the superior mesenteric plexus which accompany the middle colic artery. The filaments which accompany the superior hemorrhoidal artery form the **superior hemorrhoidal plexus.** This plexus gives off the *superior hemorrhoidal nerves* (fig. 818) which supply the upper part of the rectum and anastomose with the *middle hemorrhoidal plexus.*

4. The Hypogastric Plexus

The hypogastric plexus lies partly in the abdominal cavity and partly in the pelvic cavity. It is formed chiefly by filaments continued downward from the aortic plexus, and by the pelvic splanchnics and peripheral branches from the lumbar and sacral nerves and sympathetic trunk (figs. 813, 818). The *abdominal part* of this plexus consists of plexiform bundles of fibers descending between the common iliac arteries and interlacing in front of the fifth lumbar vertebra to form a broad, flattened, plexiform mass. In its extent it receives branches from the lumbar ganglia of the sympathetic trunk. This plexiform mass then divides into two parts, right and left, which descend into the pelvic cavity and which, by British authors, are frequently designated as the *pelvic plexuses.*

The *pelvic parts* of the hypogastric plexus (pelvic plexuses) lie at the sides of the rectum in the male, and at the sides of the rectum and the vagina in the female. They receive peripheral branches (postganglionic) from the sacral ganglia of the sympathetic trunk and visceral efferent fibers (preganglionic) by way of the *pelvic splanchnics* from the second and third or third and fourth sacral spinal nerves. Each pelvic part of the plexus accompanies the corresponding hypogastric (internal iliac) artery, and gives off secondary plexuses that continue on the branches of the artery to the pelvic viscera. Of these secondary plexuses, the middle hemorrhoidal and the vesical plexus are common to both sexes and are paired.

The **middle hemorrhoidal plexus** passes on each side along the middle hemorrhoidal artery to the rectum, where it receives the superior hemorrhoidal nerves and sends filaments into the wall of the rectum (fig. 818).

The **vesical plexus** receives some branches from the pelvic parts of the hypogastric plexus, but is largely reinforced with spinal nerve fibers by way of the pelvic splanchnics, from the third and fourth sacral nerves. On each side it passes along the corresponding vesical arteries to the bladder, and gives off two sets of branches, namely, the *superior vesical nerves* (fig. 818), which supply the upper part of the bladder-wall and send some branches to the ureter, and the *inferior vesical nerves,* which supply the lower part of the bladder and, in the male, give secondary **deferential plexuses** to the ductus deferens. These plexuses surround the ductus deferens and the vesiculæ seminales and anastomose with the spermatic plexuses.

The **prostatic plexus,** found only in the male, is formed in two parts by nerves of considerable size, and lies chiefly on the sides of the prostate gland between it and the levator ani (fig. 818). Each of these parts supplies the gland and the prostatic part of the urethra, and sends offsets to the neck of the bladder and the vesiculæ seminales. This plexus is continued forward on either side to form the **cavernous plexus of the penis** (fig. 818), which anastomoses with branches of the dorsal nerve of the penis, gives off branches to the membranous part of the urethra, and also gives origin to two sets of nerves, namely, the large and the small cavernous nerves of the penis.

The **large cavernous nerve** [n. cavernosus penis major], one on each side, runs forward to the middle of the dorsum of the penis where it anastomoses with the dorsal nerve of the penis on the corresponding side, and ends in twigs which are distributed chiefly to the walls of the sinuses of the corpus cavernosum penis, but some of the terminal filaments supply the corpus cavernosum urethræ (corpus spongiosum) (fig. 818).

The **small cavernous** nerves [nn. cavernosi penis minores], are small filaments which pierce the urogenital diaphragm and the sphincter urethra, and enter the posterior part of the corpus cavernosum.

The **uterovaginal plexus,** found in the female, is formed in its *upper part* on each side largely by fibers derived from the pelvic part of the hypogastric plexus, but it receives some fibers from the pelvic splanchnics of the third and fourth sacral nerves. The nerves from this part of the plexus accompany the uterine arteries as they pass between the layers of the broad ligament. Some accompany each uterine artery and its branches to their termination, but a considerable number of fibers leave the artery and pass into the body of the uterus to supply its lower part and cervix. Between the layers of the broad ligament this plexus anastomoses with the ovarian

plexus and sends some filaments to the uterine tube (Fallopian tube). The lowe[r] of the plexus uterovaginalis receives some fibers on each side from the pelvic part o[f] hypogastric plexus, but it is formed chiefly by visceral efferent fibers from the second, th[ird] and fourth sacral nerves. These fibers terminate in contact with intrinsic nerve cell-b[odies] whose axones supply the wall and mucous membrane of the vagina and urethra. From [the] plexus on the anterior surface of the vagina fibers pass to form the **cavernous plexus o[f] clitoris,** which gives off the great and lesser **cavernous nerves of the clitoris** for the supply o[f] clitoris. The uterovaginal plexus of the female corresponds to the prostatic plexus of the m[ale].

SECTION IX

SPECIAL SENSE-ORGANS

REVISED FOR THE SIXTH EDITION

BY G. ELLIOT SMITH, M.A., M.D., F.R.C.P., F.R.S., UNIVERSITY COLLEGE, LONDON

PROFESSOR OF ANATOMY IN THE UNIVERSITY OF LONDON

GENERAL CONSIDERATIONS

THE term special sense-organs is applied to the peripheral instruments of the senses of smell, vision, hearing and taste. These structures are specialized to respond to forms of stimulation to which the other afferent nerves are insensitive. The organs of smell, vision and hearing may convey information concerning objects and events at some distance from the body. Hence these three organs have been called *distance receptors* by Sherrington to distinguish them from the other sensory nerves which collect information from the organism itself and especially from the skin.

The essential difference between what is termed general sensibility and the special senses lies in the fact that the organs of special sense are each sensitive to a specific stimulus which does not affect any other part of the body.

Thus the waves of light or of sound, chemical substances which excite a consciousness of taste, or stimulate the olfactory epithelium—all these varied stimuli create no impression when they come into contact with the sensitive general surface of the body or sense-organs other than those specially adapted to each kind of stimulus. The vibration of sound-waves present in an organ-pipe may indeed be felt by the hand, but the sensation is that of vibration and not of sound.

This difference in function between the ordinary and the special senses as well as the difference between the individual organs of special sense, is associated with a difference in structure; for each special sense-organ has a characteristic receptive mechanism of cells highly specialized in form and structure, which receive the stimuli coming from without, and transmit their effects upon the nerve-endings to the brain in the form of a nerve-current. These cells are all derived directly or indirectly from the surface of the body. The eye and ear are highly complex in structure because an elaborate mechanical arrangement is necessary for receiving the external stimulus and converting it into a form fitted to affect the sensory cells proper.

It must always be borne in mind that sensation itself is a function of the brain—it is the response in consciousness to the afferent impressions transmitted to the brain by the sensory nerves and profoundly modified during their passage through the central nervous system. Further, the *quality* of the sensation does not arise in the sense organ, but in the brain itself. Thus, stimulation of the trunk of the optic nerve by mechanical means produces sensations of light, apart from stimulation of the retina.

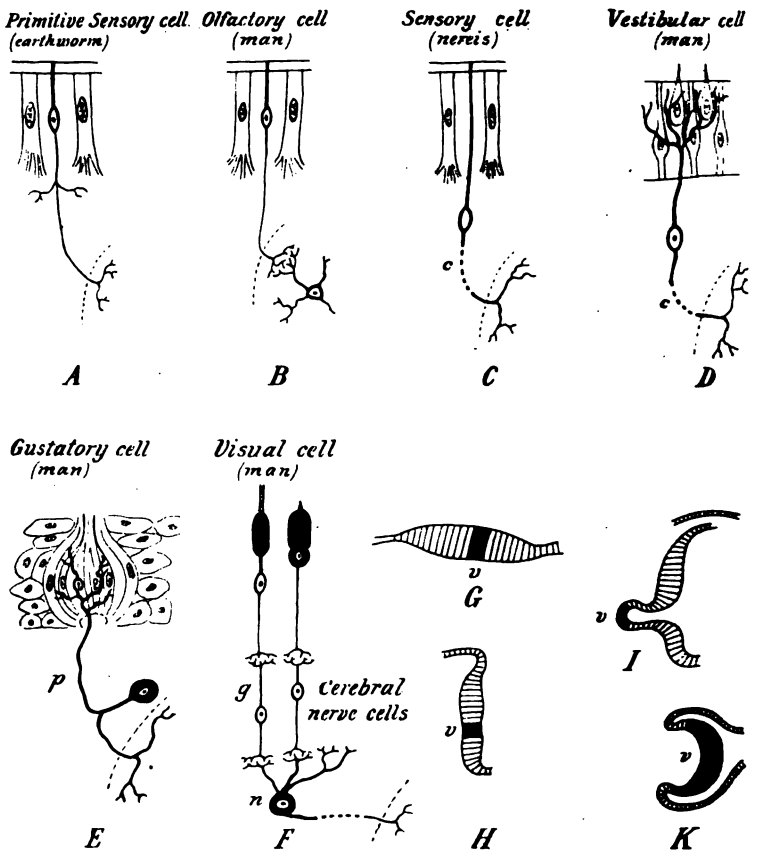
In the lowliest animals equipped with a nervous system certain of the epithelial cells distributed in the skin over the whole surface of the body are specialized as *sensory cells* (fig. 819A). They become specially sensitive to changes in the animal's environment and each gives off a long slender branch or sensory nerve which transmits the effects of stimulation to nerve-cells connected directly or indirectly with the motor mechanisms of the animal. At first every sensory cell is capable of responding to a variety of forms of stimulation; but in the more highly organized animals they become specialized so as to react more efficiently to various stimuli (olfactory, gustatory, auditory, visual, etc.).

Figure 819 illustrates the various types of sensory cells. The olfactory cells (B) preserve the morphological characters of the most primitive kind of sensory cell (A). The vestibular (D)

and cochlear cells, and the taste-cells (E) are only slightly more specialized; but the visual (F) undergo profound changes and become very intimately associated with certain supp nerve-cells to form a composite sensory membrane, the retina. The changes in the posi of this membrane (V) from the time when it was part of the skin, i.e., of the embryonal medul plate (G), then part of the neural tube (H), and then protruded to become the retina (I and will explain how its structure is reversed so that the sensory cells point away from the so of the stimulus.

The sensory cells that are specially adapted to the particular forms of stimulation con ated are found only in certain localized areas in the region of the head (fig. 820), but the of the sensory cells are distributed in the skin over the surface of the body and elsew (muscles, tendons, joints), and are differentiated into categories associated with con sensation, pressure, heat, cold and pain.

FIG. 819.—TYPES OF SENSORY CELLS (A TO F) AND ORIGIN OF VISUAL CELLS (G TO I



The former localized groups form the essential parts of the organs of the special senses taste, vision, hearing and equilibration. Of these organs those of smell and taste co little more than the special sensory cells (fig. 819) without any elaborate accessory mec Moreover the morphological characters of the cells are not only simple but also mor primitive than those of the ordinary sensory cells (see fig. 819, compare A, B, C, The olfactory cells in fact preserve the features of the most primitive type of sensory cel in the lower invertebrata.

The olfactory area arises as a thickening of the skin on the lower surface of the forem of the head. This *olfactory plate* is at first on the same plane as the rest of the skin (fig but the growth of the mesoderm soon pushes out the skin surrounding the olfactory pl B, at L and M), so that a nasal pit is formed the roof of which consists of the olfactory epi (see C). The medial extremity of the olfactory plate becomes separated from the res form the organ of Jacobson, which remains upon the lower and anterior part of the nasal while the rest of the olfactory epithelium is being drawn further and further away f external nares into the superior meatus. For further account of the development of t see pp. 49, 1238.

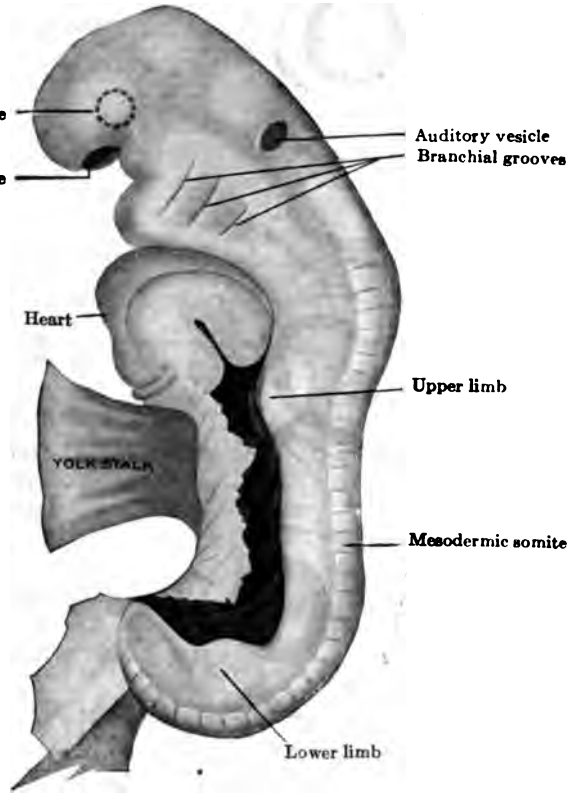
The peripheral ends of the nerves of taste are found mainly in association with th buds (Fig. 819, E). In the latter half of the fetal period these structures are found to l more widely distributed than they are in the adult—in connection with the vallate, fungi foliate papillæ, and the inferior surface of the tongue, on both surfaces of the epiglottis

the palatine arches (pillars of the fauces) as well as on the soft palate. After birth ıem begin to atrophy; and in the adult the taste-buds are concentrated chiefly on f the vallate and foliate papillæ and on some only of the fungiform papillæ. A few retained on the posterior aspect of the epiglottis.

te-buds make their appearance during the second month of fetal life as thickenings dermal epithelium. The epithelial cells become elongated and differentiated into *cells* and *taste-cells*.

ential part of the **organ of hearing and equilibration** can be recognized in human 2 mm. as an ectodermal thickening on each side of the hind brain. This becomes l to form the *otic vesicle* (fig. 822). As its ventral part expands the communication

320.—Human Embryo of 4.2 mm., Showing Sites of Special Sense-organs. (Modified from His.)



ırface persists as a narrow tube which remains open in fishes; but in man and all animals it closes and forms the endolymphatic duct. Two groups of sensory cells ıw out of the medial wall of the otic vesicle, the ventral is the cochlear ganglion and erve of hearing, the dorsal is the vestibular ganglion and nerve (fig. 823).

ɔeripheral apparatus of the different sense-organs be compared with one another, ıund that the *retina*, which is the sensory mechanism of the *eye*, differs from the re- tion of the other sense-organs in the fact that it is composed not only of sensory cells ɔones) such as are found in the cochlear, vestibular and gustatory ganglia and the rea, but also true nerve-cells (the granule layer and the nerve-cell layer of the retina

The true optic nerve —in the strictly morphological sense—consists of the central f the rods and cones. The rest of the retina is really a part of the brain and its cells .neurones. Hence the fibers which these cells transmit to the brain are not homol- ı true cerebral nerves but with such tracts of fibers as the lateral lemniscus. Just as arries acoustic impulses to the medial geniculate body and the inferior colliculus so lemniscus,' which is usually called the optic nerve, carries impulses to the lateral body and the superior colliculus.

mplexity of structure in the retina is determined primarily by the consideration that generated in the rods and cones by the stimulus of light is so feeble that a peripheral (the granule and nerve-cell layers) is necessary to reinforce the impulse before it d to the brain. The composite structure of the retina (partly sensory cells and partly f the central nervous system) is built up during development by profound modifica- ɔ method of formation that is adopted in the case of other sensory nerves. In the ıt of the latter the sensory cells, derived from the ectoderm adjoining the medullary

plate, are not absorbed into the latter when it becomes transformed into the neu
but remain outside the central nervous system, either as ganglia such as the spiral or ve
or as scattered olfactory cells occupying their primitive position in the skin. But in th
the visual apparatus the cells from which the rods and cones are derived are swept
neural tube, and afterward are carried out to the periphery in the optic vesicle along wi

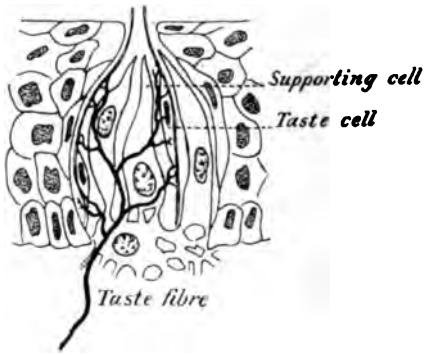
columnar cells (fig. 819, B).

ORGAN OF TASTE

The **taste-organs** [organon gustus] consist of minute epithelial struc **taste-buds** [calyculi gustatorii], situated mainly in the epithelial cover tongue and also of the epiglottis.

In the tongue, the taste-buds are collected mainly on the walls of t papillæ (see p. 1140), but they are found to a slight extent scattered whole area of distribution of the glossopharyngeal nerve, as well as on t of the foliate and fungiform papillæ, and on the plicæ fimbriatæ on the face of the tongue corresponding to the distribution of the taste-fib chorda tympani, which arise in the geniculate ganglion of the glossopalati nerve. Taste-fibers from the same ganglion pass to the palate in superfical petrosal nerve and its continuation in the palatine nerves.

FIG. 826.—DIAGRAM ILLUSTRATING THE STRUCTURE OF THE TASTE-BUI



Each **taste-bud** (fig. 826) is a somewhat conical or oval **structure,** .07–.08 mm. in length. At one end it opens by **a small channel, t pore-canal,** which passes to the surface between **adjacent epithelial** surface opening is termed the *outer pore* and the opening **at the tas** *inner taste-pore*

erical structure, whose wall is formed externally by a fibrous tunic he **sclera** (the white of the eye), and the **cornea** (the transparent area erior aspect of the eyeball). Internal to the tunic formed by these is a pigmented **vascular tunic,** which includes posteriorly the **choroid,** rly the **iris,** or the colored part of the eye.

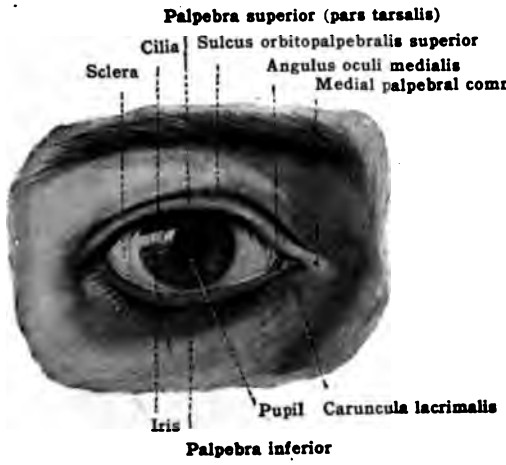
eater part of the space enclosed by these tunics is occupied by the **dy,** in a depression on the front of which the **crystalline lens** is found. in front of the lens is incompletely subdivided by the iris into anterior or chambers.

dy of the eye is best undertaken by examining the eye in the living, and ly by the dissection of specimens, and that order is followed in this

General Surface View

eyes are situated nearly in the line where the upper and middle thirds of the face e right and left of the root of the nose, the most prominent part of the front of ing about 3 cm. (1¼ in.) from the midline of the face. Each eye is overshadowed ponding eyebrow, and is capable of being concealed by its eyelids, upper and lower. al margin may be traced all round with the finger. At the junction of the medial liate thirds of the upper margin the supraorbital notch (incisura supraorbitalis) e felt, and the supraorbital nerve passing through it can sometimes be made to to side under the finger. The medial margin is the most difficult to trace in this because it is more rounded off than the others, partly because it is bridged over by **medial palpebral ligament**), passing medially from the medial angle of the eyelids; and, however, a sharp bony crest is felt, which lies anterior to the lacrimal sac. e eye is protected by the rim of the orbit, above and below, if we lay a hard flat

Fig. 827.—View of the Eye with Eyelids Open.



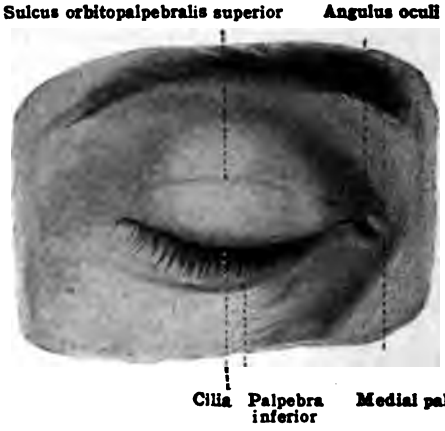
e orbital opening, it will rest upon the upper and lower bony prominences, and will e surface of the globe. Medially, the eye is protected from injury mainly by the nose; laterally it is most readily vulnerable, as here the orbital rim is compara- With one finger placed over the closed upper lid, press the eyeball gently backward t, and observe the elastic resistance met with, due to the fact that the globe rests n a pad of fat.

e between the free edges of the upper and lower lids is known as the **palpebral** ıa palpebrarum]: it is a mere slit when the lids are closed; but when they are open roughly, that of an almond lying with its long axis horizontal, and about thirty h.

e eyes are directed to an object straight in front of them, this aperture is about wide, but its width varies with upward and downward movements of the eyeball, t on looking strongly upward, diminishing gradually as the eye looks progressively **angles** formed by the meeting of the lids at each end of the palpebral aperture spectively the lateral and medial angles (or canthi) [angulus oculi lateralis, medi- h the lateral is sharp, while the medial is rounded off. On a closer inspection, it that, for the last five mm. or so before reaching the medial angle the edges of the lmost parallel course, and are here devoid of lashes. Through the open palpebral front of the eyeball comes into view, extending quite to the lateral, but not reach- the medial, angle; just within the latter we find a small reddish prominence, the ıncle [caruncula lacrimalis]; and between this and the eyeball a fold of conjunctiva e **plica semilunaris.** While the eye is open, press one finger on the skin, a little ateral angle, and draw it firmly away from the middle line; observe that the upper

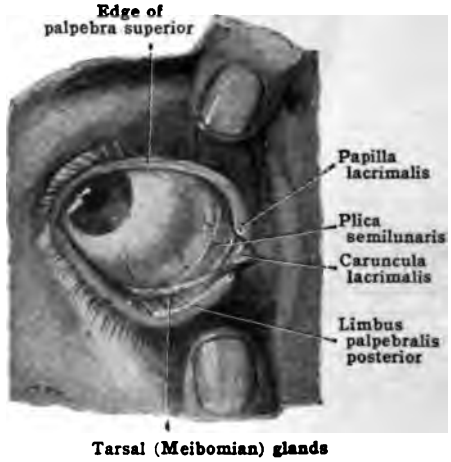
lid then falls over the eyeball, and that the outline of a firm band already referred medial palpebral ligament) becomes evident, passing between the medial angle and t The falling of the lid is caused by our dragging upon a ligament (the lateral palpebral which the lateral end of its tarsus is attached, and so putting the lid itself upon the If, while the eyeball is directed downward, we place one finger on the lateral end of th eyelid and draw it forcibly upward and laterally, we can usually cause the lower di the lacrimal gland to present just above the lateral angle.

FIG. 828.—VIEW OF THE EYE WITH EYELIDS CLOSED.



The upper eyelid [palpebra superior] is much broader than the lower, extending as far as the eyebrow. The skin covering it is loosely attached to the subjacent tissue but more firmly below, nearer the free margin, where it overlies a firm fibrous tissue tarsus superior. When the eye is open, a fold is present at the upper border of this l tightly applied portion of skin, called the superior palpebral fold, and by it the lid is into an upper or orbital, and a lower or tarsal, division. The presence of the tar readily appreciated on our pinching horizontally the entire thickness of the eyelid palpebral fold. The lower eyelid [palpebra inferior] is similarly divided anatomica tarsal and an orbital part, but the demarcation is sometimes unrecognizable on th

FIG. 829.—VIEW OF MEDIAL REGION OF THE EYE, WITH THE EYELIDS WIDELY S AND THE EYEBALL TURNED LATERALLY.



though a fold or groove (the inferior palpebral) is usually visible when the eye is wid There is no precise limit of this lid below, but it may be regarded as extending to the lower margin of the orbit. Numerous very fine short hairs are seen on the anterio both eyelids. Each eyelid presents an anterior and a posterior surface, separate margin with two edges:—(*a*) An anterior, rounded edge [limbus palpebralis ant which the stiff cilia, or eyelashes, are closely placed in a triple row; and (*b*) a sha edge [limbus palpebralis posterior] which is applied to the surface of the globe (s The cilia of both eyelids have their points turned away from the palpebral apert the upper ones curve upward, and the lower downward; the cilia of the upper lid are t and those in the middle of each row are longer than those at each end. Between th

just described, the lid-margin has a smooth surface, on which is a single row of minute apertures, the openings of large modified sebaceous glands, the **tarsal** or **Meibomian glands.** These must not be confused with the sebaceous glands associated with the hair-follicles that are superficial to the tarsal plate. It is by these glistening, well-lubricated surfaces that the opposite lids come into apposition when they are closed. The secretion of these glands is known as the *sebum palpebrale.* The sharp posterior edge of the lid-margin marks the situation of the transition of skin into mucous membrane. Near the medial end of the margin of the lids we find a prominence, the **lacrimal papilla,** on the summit of which is a small hole [**punctum lacrimale**], the opening of the lacrimal duct (ductus lacrimalis) for the passage of tears into the lacrimal sac. The lower punctum is rather larger than the upper, and is placed further from the medial angle of the eye.

If we now examine the posterior surface of the eyelids—*e. g.*, of the lower—we observe that it is lined by a soft mucous membrane, the **palpebral conjunctiva** [tunica conjunctiva palpebrarum]. Over the tarsal part of the lid the conjunctiva is closely adherent, but beyond this it is freely movable along with the loose submucous tissue here present. On tracing it backward, we find that it covers the whole posterior surface of the lids, and is then continued *forward* over the front of the eyeball, forming the conjunctival tunic of the globe [tunica conjunctiva bulbi]. The bend it makes as it changes its direction here is called the **conjunctival fornix** [fornix conjunctivæ superior or inferior]. Numerous underlying blood-vessels are visible through the palpebral conjunctiva, and under cover of its tarsal part we can see a series of nearly straight, parallel, light yellow lines, arranged perpendicularly to the free margin of the lid—the tarsal glands. The conjunctiva over the medial and lateral fourths of each lid is not quite so smooth as elsewhere, and is normally of a deeper red color; we shall find later that there are glands well developed in these positions.

When the eyelids are opened naturally, we see through the palpebral aperture the folowing: the greater part of the transparent cornea, and behind it the colored iris with the pupil in its center; white sclera to the medial and lateral sides of the cornea; the semilunar fold and lacrimal caruncle at the medial angle. The extent of the eyeball visible in this way varies according to its position. Thus, with the eyes looking straight forward, the lower margin of the upper lid is nearly opposite to the top of the cornea, or, more strictly, to a line midway between the top of the cornea and the upper border of the pupil, while the lower lid corresponds with the lower margin of the cornea. When the eyes are directed strongly upward, the upper lid is relatively on a slightly higher level, as it is simultaneously raised, but the lower lid now leaves a strip of sclera exposed below the cornea. On looking downward the upper lid covers the upper part of the cornea as low down as the level of the top of the pupil, while the lower lid is about midway between the pupil and the lower margin of the cornea.

If we draw the eyelids forcibly apart, we expose the whole cornea, and a zone of sclera about eight and a half mm. in breadth above and below, and ten mm. in breadth to the lateral and medial sides—altogether about one-third of the globe; all the eyeball thus exposed is covered by the **ocular conjunctiva** [tunica conjunctiva bulbi]. Over the sclera the conjunctiva is freely movable, and through it we see superficial blood-vessels that can be made to slip from side to side along with it (episcleral vessels). Occasionally other deeper vessels may also be seen which do not move with the conjunctiva, but are attached to the sclera (anterior ciliary arteries and veins). Near the corneal border the conjunctiva ceases to be freely movable, and it is closely adherent to the whole anterior surface of the cornea, giving the latter its characteristic bright, reflecting appearance; no blood-vessels are visible through it here in health. When the lids are shut, the space enclosed between their posterior surfaces and the front of the eyeball is thus everywhere lined by conjunctiva, and is known as the **conjunctival sac.**

Not unfrequently the tendinous insertions of some or all of the recti muscles into the sclera may be seen through the conjunctiva, each insertion appearing as a series of whitish parallel lines running toward, but terminating about seven mm. from the corresponding corneal border.

The **cornea** appears as a transparent dome, having a curvature greater than that of the sclera; the junction of the two unequally curved surfaces is marked by a shallow depression running around the cornea, known as the **scleral sulcus** [sulcus scleræ]. In outline the cornea is nearly circular, but its horizontal diameter is slightly greater than its vertical. Between it and the iris a space exists, whose depth we can estimate roughly by looking at the eye from one side; this space, or anterior chamber [camera oculi anterior] is occupied by a clear fluid, the aqueous humour. Almost the whole anterior surface of the iris is visible, its extreme preiphery only being concealed by sclera.

In color the **iris** varies greatly in different individuals. Near its center (really a little above and medially) a round hole exists in the iris, the black *pupil* [pupilla], whose size varies considerably in different eyes, and in the same eye according to temporary conditions, such as exposure to light, etc.

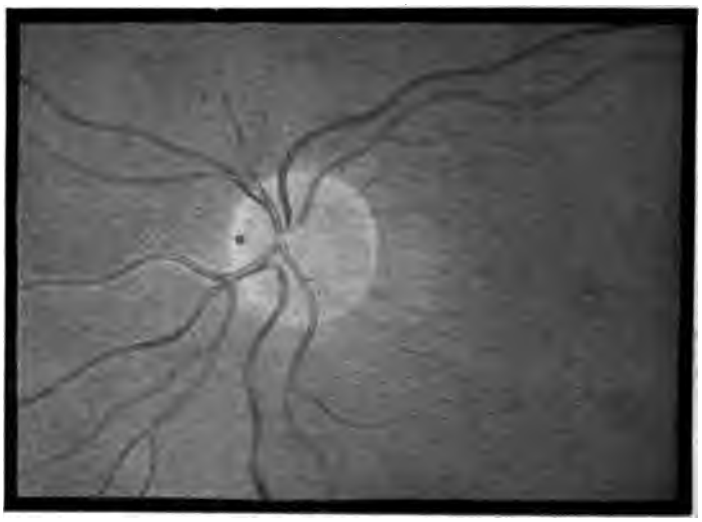
On the surface of the iris we see a number of ridges [plicæ iridis] running more or less radially; adjoining ones occasionally unite and interlace to some extent, so as to leave large depressed meshes at intervals. These are the *crypts* of the iris. The radial ridges coming from the edge of the pupil, and those coming from the more peripheral part of the iris, meet in a zigzag elevated ridge concentric with the pupil, called the *corona iridis*, and by this ridge the iris is roughly marked off into two unequal zones—an outer, the **greater** [annulus iridis major] and an inner, the **lesser** [annulus iridis minor]. The border next the pupil [margo pupillaris] is edged with small, roundish, bead-like prominences of a dark brown color, separated from one another by depressions, so that it presents a finely notched contour. Not infrequently, in a light-colored iris, we may see the sphincter muscle through the anterior layers, in the form of a ring about one mm. in breadth around the pupil. The annulus iridis major may be described as consisting of three parts:—(*a*) A comparatively smooth zone next the zigzag ridge; (*b*) a middle area, showing concentric but incompletely circular furrows; (*c*) a small peripheral darker part, presenting a sieve-like appearance. On the floor of the large depressed meshes,

or *crypts*, parallel radial vessels can be traced, belonging to the iris-stroma. The zigzag mentioned above corresponds to the position of the circulus arteriosus minor. Occasionally especially in a light iris, superficial pigment spots of a rusty brown color occur.

(In examining the living eye, the ophthalmoscope may now be used, so as to gain a view of the fundus, and to study the termination of the optic nerve, the distribution of the blood retinal vessels, etc. See fig. 830.)

The general red reflex obtained from the fundus is due to the blood in a capillary net (**choriocapillaris**) situated in the inner part of the choroid. To the nasal side of the center the fundus is a paler area of a disk shape corresponding to the intraocular end of the optic and known as the **papilla of the optic nerve** [papilla n. optici]. This papilla (or 'optic d is nearly circular, but usually slightly oval vertically; it is of a light orange-pink color, w characteristic superficial translucency; its lateral third segment is paler than the rest as n fibers and capillaries here are fewer in number. About its center we often observe a marked whitish depression [excavatio papillæ n. optici], formed by the dispersion of the n fibers as they spread out over the fundus; at the bottom of this depression a sieve-like ap ance may be seen, due to the presence of the **lamina cribrosa scleræ**, which consists of a fibrous tissue framework, with small, roundish, light-gray meshes in it, through which nerve-fiber bundles pass. Also near the center of the papilla, the retinal blood-vessels come into view, the arteries narrower in size and lighter in color than the veins; they d dichotomously as they are distributed over the fundus. The retina proper is so transp as to be ophthalmoscopically invisible, but its pigment-epithelium gives a very finely gr or darkly stippled appearance to the general red reflex. In the center of the fundus, and fore to the lateral side of the papilla, the ophthalmoscope often shows a shifting halo o

FIG. 830.—THE NORMAL FUNDUS OF THE EYEBALL. (Parsons.)



playing round a horizontally oval, comparatively dark enclosed area; this latter cor to the **yellow spot** [macula lutea] region, and about its center a small pale spot usual the position of the **fovea centralis.**

Two structures visible at the nasal end of the palpebral aperture have been p mentioned, and should now be examined more narrowly. The **lacrimal caruncle** is of modified skin, and fine hairs can commonly be detected on its surface, and it conta ceous and sweat glands. Lateral to it and separated from it by a narrow groove, is **lunar fold of conjunctive** it rests on the eyeball, and is a rudiment of the third eyelid ting membrane, present in birds and well represented in many other vertebrates.

EXAMINATION OF THE EYEBALL

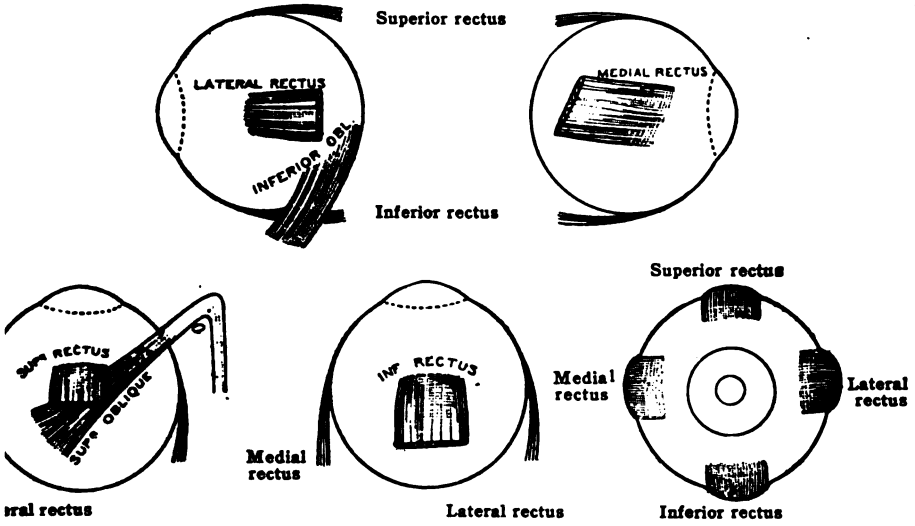
(In the following account, the structure of the eyeball is described as i appear upon dissection.)

The **eyeball** [bulbus oculi] is almost spherical, but not perfectly so, ma cause its anterior, clear, or *corneal* segment has a greater curvature than th the eye. Considering it as a globe, it has an **anterior pole** [polus anter a **posterior pole** [polus posterior]; the former corresponding to the cente front of the cornea, the latter to the center of the posterior curvature. A inary straight line joining the two poles is called the **axis of the eyeba equator** of the eye is that part of its surface which lies midway between poles. The various **meridians** are circles which intersect the poles. The axis of the globe is the greatest (about 24.5 mm.), the vertical equatorial t

rt 23.5 mm.), and the transverse equatorial axis is intermediate in length rt 23.9 mm.), so that the eyeball is in reality an ellipsoid, flattened slightly above downward. These figures refer to the adult male; in the female the ll is .5 mm. smaller in all axes. Again, if the globe is divided in its mid- al plane, the nasal division will be found to be slightly smaller than the tem- . The optic nerve joins the globe three or four mm. to the nasal side of the rior pole.

he shape of the eye depends on, and is preserved by, the outermost tunic, ed conjointly by the **cornea** and **sclera**, the entire outer surfaces of which are in view. The anterior or corneal part has already been examined. All nd the cornea there remains a little adherent conjunctiva; elsewhere, the a is directly exposed, except for some loose connective tissue which adheres to it, cially around the optic nerve entrance. In front of the equator we see the inous insertions of the four recti muscles. Behind the equator are the inser- of the two oblique muscles—that of the superior oblique tendinous, and er forward, under the superior rectus; that of the inferior more fleshy, and ed between the optic nerve and the lateral rectus.

FIG. 831.—DIAGRAMMATIC VIEW OF THE INSERTIONS OF THE OCULAR MUSCLES.



is difficult to recognize the different recti muscles by their insertions if we do not know ner the eye examined is a right or a left one. To determine this we should hold the globe the optic nerve toward us, and in the natural position with the superior oblique tendon most. The inferior oblique tendon will now point to the side to which the eye belongs, ve can consequently determine the different recti muscles.

he medial [m. rectus medialis] rectus is inserted nearest (5.5 to 7 mm. from) the corneal r; the superior [m. rectus superior] rectus commonly, sometimes the lateral [m. rectus lis], is inserted furthest from it (7.7 to 8 mm.). All the recti tendons are broad and thin, hat of the medial is the broadest (8 to 10.3 mm.); those of the lateral and inferior the west (6 to 9.2, or 9.8 mm., respectively). The greatest interval between two neighboring ns is that between the superior and medial recti (about 12 mm.); the least is between uperior and lateral (7 mm.). The form of the lines of insertion of the different tendons s considerably, the inferior being almost straight, the superior and lateral convex forward, nedial further removed from the corneal border below than above.

he insertions of the oblique muscles [mm. obliqui] are at more than double the average nce of the insertions of the recti from the corneal border. That of the superior oblique is l on the superior surface of the sclera, about sixteen mm. from the corneal edge, in the form ine 10.7 mm. long sloping from before backward and medially. The inferior oblique has a fleshy insertion lying between the lateral rectus and the optic nerve entrance; the posterior f the insertion, which is also the higher, is only about five to six mm. from the optic nerve, rom this point it slopes forward, laterally, and slightly downward.

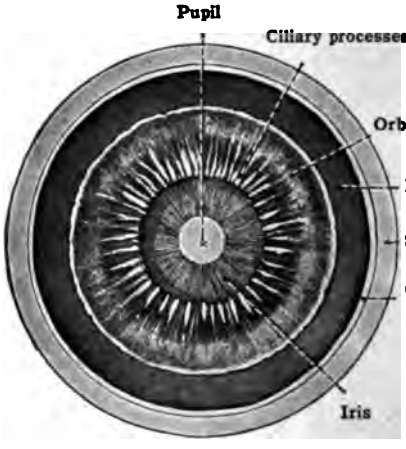
Several small nerves and two arteries may be seen running forward and ulti- ly perforating the sclera not far from the entrance of the optic nerve. The arteries are the long posterior ciliary [aa. ciliares posteriores longi]; they both rate the globe in the horizonal meridian, 3.5 mm. from the optic nerve, one he lateral, the other on the medial, side. The short ciliary arteries [aa. ciliares

posteriores breves] are too small to be seen in an ordinary examination. The nerves are the long and short ciliary [nn. ciliares longi, breves]. Nearer the equator large venous trunks emerge; they can be traced for some distance in front of their exit as dark lines, running anteroposteriorly internal to the sclera. The optic nerve is seen in section, surrounded loosely by a thick outer sheath; in the center of the nerve-section, a small red spot indicates the position of the central retinal blood-vessels [a. et v. centralis retinæ].

(The following structures appear in an eyeball divided into anterior and posterior halves by cutting through it in the equatorial plane.)

1. **Posterior hemisphere** seen from in front.—This is much the same view that the ophthalmoscope affords us. Unless the eye be very fresh, however, the **retina** will have lost its transparency, and will now present the appearance of a thin whitish membrane, detached in folds from the external coats, but still adherent at the optic papilla. The vitreous jelly lying within the retinal cup may be torn away. In the human eye the retina next the posterior pole is stained yellow [**macula lutea**]. On turning the retina over, a little pigment may be seen adhering to its outer surface here and there. Cut through the retina close to the optic disk all around and remove it: note how easily it is torn. We now see a dark brown surface, consisting of the **retinal pigment layer** [stratum pigmenti retinæ] adherent to the inner surface of the choroid. Brush off the retinal pigment under water. The **choroid** thus exposed can for the most part be fairly easily torn away from the thick sclera, as a lymph-space exists between them, but the

FIG. 832.—ANTERIOR HEMISPHERES OF EYEBALL, VIEWED FROM BEHIND.



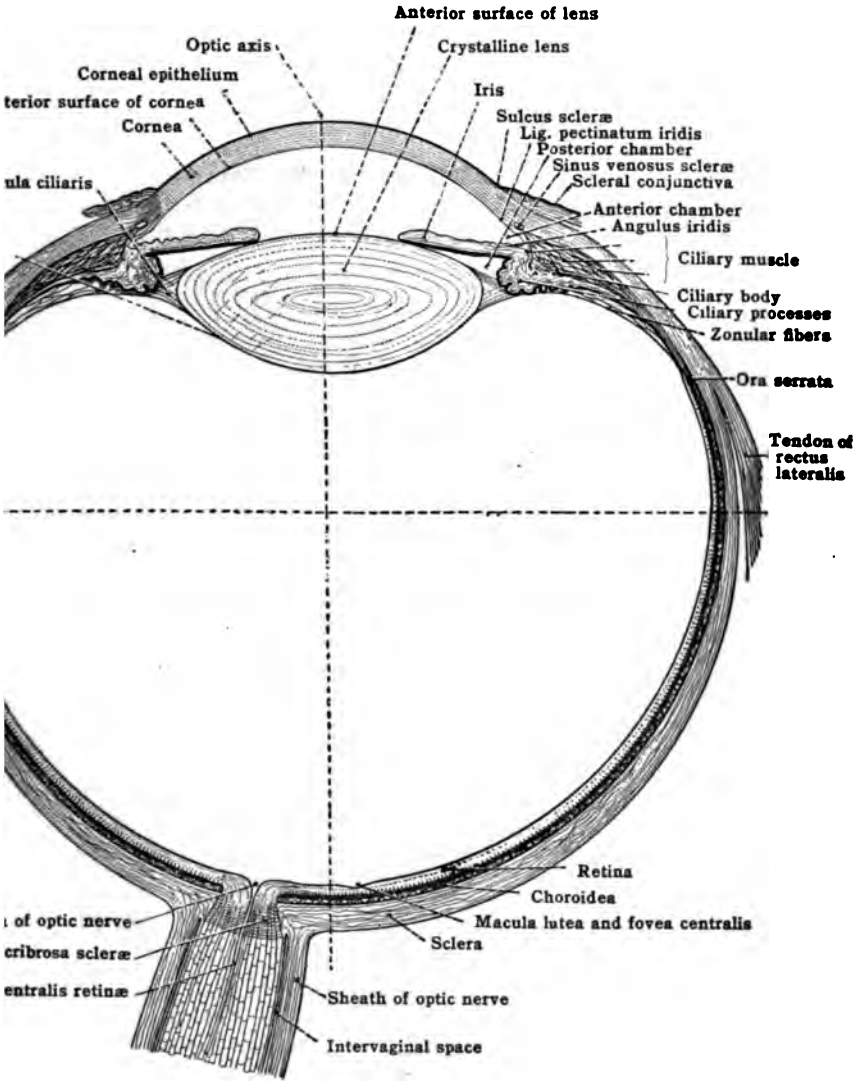
attachment is firm around the optic nerve entrance, and also where the arteries and nerves join the choroid after penetrating the sclera. The choroid is darkly pigmented, of a brown color with markings on its surfaces corresponding to the distribution of its large veins. The inner surface of the sclera is of a light brownish color, mainly from the presence of a delicate pigmented layer, the **lamina suprachoroidea**, which adheres partly to it, partly to the choroid, giving to their adjacent surfaces a flocculent appearance when examined under water.

2. **Anterior hemisphere** viewed from behind (fig. 832).—The round opening of the pupil is visible in the middle, in front of the large clear **crystalline lens**. The retina proper extends forward a little way from the line of section, and then ends abruptly in a wavy line called the **ora serrata**, beyond which it is represented only by a very thin membrane [**pars ciliaris retinæ**]. Outside the periphery of the lens are a number of **ciliary processes** arranged closely together in a circle concentric with the pupil, and each radially elongated; posteriorly they are continuous with numerous fine folds, also radial, which soon get very indistinct as they pass backward, but reach almost to the ora serrata [**plicæ ciliares**]. Between the front of the ciliary processes and the edge of the pupil lies the **iris**. On removal of the retina the inner surface of all this region is seen to be darkly pigmented, but especially dark in front of the position of the ora serrata. Vitreous probably still adheres to the back of the lens, and by pulling upon it the lens can be removed along with its capsule and suspensory ligament; some pigment will now be found adhering to the front of the vitreous, torn from the ciliary processes, which are consequently now lighter in color than before. The **lens-capsule** is transparent, and has a smooth glistening outer surface; through it a gravish, star-shaped figure [**radii lentis**] may be observed on the anterior and posterior surfaces of the lens. The **suspensory ligament** is a transparent membrane attached to the capsule of the lens about its equator, and is best seen by floating the lens in water in a glass vessel placed on a dark ground. On opening the capsule we expose the lens itself, which is superficially soft and glutinous to the touch, but becomes firmer as we rub off its outer layers and approach its center. Carefully tear the choroid and iris from the sclerotic as far as possible; a firm adhesion exists just behind the corneal periphery. The outer surface of the choroid thus exposed is found to be also rather darkly pigmented, but it shows a white ring corresponding to the adhesion just mentioned, and a pale area behind this ring indicates the position of the **ciliary muscle** [m. ciliaris]. On this surface numerous white nerve-cords are

ning forward. Observe that the iris, the ciliary processes, etc., and the choroid are all arts of the same ocular tunic—mere local modifications of it. Similarly the sclera are seen to blend together to form one outer coat.

ball should now be placed for half an hour in a freezing mixture of crushed ice and ill thus become quite hard, and should at once be divided into two parts by cutting osteriorly through the center of the cornea and the optic nerve. We thus gain ew of the relations of parts, the position of the lens between the aqueous and vitreous etc. On removing the lens, vitreous, and retina, and brushing off its pigment, the ings corresponding to the choroidal veins (**venæ vorticosæ**) should be noted, and their n studied. Usually four vortices or fountain-like markings are found in the whole

FIG. 833.—HORIZONTAL SECTION OF THE EYEBALL. × 4.



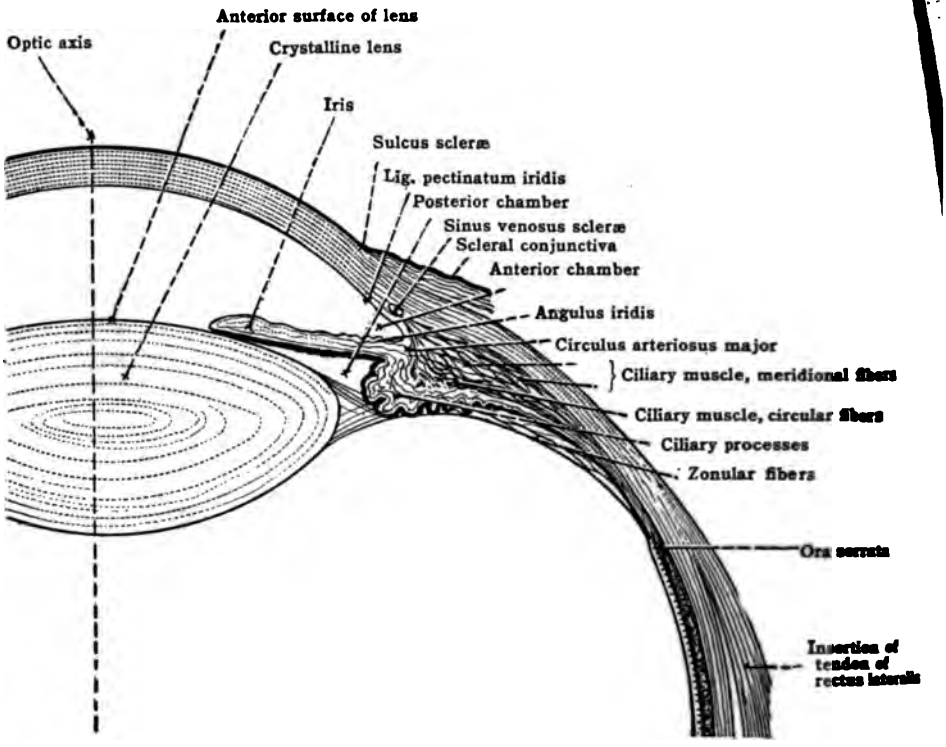
eir points of junction situated at approximately equal distances from one another at line where the posterior and middle thirds of the globe meet. These sections should r reference while following the further description of the ocular tunics.

coats of the eyeball.—1. The **outer, fibrous coat of the eye** [tunica culi] is formed by the **sclera** and **cornea,** which pass into one another leral sulcus. It consists throughout mainly of fine connective tissue ranged in interlacing bundles, with small lymph-spaces at intervals them. The naked-eye appearance of the two divisions of this fibrous however, quite different, the cornea being transparent, while the sclera and opaque.

The **sclera** encloses the posterior five-sixths or so of the eyeball. It is perforated by the entrance of the optic nerve, and the opening in the sclera, only partially bridged across by fibers from the inner layers, forms the **lamina cribrosa**.

The fiber-bundles composing the sclera are arranged more irregularly than in the cornea and run mainly in two directions, viz., anteroposteriorly and circularly; the circular fibers are particularly well developed just behind the sulcus. It is thickest (about 1 mm.) posteriorly, where it is strengthened chiefly by the outer sheath of the optic nerve, and partly also by the tissue surrounding the ciliary vessels and nerves. It becomes gradually thinner as it passes forward, up to the line of insertion of the recti muscles, where it is .3 mm. thick. In front of that line it is again reinforced by their tendinous fibers becoming incorporated with it and its thickness increases to .6 mm. In children the sclera is often so thin as to allow the underlying choroidal pigment to show through, its color then appearing bluish white. In the aged, again, it is sometimes yellowish. It always contains a few pigment-cells, but these are in the deep layer termed the *lamina fusca*, and only become visible externally where the sclera is pierced by vessels and nerves going to the choroid. It is almost non-vascular, but quite at its anterior end the **sinus venosus scleræ** or **canal of Schlemm** [canalis Schlemmi (Lauthi)] runs in its deeper layers circularly around the cornea. Just in front of this sinus, at the corneal limbus, the sclera merges into the cornea, its inner layers changing first, and finally the outer ones.

FIG. 834.—PORTION OF FIG. 833, ENLARGED.



The **cornea** forms the anterior sixth of the eyeball. It is thickest at its periphery (1.1 mm.) and becomes gradually thinner toward its center (0.8 mm.); the curvature of its posterior is consequently greater than that of its anterior surface, but even the latter is more curved than the surface of the sclera.

In the cornea proper, fiber-bundles are arranged so as to form a series of superposed lamellæ each of which is connected here and there to the adjacent ones by fibers passing from one to the other, so that they can only be torn apart with difficulty. The corneal lymph-spaces communicate with one another by very fine canals, and thus a thorough lymph-circulation is provided for. The cornea contains no blood-vessels, with the exception of a rich plexus at its extreme periphery, on which its nutrition is ultimately dependent. It is richly supplied with nerves, however, especially in its most superficial layers.

The outer surface of the cornea is covered by an extension of the ocular conjunctiva, with an epithelium several layers deep. The most anterior part of the true cornea appears homogeneous, even when highly magnified and constitutes the anterior elastic lamina, Bowman's membrane. Posteriorly, the cornea is lined by a firm, thin, glass-like layer (posterior elastic lamina, membrane of Descemet), distinct from the corneal tissue both anatomically and chemically. At the periphery this membrane breaks up into a number of fibers, which mainly arch

...r to join the base of the iris and form part of the **ligamentum pectinatum iridis.** The pectin... ligament is an open network of interlacing fibers, directly continuous with the circular ... longitudinal bundles of sclera surrounding the venous sinus of Schlemm (Henderson). ... interstices between these fibers constitute spaces (**spaces of Fontana**) [spatia anguli iridis ...ontanæ)] freely communicating with the aqueous chamber on the one hand, and indirectly ...th the venous sinus of the sclera on the other. The posterior elastic lamina is in turn lined ...y a single layer of flat cells, which are continuous peripherally with cells lining the spaces of the ...le and the anterior surface of the iris which form the endothelium of the anterior chamber. ...e relation of the spaces and chanbers in the circulation of fluids is considered later (p. 1101) ...der the *filtration angle.*

2. The dark, **middle,** or **vascular coat of the eye** [tunica vasculosa oculi] is formed by the **iris, ciliary body,** and **choroid.** It is closely applied to the sclera, but actually joins it only at the anterior and posterior limits of their course together, viz., at the scleral sulcus, and around the optic nerve entrance. It is separated from the sclera between these two points by a narrow slit-like lymph-space [spatium perichoroideale]. In front of the sulcus, the middle coat is separated from the outer (i. e., the iris from the cornea) by the *anterior aqueous chamber* (fig. 839). The vascular coat has two openings in it; a larger one in front, the *pupil,* and a smaller one behind, for the passage of the optic nerve. Its structure is that of a pigmented connective tissue, supporting numerous blood-vessels and containing many nerves and three deposits of smooth muscle-fibers.

The **choroid** [choroidea] forms the posterior part of the vascular coat, and extends, with slowly diminishing thickness, forward as far as the ora serrata. Its outer and inner surfaces are both formed by non-vascular layers; that covering the outer, the **lamina suprachoroidea** is pigmented, arranged in several fine loose lamellæ; that covering the inner surface is a thin, transparent, homogeneous membrane, called the **basal lamina** of the choroid. The intervening choroidal stroma is very rich in blood-vessels, which are of largest size next its outer surface constituting the **lamina vasculosa.** These become progressively smaller toward the basal lamina, next to which is a layer of closely placed wide capillaries, called the **lamina choriocapillaris.** The pigment becomes less in amount as we pass inward, and finally ceases, being absent entirely from the choriocapillary and basal laminæ.

In front of the ora serrata the vascular coat becomes considerably modified, and the part reaching from the ora serrata of the retina to the iris is termed the ciliary region of the tract, or **ciliary body** [corpus ciliare]. Its superficial aspects have been already briefly described. In front, the ciliary processes, about seventy in number, project toward the interior of the eye, forming the **corona ciliaris.** Behind this part lies the **orbiculus ciliaris,** whose inner surface is almost smooth, faint radial folds [plicæ ciliares] only being present, three or four of which join each ciliary process.

The more minute structure of this ciliary region resembles closely that of the choroid, except that the choriocapillaris is no longer present, that the stroma is thicker and richer in blood-vessels, and that a muscular element (ciliary muscle) exists between the vascular layer and the lamina suprachorioidea. On anteroposterior section the ciliary body is triangular; the shortest side looks forward, and from about its middle the iris arises; the two long sides look respectively inward and outward, the inner having the ciliary processes upon it, while the outer is formed by the **ciliary muscle.** This muscle possesses smooth fibers and consists of an outer [fibræ meridionales (Brueckei)] and an inner division [fibræ circulares (Muelleri)]. The meridional fibers take origin from the outer fibrous coat of the eye at the sclerocorneal junction in front, and passing backward to join the outer layers of the orbiculus ciliaris and choroid; the circular fibers are situated next to the ciliary processes. The entire muscle is destitute of pigment, and therefore is recognizable in the section by its light color. The whole thickening of the vascular tunic in this region, muscle and folds and processes together, is named the **ciliary body.** It includes the corona ciliaris, formed of the ciliary processes and folds, and the orbicularis ciliaris containing the ciliary muscle.

The **iris** projects into the interior of the front half of the eye in the form of a circular disk, perforated in the middle. The appearance of its anterior surface has already been described. The anterior surface is covered with a layer of endothelium except at the crypts near the ciliary border. Thus the lymph-spaces between the stroma-cells communicate directly with the anterior chamber. Its posterior surface exhibits numerous radial folds running from the ciliary processes to near the pupillary margin; a thick layer of black pigment covers it and curls around this edge, so as to come into view all around the pupil as seen from in front. The *ciliary border* of the iris is continuous with the front of the ciliary body, and there it also receives fibers from the ligamentum pectinatum iridis; in other respects the iris is quite free, merely resting on the front of the lens-capsule near the pupil.

Its stroma [stroma iridis] is spongy in character, being made up of vessels, running from the periphery to the pupillary border, with interspaces filled by branching *pigment-cells,* which are particularly abundant near the front surface. Deep in the stroma, running around near the pupillary border, we find a broad flat band of smooth muscle-fibers, constituting the **m. sphincter pupillæ.** Immediately behind the vascular tissue lies a thin membrane, consisting of fine, straight fibers running radially from the ciliary border to the stroma behind the sphincter. These comprise the **m. dilatator pupillæ.**

The *m. sphincter pupillæ* and the *ciliary muscle* are supplied indirectly by the oculomotor nerve through the ciliary ganglion. The preganglionic fibers of the nerve end in the ciliary ganglion, from the cells of which arise the fibers which innervate the ciliary and sphincter

pupillæ muscles. They are unique among postganglionic fibers in being medullated. The dilatator pupillæ is supplied by *sympathetic fibers*, which have their origin from the cells of the superior cervical ganglion. Thence they ascend in the carotid and cavernous plexuses, and join the ophthalmic division of the trigeminal nerve, passing to the eyeball by way of the long ciliary nerves. The preganglionic sympathetic fibers leave the spinal cord by the motor roots of the first two or three thoracic nerves, and ascend the sympathetic trunk to the superior cervical ganglion without interruption (fig. 744).

The posterior surface of the iris is coated by pigment already mentioned, consisting of two layers of pigmented cells, representing the extension forward of the two walls of the optic cup, retina and pigment layer, respectively. The anterior surface of the iris is covered by a delicate epithelial layer, continuous with the cells of the posterior elastic lamina of the cornea. The variations in the color of the iris in different individuals depend upon the amount of stroma pigment.

FIG. 835.—DIAGRAMMATIC HORIZONTAL SECTION OF EYEBALL AND ORBIT.
(After Fuchs, much modified.)

3. **The retina.**—The inner surface of the vascular coat is everywhere lined by a layer of pigment of corresponding extent, which usually adheres to it closely on dissection.

Developmentally this general pigment lining is quite distinct from the vascular coat, and represents the *outer wall* of the secondary optic vesicle or embryonic retina; it consists of a single layer of pigmented epithelial cells, the *stratum pigmenti*. In the ciliary region these cells have recently been described as lining numerous narrow tubular depressions in the inner part of the vascular tract, and they are said to have here a special function, viz., that of secreting the intraocular fluid.

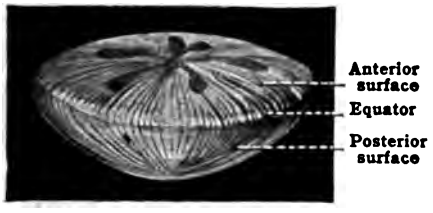
From the manner in which the secondary optic vesicle, or *optic cup*, is formed, its two walls are necessarily continuous in front, at what may be termed the *lip* of the cup; we have just observed that the outer wall lines the vascular coat everywhere and corresponds in extent; consequently, the lip must be looked for at the edge of the pupil, *i.e.*, at the termination of this coat anteriorly. The inner wall of the cup, consequently, reaches from the lip, or pupillary edge, in front to the optic stalk or nerve behind, and is in close apposition to the pigment-epithelium: unlike the outer, however, this wall is represented in the developed eye by tissues

milar in structure in different parts of its extent. Tracing it backward pupillary edge, we find that over the whole posterior surface of the iris it a single layer of pigmented epithelium, the two layers of the cup having uced a double layer of pigment cells. At the root of the iris the single r of cells still exists; but now they become destitute of pigment, and this obtains over the entire ciliary region, constituting what is known as the **is retinæ.** At the line of the ora serrata the tissue derived from the inner ptly increases in thickness, and rapidly acquires that complexity of characteristic of the **retina proper,** which extends from here to the optic is termed the *pars optica retinæ.* It consists of several layers—nerve-rve-cells, and nerve-epithelium—held together by a supporting frame-elicate connective tissue.

hological **detachment of the retina** is really a separation of the two layers of the

inal nerve-epithelium is on the outer surface, immediately applied to the pigment- at the posterior pole of the eye a small spot [**fovea centralis**] exists, where this is the layer represented, and where consequently the retina is extremely thin. The nerve- n the inner surface of the retina and are continuous with those of the optic nerve; itute the only retinal layer that is continued into the intraocular end of the e nerve-cells are found between these surface layers. The larger blood-vessels of the n the inner layers, and do not encroach on the layer of nerve-epithelium.

FIG. 836.—THE LENS. (Side view; enlarged.)



the coats mentioned, the interior of the eyeball is fully occupied by con- ich are divided into three parts, named according to their consistence omical form. They are all transparent, as through them the light ss so as to gain the retina. Of these, the only one that is sharply and ntly outlined is the lens, which is situated in the anterior half of the he level of the ciliary processes, where it is suspended between the other which fill respectively the space in front of it and the space behind it. in front of the lens called the aqueous chamber; that behind the lens is us chamber.

ns [lens crystallina] (fig. 834, 836) is a biconvex disk, with its surfaces nteriorly and posteriorly; these surfaces meet at its rounded-off edge or æquator lentis] which is near (but does not touch) the adjacent ciliary

The posterior is considerably more convex than the anterior surface; l point on each surface is called its **pole** [polus anterior; polus posterior]. s closely encased in a hyaline elastic **capsule** [capsula lentis] thicker over or than over the posterior surface. Thus enclosed, it is held in position be by a **suspensory ligament,** attached to the lens-capsule near the f the eye, and swung from the ciliary region. Posteriorly, the lens cup formed by the front part of the vitreous, while its anterior capsule ct with the aqueous fluid and lies close against the back of the pupillary the iris. When in position the lens measures nine mm. across, and r mm. between its poles.

surface a series of fine, sinuous, gray lines can be seen radiating from the pole to- quator, called respectively the anterior and posterior **stellate figures** [radii lentis]. or lines are always so placed as to be intermediate with those on the anterior surface, viewing them *through the lens* they occupy a position corresponding to the intervals e lines on the anterior surface. The lens-capsule is comparatively brittle, and can ut through when scraped with a sharp-pointed instrument; on doing so the divided outward, away from the lenticular substance. When removed from its capsule, rtion of the lens is found to be soft and glutinous, but its substance gets progressively e approach the center. This harder central part is known as the **nucleus** [nucleus the surrounding softer matter as **cortex** [substantia corticalis]. The cortical part idency to peel off in successive layers. It consists of long fibers, the ends of which nt and behind at the anterior and posterior stellate figures.

Histologically the capsule is not in immediate contact with the cortex over the front surface of the lens, a single layer of cells intervening, called the **epithelium lentis.**

The **zonula ciliaris or suspensory ligament of the lens** is formed by a number of fine zonular fibers [fibræ zonulares] passing from the ciliary body. They are attached to the lens-capsule a little in front of and behind the equator, and the spaces included between the fibers of the ligament are termed the *zonular spaces* [spatia zonularia]. A continuous space, which can be injected after death round the margin of the lens is known as the *canal of Petit.* This space is bridged across by fine intermediate suspensory fibers, and is occupied by fluid.

The **vitreous body** [corpus vitreum] is a transparent, colorless, jelly-like mass, the **vitreous humor,** enclosed in a delicate, clear, structureless membrane, the *hyaloid membrane.* This latter is closely applied to the back of the posterior lens-capsule and of the suspensory ligament, and to the inner surface of the ciliaris retinæ, retina proper, and optic papilla.

Although possessing some degree of firmness, the vitreous humor contains quite 98% of water, and has no definite structure. Membranes have been described in it, but these are artificial products. In certain situations spaces exist in the vitreous mass, the most distinct of which runs in the form of a canal from the optic papilla to the posterior pole of the lens, corresponding to the position of the fetal hyaloid artery (hyaloid canal or canalis hyaloideus), which occasionally persists in the adult. Other very fine spaces are described running concentrically in the peripheral part of the vitreous concentric with its outer surface. Microscopic wandering cells are found in the vitreous, which often here assume peculiar forms which the observer can, not infrequently, study subjectively.

ous humor is a clear, watery fluid, occupying the space between the
e one hand, and the ciliary body, zonula ciliaris, and lens on the other.
jecting into this space, has both its surfaces bathed in the aqueous;
ıer part rests on the lens, it is regarded as dividing the space into two
erior larger, and a **posterior** smaller, **aqueous chamber** [camera oculi
ıterior], which communicate freely through the pupil.
erves of the eyeball.—The long and short ciliary nerves, after per-
sclera, run forward between it and the choroid to the ciliary region,
ɔrm a plexus, from which proceed branches for the ciliary muscle, the

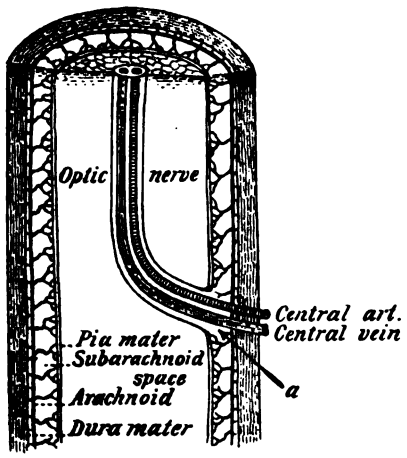
of the iris enter it at its ciliary border, and run toward its pupillary edge, losing
r sheath sooner or later, and supplying especially the sphincter muscle. The
form an annular plexus near the limbus, from which a few twigs proceed to the
unctiva, while most of the offsets enter and run radially in the corneal stroma,
anastomosing so as to form a plexus. The nerves entering the cornea are about
r.

LATIONS OF CENTRAL RETINAL VESSELS TO OPTIC NERVE. *a*. Point where rise
essure in the subarachnoid space affects the central vein of the retina. (Wolff.)



ıseis of the eyeball.—The eyeball receives blood from two sets of the **retinal** and the **ciliary arteries,** as described in the section on ASCULAR SYSTEM. (See figs. 837, 839.)

ia centralis rétinæ either comes direct from the ophthalmic artery, or from one near the apex of the orbit. Entering the optic nerve about fifteen mm. behind is forward in its axis to enter the eye, and then divides into branches which run ers of the retina, and divide dichotomously as they radiate toward the equator. nches lie more deeply in the retina, but none penetrate into the nerve-epithelium, a centralis is non-vascular. *In the retina, the branches of the central artery do not th any other arteries.* Therefore embolism of the central artery causes profund retinal function and even total blindness. But (*a*) minute twigs from it, which the axial part of the nerve, communicate with those running in the septa derived heath. Again, as the nerve passes through the sclera, it is surrounded by a ircular vasculosus n. optici (Halleri)], formed of fine branches derived from the ciliary arteries; fine twigs passing inward from this ring to the optic nerve join ıe pial sheath, and (*b*) an indirect communication is thus brought about between ciliary vessels. Finally, as the nerve passes through the choroid, there is (*c*) a ɔn between these two sets of vessels, the capillary network of the optic nerve tinuous with the choriocapillaris. Not infrequently, a branch from a short ' artery pierces the optic papilla, and then courses over the adjoining retina tery), supplying the latter in part in place of the central artery.
ɛs of the a. centralis retinæ in the retina are: arteriola temporalis retinæ supe-
emporalis retinæ inferior, arteriola nasalis retinæ superior, arteriola nasalis
arteriola macularis superior, arteriola macularis inferior, arteriola retinæ

ntralis retinæ returns the blood of the corresponding artery and has branches o those of the artery.
walled central vein of the retina leaves the optic nerve it crosses the subarach-
so becomes exposed to the effects of any rise of pressure to which the fluid in be subject (fig. 838). Thus in patients suffering from cerebral tumor the rise

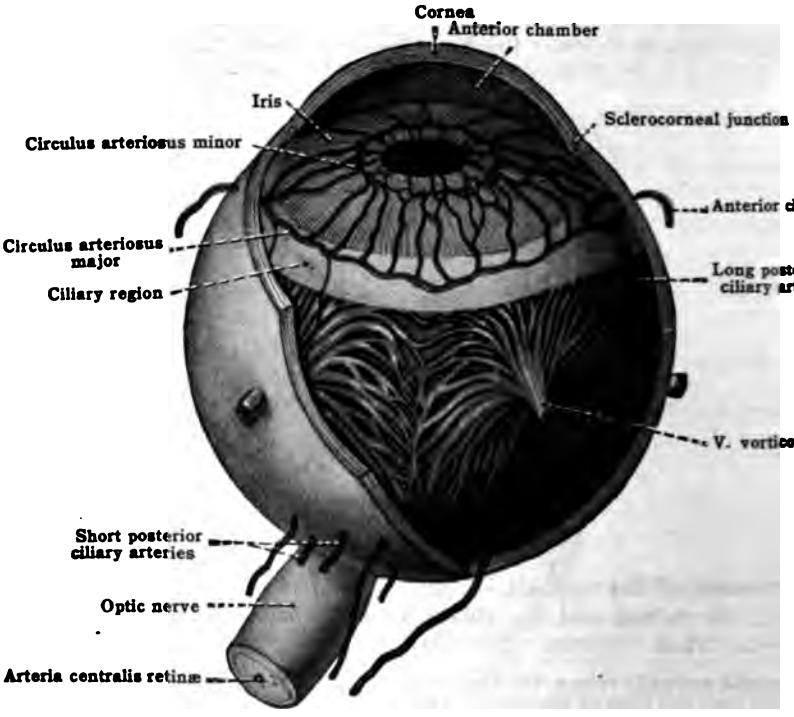
of pressure in the subarachnoid fluid may impede the escape of blood from the retina, producing a condition known as 'choked disk.'

2. **The ciliary system of blood-vessels** (see *Blood-Vascular System*).—There are three sets of arteries belonging to this system, all derived directly or indirectly from the ophthalmic artery.

(1) **Short posterior ciliary arteries** twelve to twenty in number, pierce the sclera around the optic nerve entrance, and are distributed in the choroid. Before entering the eyeball, small twigs are given off to the adjoining sclera and to the dural sheath of the optic nerve.

(2) Two **long posterior ciliary arteries**, medial and lateral, piercing the sclera further from the nerve than the short ciliaries, run horizontally forward between the sclera and choroid, one on each side of the globe. On arriving at the ciliary body, they join with the anterior ciliary arteries, forming the **circulus arteriosus major**, which sends off branches to the ciliary processes and the iris. The long ciliaries also give twigs to the ciliary muscle, and small recurrent branches run backward to anastomose with the short ciliary arteries. The arteries of the iris run radially toward the pupillary border, anastomosing with one another opposite the outer border of the sphincter and forming there the **circulus arteriosus minor.**

FIG. 839.—BLOOD-VESSELS OF THE EYEBALL, LATERAL VIEW.



(3) The **anterior ciliary arteries** come from the arteries of the four recti muscles, one or two from each; they run forward, branching as they go, and finally pierce the sclera near the corneal border. Externally to the globe they send twigs to the adjoining sclera, to the conjunctiva, and to the border of the cornea. After passing through the sclera the arteries enter the ciliary muscle, where they end in twigs to the muscle and to the circulus arteriosus major, and in recurrent branches to the choroid.

Veins.—The venous blood from almost the whole middle coat (choroid ciliary processes and iris, and part of the ciliary muscle) ultimately leaves the eyeball by—(1) the venæ vorticosæ which have been already noticed in describing an anteroposterior section through the globe. One large vein passes backward from each vortex, piercing the sclera obliquely; it is joined by small episcleral veins when outside the globe.

(2) The anterior ciliary veins commence by the junction of a few small veins of the ciliary muscle; they pass outward through the sclera near the corneal border, receiving blood from the veins in connection with the sinus venosus of the sclera, and afterward from episcleral and conjunctival veins, and from the marginal corneal plexus. Finally they join the veins running in the recti muscles.

Lymphatic system of the eyeball.—Apart from those in the conjunctiva there are no lymphatic *vessels* in the eyeball, but the fluid is contained in *spaces* of various sizes. These are usually divided into an anterior and a posterior set. (fig. 841.)

1. Anteriorly, we have the anterior and posterior aqueous chambers (together composing the aqueous chamber of the eye), which communicate freely through the pupil. The aqueous humor is formed in the posterior of these chambers by transudation from the vessels of the ciliary body and posterior surface of the iris (see also page 1095). The stream passes mainly forward through the pupil into

FIG. 840.—DIAGRAM TO ILLUSTRATE THE COURSE OF THE STREAM FROM THE CILIARY BODY TO THE FILTRATION ANGLE. (Based on Arthur Thomson's figures.)

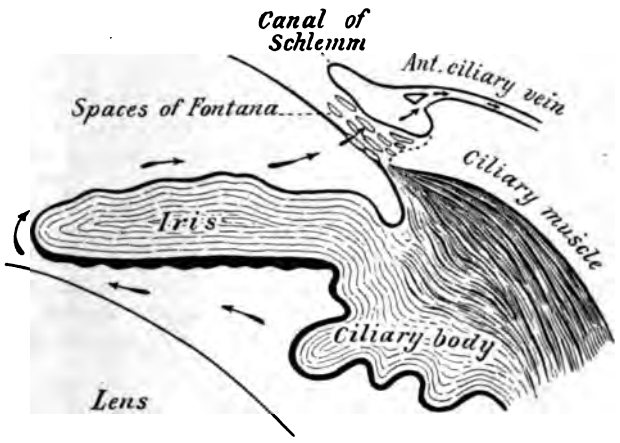


FIG. 841.—LYMPHATIC SPACES OF THE EYEBALL (in green).

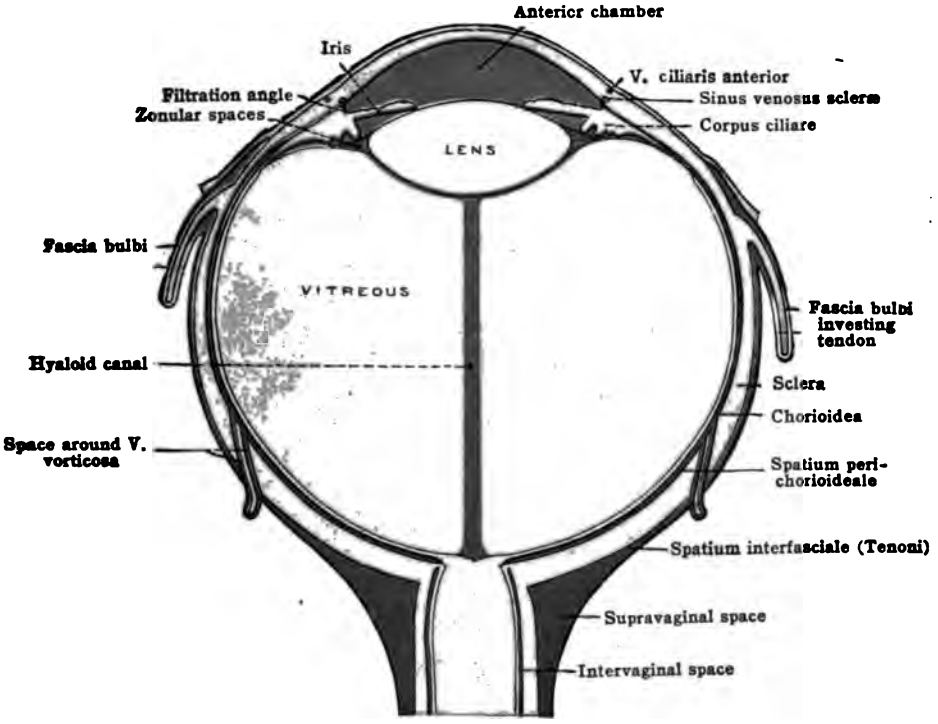

the anterior aqueous chamber, whence it escapes slowly by filtering from the spaces of Fontana into the canal of Schlemm and thence into the anterior ciliary veins. Part of the lymph-stream passes from the posterior aqueous chamber backward into the zonular spaces, out of which fluid can pass in front of the vitreous body to the hyaloid canal.

The space between the iris and the cornea where the fluid in the anterior chamber makes its escape into the spaces of Fontana has been called the **filtration angle.** Any interference with the

normal outflow of fluid in this area will raise the tension of the eyeball, and may produce *glaucoma*. According to Thomson, contraction of the ciliary muscle tends to dilate the spaces of Fontana and the canal of Schlemm (fig. 840), and hence facilitates the flow of fluid into the latter.

In the **cornea** the lymph travels in the spaces already mentioned as existing between the fiber-bundles, and in the nerve-channels and at the periphery of the cornea it flows off into the lymphatic vessels of the conjunctiva.

In the **iris** there is a system of lymphatic spaces opening anteriorly into the crypts of the surface, and communicating peripherally with the spaces of the angle of the iris.

2. **Posteriorly,** we have (*a*) the hyaloid canal, between the posterior pole of the lens and the place of entrance of the optic nerve, and (*b*) the perivascular canals of the retina; the lymph from both of these situations flows into the spaces of the optic nerve, which communicate with the intervaginal spaces of the nerve, and thus with the great intracranial spaces. Further, between choroid and sclera we have (*c*) the perichoroidal space, which gets the lymph from the choroid, and communicates with the interfascial space (of Tenon) outside the sclera by perforations corresponding to the vasa vorticosa and posterior ciliary arteries, and with the intervaginal spaces around the optic nerve entrance. The interfascial space of Tenon, again, is continuous with the supravaginal space around the optic nerve, which communicates both with the intervaginal spaces, with the lymph-spaces of the orbit, and directly with the intracranial spaces at the apex of the orbit.

CAVITY OF THE ORBIT

General Arrangement of its Contents (Figs. 842, 843, 844)

The anterior wider half of the cavity is mainly occupied by the eyeball, which lies almost axially, but is rather nearer to the upper and lateral than it is to the other walls. The posterior two-thirds of the globe are in relation with soft parts, chiefly muscles and fat, and its posterior pole is situated midway between the base (or opening) and the apex of the orbital cavity. The anterior third of the eyeball is naturally free, except for a thin covering of the conjunctiva, and projects slightly beyond the opening of the oribit, the degree of prominence varying with the amount of orbital fat, and also to some extent with the length of the globe. A straight line joining the medial and lateral orbital margins usually cuts the eye behind the cornea—laterally behind the ora serrata, medially further forward, at the junction of the ciliary body and iris. The globe is held in position by numerous bands of connective tissue. The lacrimal gland lies under the lateral part of the roof of the orbit anteriorly. The orbit fat occupies the spaces between the orbital muscles, and is in greatest amount immediately behind the eyeball; it also exists between the muscles and the orbital walls in the anterior half of the cavity. The optic nerve with its sheaths passes from the optic foramen to the back of the eyeball, surrounded by the orbital fat, and more immediately by a loose connective tissue. Among the contents of the cavity are also to be enumerated many vessels and nerves and fibrous tissue septa, while its walls are clothed by periosteum(periorbita).

Six muscles, viz., the four recti, the superior oblique, and the levator palpebræ superioris, arise at the apex of the orbit, and diverge as they pass forward. The recti muscles—superior, inferior, lateral, and medial—run each near the corresponding orbital wall, but the superior is overlapped in part by the levator palpebræ. The superior oblique lies about midway between the superior and medial recti. A seventh muscle, the inferior oblique, has a short course entirely in the anterior part of the orbit, coming from its medial wall and passing below the globe between the termination of the inferior rectus and the orbital floor.

Of the seven muscles of the orbit, six are *ocular, i.e.*, are inserted into the eyeball and rotate it in different directions. These ocular muscles are arranged in opponent pairs, viz., superior and inferior recti, superior and inferior obliques, lateral and medial recti. With the exception of the short inferior oblique, they all arise from the back of the orbit along with the seventh orbital muscle, the levator palpebræ superioris. All these long muscles take their origin from the periosteum in the vicinity of the optic foramen. The four recti muscles arise from a fibrous ring, the annulus tendineus communis, which arches close over the upper and medial edge of the foramen, and extends down and out so as to embrace part of the opening of the superior orbital

Their origins may be said at first to form a short, common, tendinous tube, from which vidual muscles soon separate, taking the positions indicated by their respective names. ral rectus has two origins from bone, one on either side of the superior orbital fissure.

. 842.—Horizontal Section of the Orbital Region, Viewed From Above.

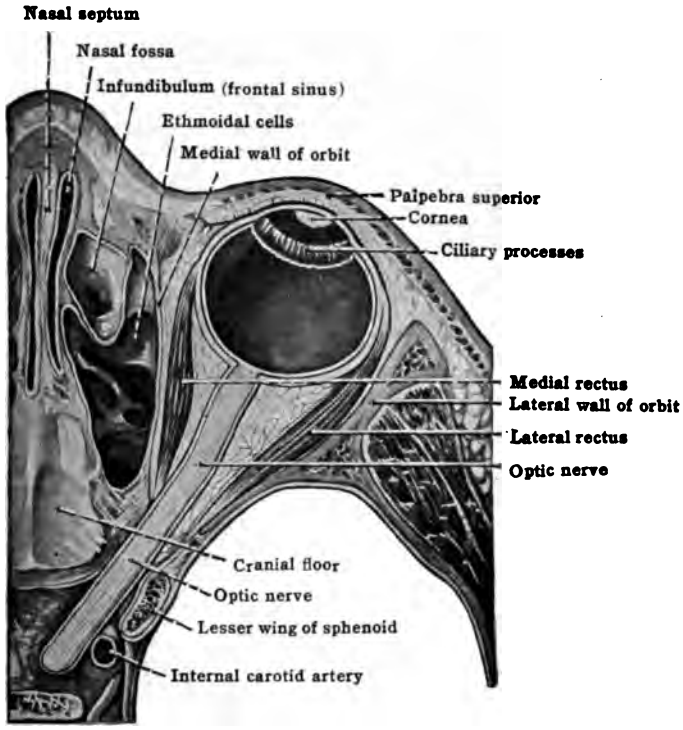

Fig. 843.—Dissection of the Left Orbit from in Front.

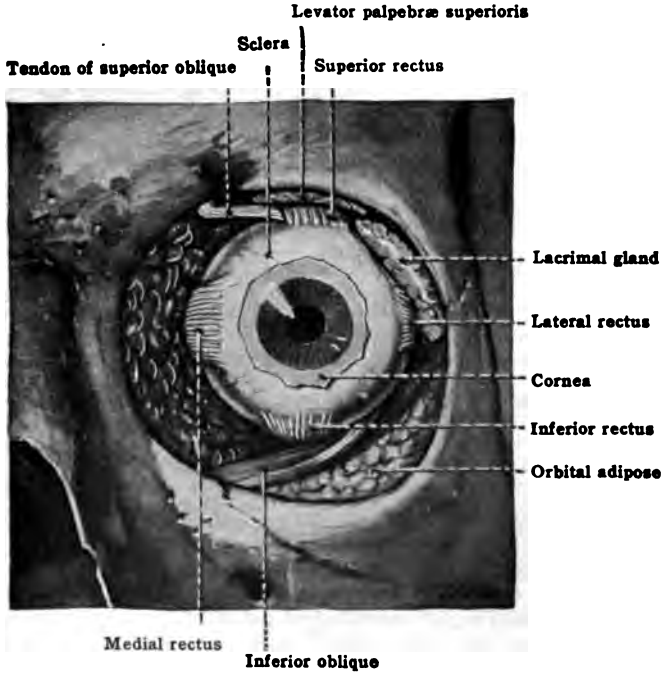
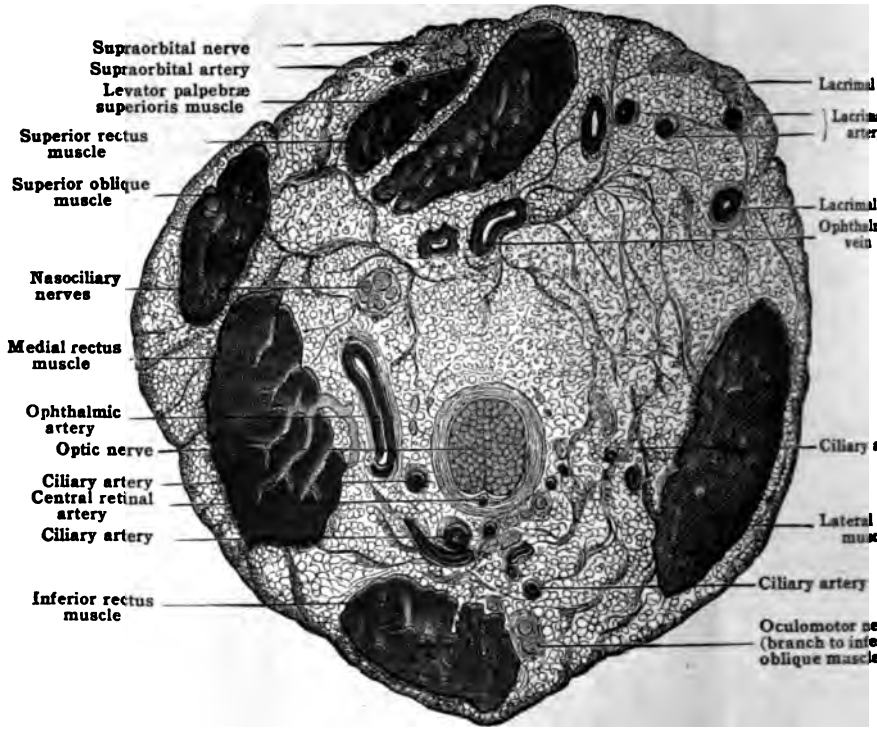


the fresh state the fissure is here bridged across by fibrous tissue, from which this rectus ings, so that its origin is in reality continuous. The part of this fibrous ring nearest men (corresponding to the origins of the superior and medial recti) is closely connected

with the outer sheath of the optic nerve. The remaining two long muscles arise just outside the upper and medial part of the above-mentioned ring, and are often partially united; the levator palpebræ tendon is in close relation to the origin of the superior rectus, while the superior oblique arises from the periostum of the body of the sphenoid bone one or two mm. in front of the origin of the medial rectus.

The four recti muscles (figs. 843, 846) lie rather close to the corresponding orbital walls for the first half of their course, the superior rectus, however, being overlapped in part by the levator palpebræ; they then turn toward the eyeball, running obliquely through the orbital fat, and are finally inserted by broad, thin tendons into the sclera in front of the equator. From their respective positions in the orbit, the axis of this cone of muscles is oblique to the anteroposterior axis of the eyball. The thickest of these muscles is the medial rectus, next the lateral, then the inferior, and the superior rectus is the thinnest. As regards length, the muscular belly of the superior rectus has the longest course, and the others diminish in the order—medial, lateral, and inferior rectus. The lateral rectus is supplied by the abducens nerve. The other three recti muscles are all supplied by the oculomotor nerve.

FIG. 844.—CROSS-SECTION RIGHT ORBIT 8–11 MM. BEHIND THE EYEBALL; VIEWED FROM BEHIND (After Lange.)



The levator palpebræ superioris (figs. 843–846) courses along the roof of the orbit close to the periosteum for the greater part of its course, partially overlapping the superior rectus; it finally descends through the orbital fat, and widens out to be inserted into the root of the upper lid. It may be briefly described as being inserted in two distinct layers separated by a horizontal interval. The upper or anterior layer of insertion is fibrous, and passes in front of the tarsus, where it comes into relation with fibers of the orbicularis. The lower layer consists of smooth muscle (Müller's superior tarsal muscle), and is inserted along the upper border of the tarsus. The levator has also connections with the sheath of the superior rectus. These different insertions of the muscle will be referred to later along with the description of the orbital fasciæ and of the upper eyelid. It gets its nerve supply from the oculomotor nerve, but the smooth muscle developed in its lower layer of insertion is supplied by the sympathetic nervous system. As its name expresses, its *action* is to raise the upper lid and to support it while the eye is open.

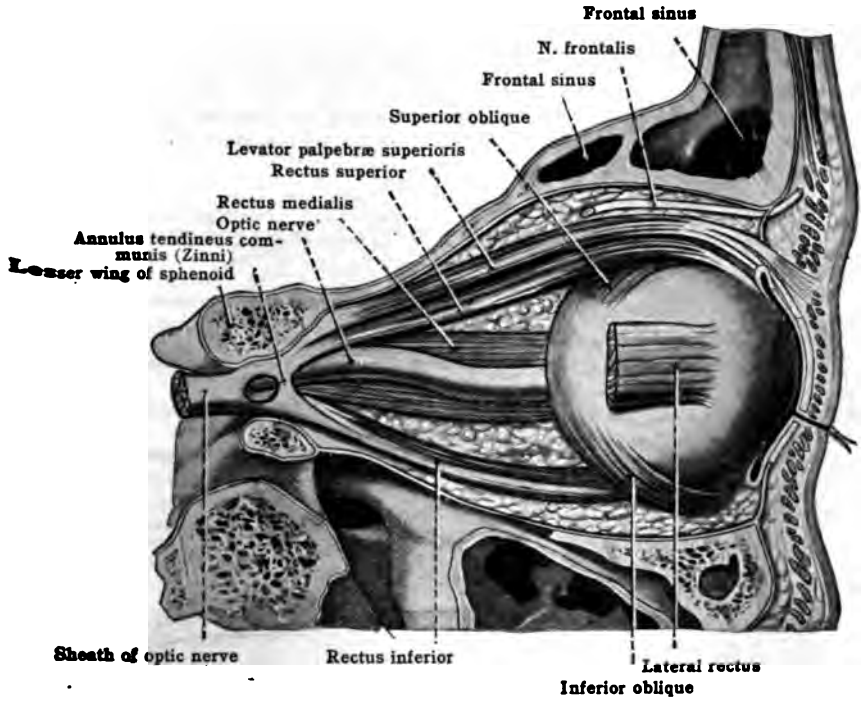
The superior oblique (figs. 843, 846) runs forward close to the medial part of the orbital roof until it reaches the fovea trochlearis near the medial angular process, where it becomes tendinous and passes through a fibro-cartilaginous pulley attached to the fovea just named. On passing through this pulley, or trochlea, the tendon bends at an angle of 50°, running posteriorly and laterally under the superior rectus to its insertion into the sclera. It is supplied by the trochlear nerve.

The inferior oblique (figs. 843, 845) arises from the front of the orbit, about the junction of its medial and inferior walls, just lateral to the lower end of the lacrimal groove. It runs, in a sloping direction, laterally and posteriorly, lying at first between the inferior rectus and the orbital floor, then between the lateral rectus and the globe; finally it ascends slightly, to be inserted by a short tendon into the sclera at the back of the eye. Its nervous supply is derived from the oculo-

[illegible]tor nerve, a long branch of which extends forward on the floor of the orbit alongside the [illegible]ral border of the inferior rectus (fig. 844) and enters the inferior oblique muscle on its lower [illegible]face. The precise manner of insertion of the different ocular muscles has been described above [illegible]. 1091). For muscles of the eyelids and eyebrows, see pp. 370 and 1111.

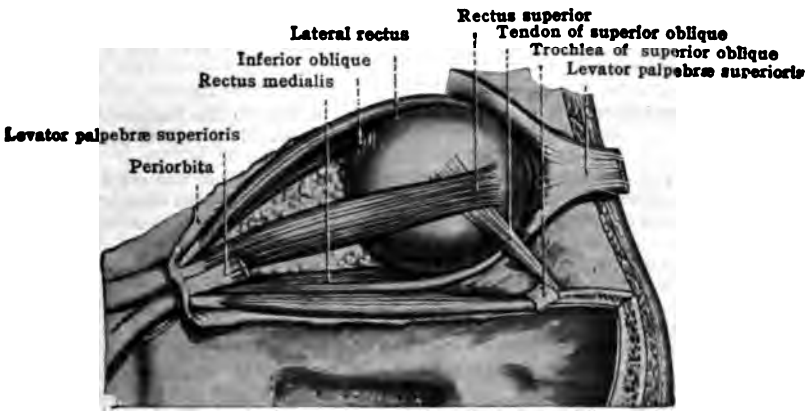
Action of the ocular muscles.—Tenon's capsule forms a socket in which the eyeball is said to [illegible]work when the muscles move the eye so as to turn the cornea in different directions. The

FIG. 845.—DISSECTION OF THE MUSCLES OF THE RIGHT ORBIT, LATERAL VIEW.



position of this socket (and of the contained eyeball) in the orbit is not subject to alteration: it is merely the direction and not the situation of the eye that changes when the muscles act. The movements that take place can be described in reference to three principal axes passing through the center of the roughly spherical eyeball. These axes are (1) vertical, (2) frontal horizontal (transverse or equatorial) and (3) anteroposterior or sagittal horizontal. The

FIG. 846.—DISSECTION OF THE MUSCLES OF THE LEFT ORBIT, FROM ABOVE.



movements that occur may be analyzed into upward and downward (around the frontal horizontal axis), medial and lateral (around the vertical axis), and rotation (i. e. wheel rotation around the anteroposterior axis). Taking twelve o'clock in a dial as the moving point rotation may be described as medial (nasalward) or lateral (temporalward).

Confusion is often introduced into the description of eye movements by using the term 'rotation' for any movement of the globe. It is important clearly to distinguish between movements of the eye in a definite radial direction and those in which the cornea is rotated clockwise.

The only two muscles that move the eyeball merely on one axis are the lateral rectus and the **medial rectus**; their names, lateral and medial, describe the effects in the cornea. The action of the superior and inferior recti is complicated by the obliquity of the axes of muscle and globe previously mentioned.

The chief action of the **superior rectus** is to make the eye look upward and somewhat medially.

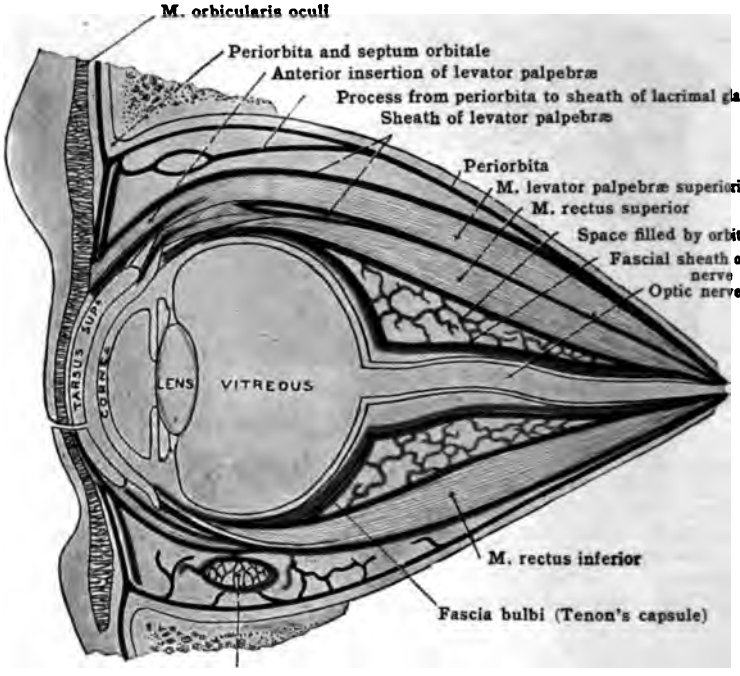
The **inferior rectus** makes the eye look downward with a slight inclination medially.

The chief action of the **superior oblique** is to move the eye as as to make it look downward and laterally, at the same time rotating it medially.

The **inferior oblique** mainly turns the eye so as to make it look upward and laterally, at the same time rotating it laterally.

The fasciæ of the orbit [fasciæ orbitales].—The orbital contents are bound together and supported by fibrous tissues, which are connected with one another, but which may conveniently be regarded as belonging to three systems. These are:—(1) Those lining the bony walls; (2) the tissue which partially encapsules the eyeball; and (3) those ensheathing the muscles.

FIG. 847.—DIAGRAM REPRESENTING THE ORBITAL FASCIÆ IN VERTICAL SECTION. Periorbita *black;* muscular sheaths *violet;* Interfascial (Tenon's) space *green.*



1. The **orbital periosteum** [periorbita], is closely applied to the bones forming the walls of the cavity, but may be stripped off with comparative ease. It presents openings for the passage of vessels and nerves entering and leaving the orbit.

Posteriorly this tissue is very firm, being joined by processes of the dura mater at the optic foramen and superior orbital fissure; at the optic foramen it is also connected with the dural sheath of the optic nerve. As it covers the inferior orbital (sphenomaxillary) fissure its fibers are interwoven with smooth muscle, forming the **orbital muscle of Müller.** From its inner surface processes run into the orbital cavity, separating the fat lobules. One important process comes from the periorbita about midway along the roof of the orbit, runs forward to the back of the upper division of the lacrimal gland, and there becomes continuous with the fibrous tissue forming the gland-capsule; this capsule is joined at its medial border by other periorbital bands coming off near the upper orbital rim, and forming the suspensory ligament of the gland. On the side of the orbit the periorbita sends fibrous processes to the trochlea of the superior oblique, which keep it in position. On arriving at the lacrimal groove the periorbita divides into two layers, a thin posterior one continuing to line the bone forming the floor of the groove, whilst the thicker anterior layer bridges over the groove and the sac which lies in it, forming the limbs of the medial palpebral ligament (pp. 1087, 1113).

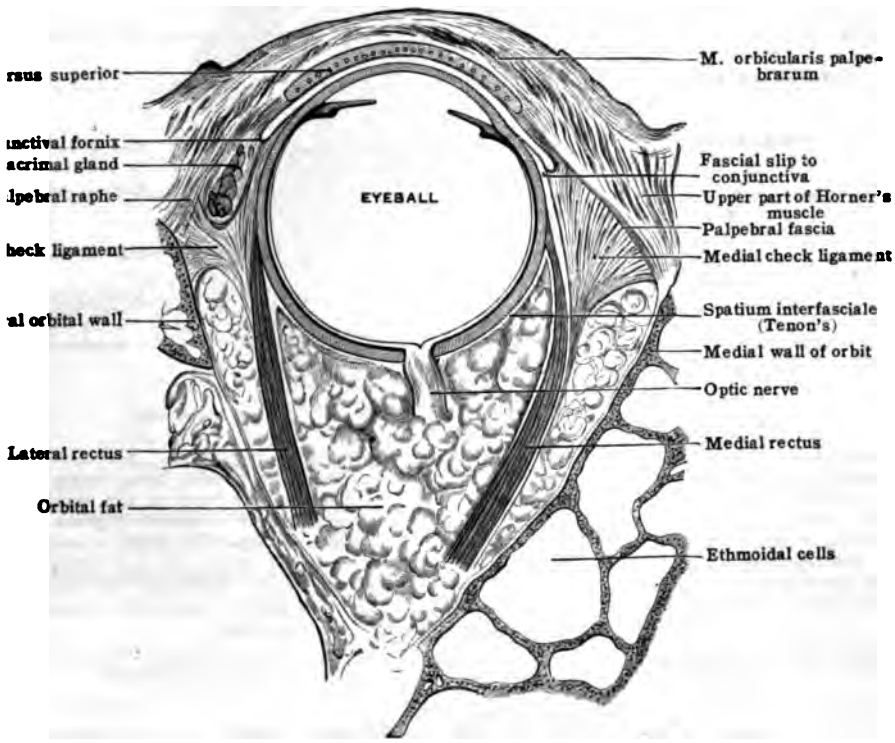
Quite anteriorly, at the rim of the orbit, the periorbita sends off a membranous process which aids in forming the fibrous tissue of the eyelids (**orbitotarsal ligament, or palpebral fascia**), and is itself continuous with the periosteum of the bones outside the orbital margin.

2. The hollow in the front of the orbital fatty tissue is lined by a layer of fibrous tissue known as the **fascia bulbi** or **capsule of Tenon** (figs. 835, 847), which covers the posterior

arths of the eyeball and becomes continuous with the sheath of the optic nerve. The rface of the fascia is smooth and is connected with the sclera only by a loose, wide- areolar tissue. This interval between the sclera and fascia, known as the **interfascial s) space** (figs. 835, 841, 847, 848), is a lymph-space, which permits free movements yeball within the capsule. The space of Tenon extends as far forward as the conjunctiva e corneal margin, the fascia bulbi being attached to the conjunctiva anterior to the n of the recti muscles into the sclera. Posteriorly, however, it approaches the optic forming the supravaginal space, and communicates with the subdural (intervaginal) space around the nerve which in turn opens into the corresponding intracranial lymph- Around the place where the posterior ciliary vessels and nerves perforate the sclera ce of Tenon is obliterated.

he tendons of the recti perforate the fascia bulbi to reach the sclera and the fascia s thickened to form a ring by means of which the muscles are prevented from compress,

FIG. 848.—HORIZONTAL SECTION THROUGH LEFT ORBIT, VIEWED FROM ABOVE. (After von Gerlach.)



so distorting the eyeball when they contract. These rings of thickened fascia are ious with the sheaths of the muscles. Bands of fibrous tissue connect the fascia of the r rectus to the tendon of the levator palpebræ superioris, and that of the inferior passes to the inferior border of the tarsal plate of the lower eyelid (fig. 847). From eaths of the medial and lateral recti respectively strong bands of connective tissue, the **medial** and **lateral check ligaments** (figs. 835, 845) pass to the walls of the orbit rmer to thecrest of the lacrimal bone and the latter to the orbital surface of the atic bone. A thickening of the lower part of the fascia bulbi, attached medially and later- he lacrimal and zygomatic bone respectively, forms the **suspensory ligament.** (Lockwood.)

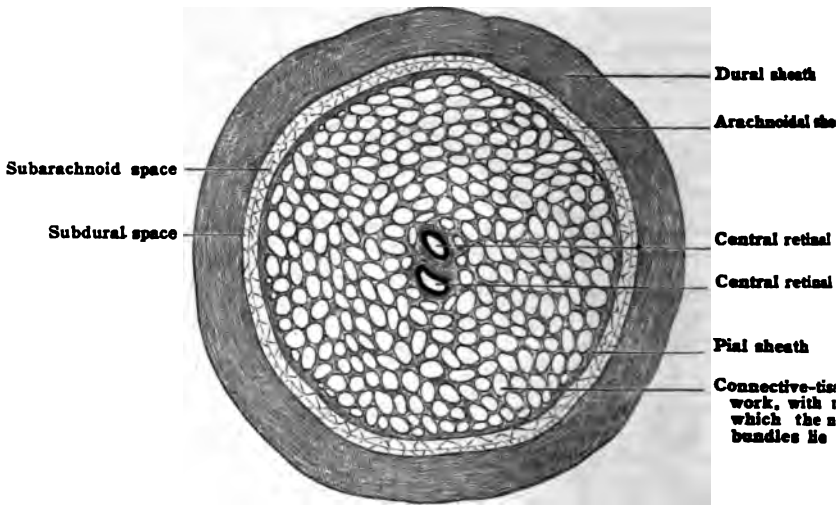
THE OPTIC NERVE

e part of this nerve with which we have here to do lies within the orbit, ex- g from the eyeball to the optic foramen (figs. 841, 845, 849, 850). The of this portion of the nerve is from 20 to 30 mm. and its diameter about . Its course is somewhat S-shaped.

leaving the globe 3 or 4 mm. to the medial side of its posterior pole, the optic nerve directly backward: then it becomes slightly curved, with the convexity of the curve l medially, and finally it undergoes a more pronounced deflection with its convexity ard and laterally before it leaves the orbit by the optic foramen. As the nerve passes, r fibrous sheath blends with the periorbita, and the composite structure becomes con- with the dura mater. In the orbit the outer or **dural sheath** loosely surrounds the erve, which through the optic foramen is closely enveloped by a vascular covering

derived from the pia mater, named accordingly the **pial sheath.** The space between th two sheaths is subdivided by a fine prolongation of the arachnoid (the **arachnoidal tha** into two parts, termed the intervaginal spaces [spatia intervaginalia], viz., an outer, nam *subdural*, and an inner, wider, *subarachnoid space*, communicating with the correspon intracranial spaces and also with the supravaginal (interfascial) spaces of the orbit. The ar noidal sheath is connected with the sheath on each side of it by numerous fine processes w bridge across the intervening spaces. The pial sheath sends processes inward, which fo framework separating the bundles of nerve-fibers; between the enclosed nerve-fibers and

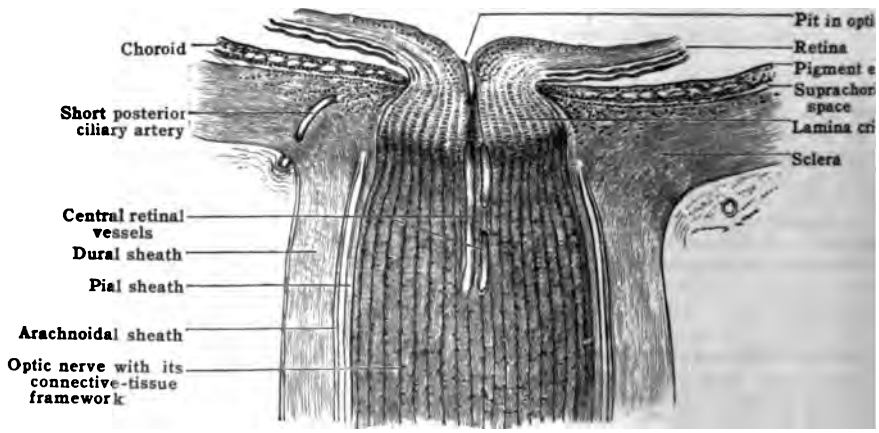
FIG. 849.—TRANSVERSE SECTION THROUGH OPTIC NERVE, SHOWING THE RELATIONS OF SHEATHS AND CONNECTIVE TISSUE FRAMEWORK.



mesh of this framework there is a narrow interval occupied by lymph. The nerve-f medullated, but have no primitive sheath. About fifteen or twenty mm. behind t the central vessels enter, piercing obliquely the lower lateral quadrant of the nerve, run forward in its axis. They are accompanied throughout by a special process of sheath, which forms a fibrous cord in the center of the nerve (figs. 838, 849).

On reaching the eyeball, the dural sheath is joined by the arachnoid, and turns av the nerve to be continued into the outer two-thirds of the sclera. Similarly the pial sh here leaves the nerve, its greater part running into the inner third of the sclera, while a

FIG. 850.—LONGITUDINAL SECTION THROUGH RETINAL END OF OPTIC NERVE.



fibers join the choroid; the intervaginal spaces consequently end abruptly in the sclera the nerve-entrance. In this locality the connective tissue framework of the nerve thicker and closer in its meshwork, and has been already alluded to as the lamina scleræ. It is formed by processes passing out from the central fibrous cord at its ter and by processes passing inward from the pial sheath, sclera, and chorioid. It does straight across the nerve, but follows the curve of the surrounding sclera, being therefor convex backward. The nerve-trunk here quickly becomes reduced to one-half its form eter, the fibers losing their medullary sheaths. Apart from the consequent loss of t

stological change may be readily recognized macroscopically in a longitudinal section of the erve (fig. 850), its aspect here changing from opaque white to semi-translucent gray. The art of the nerve within the lamina cribrosa has already been noted in the ophthalmoscopic xamination of the living eye (p. 1090).

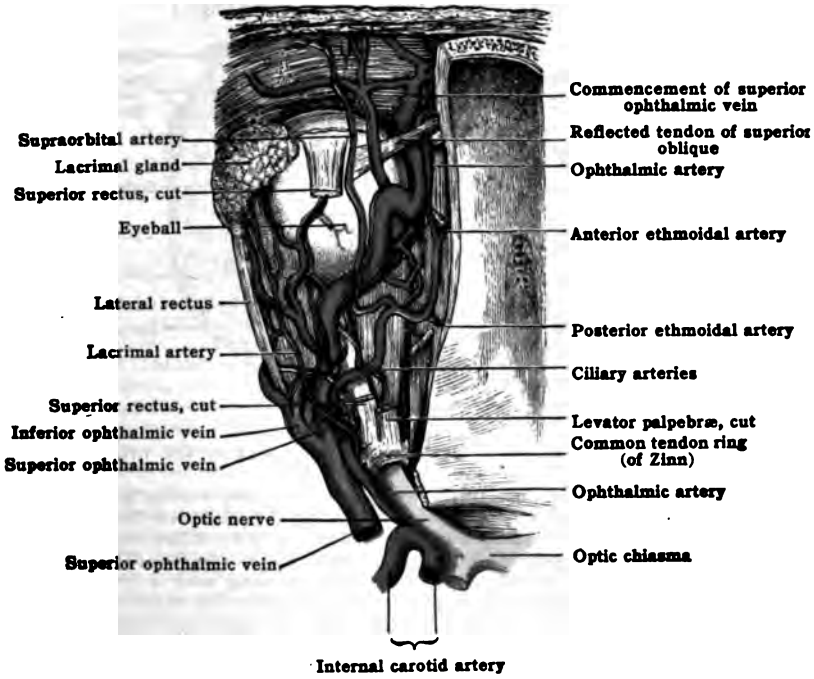
The optic nerve is mainly nourished by fine vessels derived from those of the pial sheath, hich run into the substance of the nerve in the processes above mentioned. In front of the ntrance of the central retinal artery this vessel aids to some extent in the blood-supply of the xial part of the nerve.

The Blood-vessels and Nerves of the Orbit

As these structures will be more particularly described in other sections of this work, a very short general account will suffice here.

Arteries.—The main blood-supply is afforded by the **ophthalmic artery,** a branch of the internal carotid, which gains the orbit through the optic foramen, where it lies below and lateral to the nerve. On entering the orbit it ascends and passes obliquely over the optic nerve to the medial wall of the orbit; in this early part of its course it gives off most of its branches, which

Fig. 851.—The Blood-vessels of the Left Orbit, viewed from above.



vary much in their manner of origin and also in their course. The arteries of the orbit are remarkable for their tortuous course, for their delicate walls, and for their loose attachment to the surrounding tissues. The ophthalmic artery gives off special branches in the orbit to the lacrimal gland, the muscles, the retina (through the optic nerve), and the eyeball, as well as to the meninges the ethmoidal cells, and the nasal mucous membrane. Twigs from all the different branches go to supply the fat, fasciæ, and ordinary nerves of the orbit. Branches which leave the orbit anteriorly ramify on the forehead and nose, and also go to the supply of the eyelids and the tear-passages The ophthalmic artery has many anastomoses with branches of the external carotid. The contents of the orbit are also supplied in part by the **infraorbital artery,** a branch of the internal maxillary; in particular this artery supplies part of the inferior rectus and inferior oblique muscles in the cavity, and also gives a branch to the lower eyelid.

Veins.—Branches, corresponding generally to those of the artery, unite to form the **superior and inferior ophthalmic veins,** which ultimately, either separately or united into one trunk, pass through the superior orbital fissure and empty into the cavernous sinus. The inferior vein is connected with the pterygoid plexus by a branch which leaves the orbit by the inferior orbital fissure.

Nerves of the orbit.—These are (A) **motor,** (B) **sensory,** and (C) **sympathetic,** and all enter the orbit by the superior orbital fissure, with the exception of one small sensory branch passing through the inferior orbital fissure. (The optic nerve has been already described, and is not included in this account.)

A. The **motor nerves** are the oculomotor, trochlear, and abducens.

1. The **oculomotor nerve** enters the orbit in two parts, an upper smaller, and a lower larger, division. The ***upper division*** [ramus superior] gives off two branches: one supplies the superior

rectus, entering its lower surface far back; the other branch goes to the levator palpebræ, entering its lower surface in its posterior third. The *lower division* [ramus inferior] divides into three branches, of which one supplies the inferior rectus, entering its upper surface far back, and another supplies the medial rectus, entering its medial surface a little behind its middle. The third branch of the lower division gives (1) the short root to the ciliary ganglion, and (2) one or more twigs to the inferior rectus, and the remainder of this branch then enters the lower surface of the inferior oblique muscle about its middle.

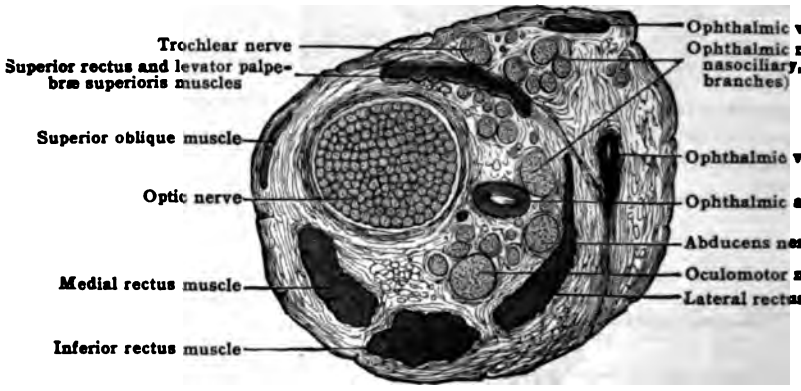
2. The **trochlear nerve** supplies the superior oblique muscle, entering its upper surface about midway in its course.

3. The **abducens nerve** supplies the lateral rectus, entering its medial surface about the junction of the posterior and middle thirds of the muscle.

As regards the manner of termination of these motor nerves, it is found that in all the ocular muscles the nerve on its entrance breaks up into numerous bundles of fibers, which form fine coarse and then fine plexuses, the latter ultimately sending off fine twigs supplying the muscle throughout with nerve-endings. The *posterior third* of these muscles is, however, comparatively poorly supplied with both kinds of plexuses and with nerve-endings.

B. The **sensory nerves** are supplied by the ophthalmic and maxillary divisions of the trigeminal cranial nerve. The ophthalmic division is chiefly orbital; while the maxillary sends only a small branch to the orbit.

FIG. 852.—CROSS-SECTION THROUGH RIGHT ORBIT 1–2 MM., IN FRONT OF THE OPTIC FORAMEN VIEWED FROM BEHIND. (After Lange.)



1. The **ophthalmic division** of the trigeminal nerve enters the orbit in three divisions, namely:—

(1) **Frontal**, splitting subsequently into *supratrochlear* and *supraorbital*, both passing out of the orbit. It is distributed to the corresponding upper eyelid, and the skin over the root of the nose, the forehead, and the hairy scalp as far back as the coronal suture on the same side. It also gives branches to the periosteum in this region, and to the frontal sinus.

(2) **Lacrimal**, supplying the lacrimal gland, anastomosing with a branch of the maxillary in the orbit, and finally piercing the upper eyelid. Outside the orbit it is distributed to the lateral part of the upper lid, the conjunctiva at the lateral angle, and the skin between this and the temporal region.

(3) **Nasociliary** giving off—(*a*) a branch to the ciliary ganglion, constituting its long root; (*b*) two or three *long ciliary nerves;* and (*c*) the *infratrochlear*, passing out of the orbit. The nerve then leaves the orbit as the anterior ethmoidal nerve, reentering the cranial cavity before being finally distributed to the nose. The infratrochlear branch [n. infratrochlearis], supplies the eyelids and skin of the side of the nose near the medial angle of the eye, the lacrimal sac, caruncle, and plica semilunaris. The anterior ethmoidal nerve, after its course in the cranial cavity, passes through an aperture in the front of the lamina cribrosa of the ethmoid bone, and is ultimately distributed to the nasal mucous membrane, and to the skin of the side and ridge of the nose near its tip.

2. The **maxillary division of the fifth nerve** gives a branch, called the **zygomatic nerve**, which passes into the orbit through the inferior orbital fissure, anastomoses with the lacrimal, and leaves the orbit in two divisions. These are distributed to the skin of the temple and of the prominent part of the cheek.

A few minute twigs from the sphenopalatine ganglion, and sometimes from the maxillary division of the fifth nerve, also pass through the inferior orbital fissure to supply the periorbita in this neighborhood.

C. The **sympathetic nerves of the orbit** are mainly derived from the plexus on the internal carotid artery. With the exception of branches accompanying the ophthalmic artery, and of the distinct sympathetic root of the ciliary ganglion, they enter the orbit in the substance of the other nerve-cords. The connections between the ocular nerves and the carotid plexus are recognizable as fibers going to the oculomotor, abducens, and ophthalmic nerves; as a rule, the comparatively large twigs going to the abducens join it furthest back, and those to the oculomotor furthest forward. Sympathetic connections with the trochlear nerve are very doubtful. The special courses of the motor fibers to the dilatator pupillæ muscle have already been described.

The **ciliary ganglion** is situated between the optic nerve and lateral rectus far back in the orbit. Its three roots—motor, sensory, and sympathetic—have been already mentioned Anteriorly, it gives off three to six small trunks, which subdivide to form the **short ciliary nerve.** nn. ciliares breves] about twenty in number, piercing the sclera around the optic nerve entrances.

The lymphatic system of the orbit.—Although there are no lymphatic *vessels* or *glands* in the orbit, the passage of lymph is nevertheless well provided for. We have already observed the lymph-channels within, between, and outside the sheaths of the optic nerve, and have seen how these communicate anteriorly with the lymph-channels of the eyeball, and posteriorly with the intracranial meningeal spaces.

The circulation of fluid in the anterior and posterior chambers was noted on p. 1101. In addition, there are lymph-spaces around the blood-vessels, situated between the outer coat and the loose investment furnished by the muscle-fascia. The nerves of the orbit (apart from the optic) are probably similarly surrounded by lymph-spaces. In the absence of lymphatic vessels it is difficult to trace the circulation thoroughly; much of the lymph from the orbital cavity is said to pass into the parotid nodes.

The Eyelids

The cutaneous and conjunctival surfaces of the eyelids [palpebræ] have already been examined (p. 1089), and the position of the tarsus has been indicated. We have now to ascertain the nature and relations of the tarsus, and describe the other tissues entering into the formation of the eyelids (fig. 853).

The skin here is thin, bearing fine hairs, and having small sebaceous and numerous small sweat-glands. Immediately beneath it is a loose subcutaneous tissue, destitute of fat, separating the skin from the palpebral part of the **orbicularis muscle.**

The lid-fibers of this muscle arise from the medial palpebral ligament, and course over the whole upper and lower eyelids in a succession of arches, so as to meet again beyond the lateral angle; there they in part join one another, in part are inserted into the lateral palpebral raphe. The muscular fibers are arranged in loose bundles, with spaces between them occupied by connective tissue; in the upper lid these connective tissue fibers may be traced upward and backward into the fibrous expansion of the tendon of the levator palpebræ superioris. One strong bundle of orbicularis fibers, called the **musculus ciliaris Riolani,** is found near the edge of the lid, in front of and behind the efferent ducts of the tarsal glands (fig. 853).

A connective tissue layer separates the orbicularis muscle from the tarsus in the tarsal division of the lids. In the upper lid this is to be regarded as mainly the anterior or fibrous expansion of the tendon of the levator palpebræ, which sends connective tissue septa between the bundles of the overlying orbicularis (as just mentioned) going to the skin. In the orbital part of this lid the central connective tissue includes also the palpebral fascia, lying here immediately beneath the orbicularis muscle; but this soon thins off and fades into the more deeply placed levator expansion. This latter is strengthened by an extension of the sheath of the superior rectus, by which this muscle is enabled to influence the elevation of the lid indirectly. In the lower lid the central connective tissue similarly consists of palpebral fascia, blended with a thin fibrous extension of the sheath of the inferior rectus. Immediately in front of each tarsus is a little loose connective tissue, which contains the large blood-vessels and nerves of the lids.

The **tarsus** of each lid is a stiff plate of dense fibrous connective tissue, with its surfaces directed anteriorly and posteriorly; in its substance the tarsal glands are embedded. One tarsal border is free, viz., toward the edge of the lid, the other is attached; the former is straight, while the latter is convex, especially in the upper lid.

The length of each tarsus is about 20 mm. Its breadth is greatest in the middle of the lid and becomes gradually smaller toward each angle, where the tarsi are joined to the lateral raphe and medial palpebral ligament. The breadth of the upper tarsus (10 mm.) is about twice that of the lower. The thickness of each is greatest, and its texture closest, at the middle of its length, thinning off toward the angles of the eye and toward both borders. Into the superior anterior border of the upper tarsus the lower layer of the levator expansion is attached, consisting of smooth muscle-fibers constituting the **superior tarsal muscle** of Müller. In like manner, at the inferior border of the lower tarsus, bundles of smooth muscle are inserted (the **inferior tarsal muscle** of Müller), developed in what has been regarded as part of the extension of the sheath of the inferior rectus.

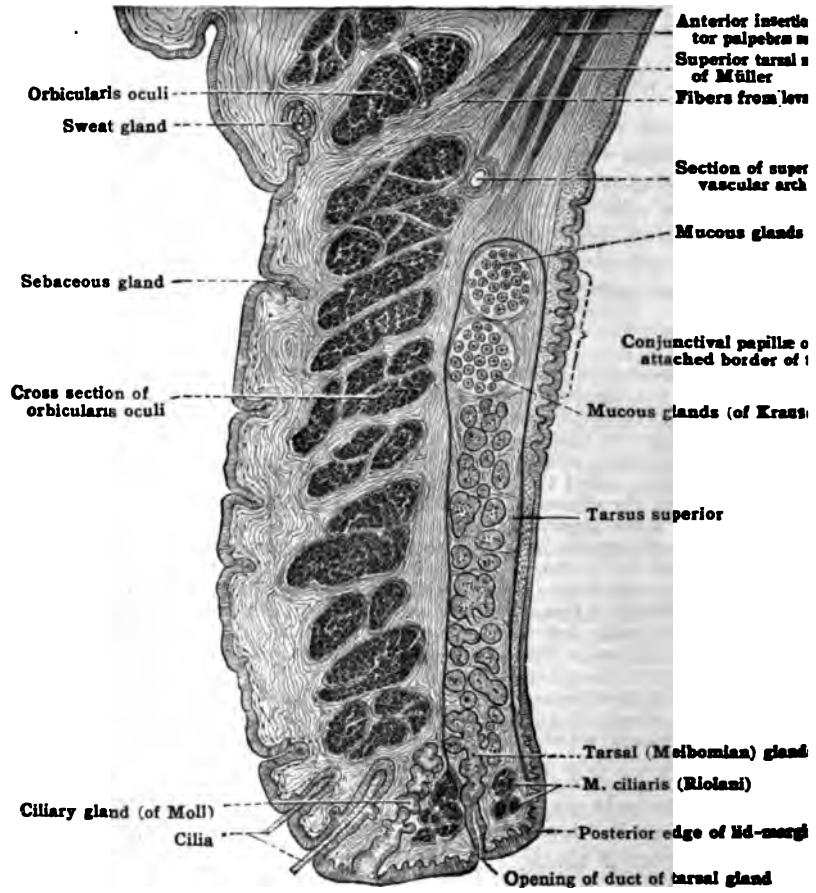
The **palpebral conjunctiva** is firmly adherent to the posterior aspect of the tarsus; but in the orbital part of the lid loose subconjunctival tissue intervenes between it and Müller's tarsal muscle.

Lymphoid tissue occurs in the substance of the conjunctiva, especially in its orbital division. Near the upper fornix, the conjunctiva receives expansions the tendon of the levator palpebræ and of the sheath of the superior rectus, and, at the lower fornix, of the sheath of the inferior

rectus. The surface of the tarsal conjunctiva shows small elevations or papillæ ever but these are particularly well marked over the attached border of the tarsus.

Glands of the eyelids.—From its manner of formation the eyelid m regarded as consisting of two layers of skin, the posterior having been d back upon the anterior at the edge of the lid; thus the epidermis and c of the skin proper are represented respectively by the conjunctival epit and tarsus of the inner layer. At the free border of the lid, accordingly, t glands corresponding to the sebaceous and sweat-glands of the skin, viz. sebaceous glands of the cilia (Zeiss's glands) and the ciliary glands of Moll, are modified sweat-glands. Again, in the inner skin-layer of the lid, the (Meibomian) glands are sebaceous.

FIG. 853.—SAGITTAL SECTION OF THE UPPER EYELID. (After Waldeyer and Fuchs.) surrounded by a red line.



Acinotubular mucous glands occur at the attached border of the tarsus (Krause' deyer's glands), and similar glands also occur at the fornix, and are especially abun the lateral angle of the upper lid, close to the efferent ducts of the lacrimal gland; t structure and the character of their secretion, these acinous or acinotubular glands termed by Henle 'accessory lacrimal glands.' Other simple tubular glands (Henl merely by the depressions between the papillæ, are best developed in the medial a fourths of the tarsal conjunctiva of both lids.

Blood-vessels.—The arteries run in the central connective tissue of the lids, the form of arches near the borders of the tarsus, from which twigs go to the diff pebral tissues. They are supplied by the lacrimal and palpebral branches of the op and by small branches derived from the temporal artery. The veins are more num larger than the arteries, and form a close plexus beneath each fornix. They empty t into the veins of the face at the medial, and into the orbital veins at the lateral angle

The lymphatic vessels of the lids are numerous, and are principally situated in junctiva. Lymph-spaces also surround the follicles of the tarsal glands. The lymphatic vessels from the lateral three-fourths of the lid pass through the anterior and parotid nodes; those from the medial fourth of the lower lid go to the facial and lary lymphatic nodes.

s.—(*a*) **Sensory.** The upper lid is chiefly supplied by branches of the supraorbital ıtrochlear nerves, the lower lid by one or two branches of the infraorbital. At the ıgle the infratrochlear nerve also aids in the supply, and, at the lateral angle, the (*b*) **Motor.** The palpebral part of the orbicularis is supplied by branches of the ve, which mainly enter it near the lateral angle. The tarsal muscles are supplied mpathetic nervous system.

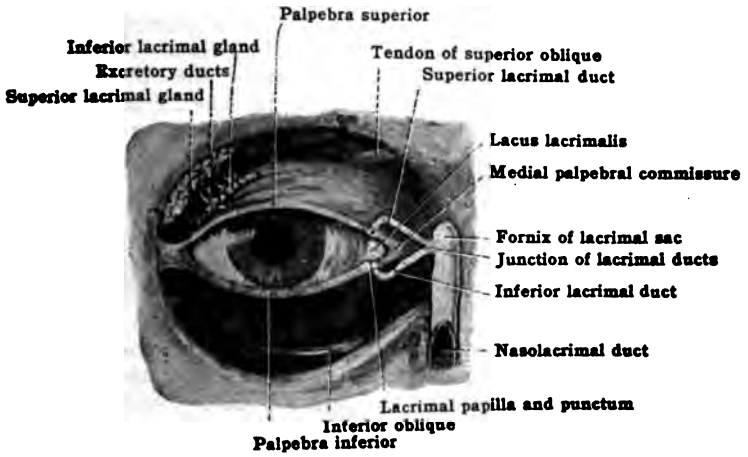
medial palpebral ligament has been referred to previously (p. 1106). from the frontal process of the maxilla, it extends laterally over the front he lacrimal sac, bends round the lateral wall of the sac, and then passes d to the posterior crest on the lacrimal bone.

hus U-shaped, having its limbs anterior and posterior, embracing the lacrimal sac; or limb lies immediately beneath the skin, and is visible in the living. The palpebral he orbicularis are inserted into the anterior surface of both limbs, those attached to rior limb constituting the pars lacrimalis of the orbicularis palpebrarum (Horner's The **lateral palpebral raphe** is merely a stronger development of connective tissue in ılaris. Both ligaments are connected with the tarsi as already mentioned.

THE LACRIMAL APPARATUS

tears are secreted by an acinous gland, and flow through fine ducts to the teral part of the conjunctival sac, whence they pass over the cornea and ıed off through the puncta, pass along the canaliculi into the lacrimal sac, mately down the nasolacrimal duct to the inferior meatus of the nose.

—DISSECTION OF THE EYE TO SHOW THE LACRIMAL APPARATUS, ANTERIOR VIEW.



lacrimal gland is situated near the front of the lateral part of the roof of ;, lying in a depression in the orbital plate of the frontal bone. It consists ery unequal parts, one placed above and the other beneath the tendinous ın of the levator palpebræ superioris, but small gaps in the expansion per- onnections between these two parts of the gland. The upper and larger ion (*superior lacrimal gland*) is a firm elongated body, about the size of almond; it has a grayish-red color, and is made up of closely aggregated The upper surface (next the orbital roof) is convex, and its lower surface y concave.

orly, the gland almost reaches the upper orbital margin, and it extends backward ximately one-fourth the depth of the orbit, measuring about 12 mm. in this direction. al border of the gland descends to near the insertion of the fascial expansion of the tus, while its medial border almost reaches the lateral edge of the superior rectus; its measurement is about 20 mm. It is enveloped in a capsule, which is slung by strong ınds passing to its medial border from the orbital margin (suspensory ligament of the

lower subdivision of the gland (*inferior lacrimal gland*) is composed of ıpplied lobules, and lies immediately over the lateral third of the upper ival fornix, reaching lateralward as far as the lateral angle.

ı subdivision of the gland possesses several **excretory ducts,** which all open lateral part of the upper fornix conjunctivæ, about 4 mm. above the ırder of the tarsus.

Those of the superior gland, three or four in number, pass between the lobules of the lower gland; the most lateral duct is the largest, and opens at the level of the lateral angle of the eye. The ducts of the inferior gland in part discharge themselves into those of the upper, but there are also several fine ducts from this subdivision that run an independent course.

Near the medial angle are the two **puncta lacrimalia**, upper and lower, each situated at the summit of its papilla. The top of each papilla curves backward toward the conjunctival sac, so that the puncta are well adapted for their function of draining off any fluid collecting there.

The **ductus lacrimales** (canaliculi) extend from the puncta to the lacrimal sac. The lumen at the punctum is horizontally oval, its lips being slightly compressed anteroposteriorly; the lumen of the lower punctum is somewhat larger than that of the upper. As the lower papilla is a little further from the medial angle of the eye than the upper, the corresponding duct is longer.

On tracing either ductus from its origin, we find that at first it runs nearly vertically for a short distance, then bends sharply toward the nose, and finally courses more or less horizontally, converging slightly toward its fellow, and not infrequently joining it before opening into the sac. The caliber varies considerably in this course, being narrowest a short distance from the punctum, and widest at the bend, from which point it again narrows very gradually as it nears the sac.

The wall of the ductus consists mainly of elastic and white fibrous tissue, lined internally by epithelium, and covered externally by striated muscle (part of the orbicularis). The muscle-fibers run parallel with the ductus in the horizontal part of its course; but they are placed, some in front and some behind, around the vertical part, acting here as a kind of sphincter. Just before their termination, the ducts pierce the periosteal thickening that constitutes the posterior limb of the medial palpebral ligament.

The **lacrimal sac** [saccus lacrimalis] lies in a depression (the lacrimal fossa) in the anterior part of the medial wall of the orbit. The sac is vertically elongated, and narrows at its upper and lower ends; the upper extremity or *fundus* is closed, while the lower is continuous with the nasolacrimal duct. Laterally, the sac is somewhat compressed, so that its anteroposterior is greater than its transverse diameter. The ducts, either separately or by a short common tube, open into a bulging on the lateral surface of the sac near the fundus.

As has previously been mentioned, the sac is surrounded by periosteum, but between this and the mucous membrane forming the true sac-wall there is a loose connective tissue, so that the cavity is capable of considerable distention. The relations of the medial palpebral ligament have already been described; it is to be noted that the fundus of the sac extends above this ligament.

The **nasolacrimal duct** [ductus nasolacrimalis] reaches from the lower end of the sac to the top of the inferior meatus of the nose, opening into the latter just beneath the adherent border of the inferior nasal concha. Traced from above, its main direction is downward, but it has also a slight inclination backward and laterally. It lies in a bony canal, whose periosteum forms its outer covering. Between this and the mucous membrane of the duct there is a little intermediate tissue, in which run veins of considerable size connected with the plexus of the inferior concha. The duct does not usually open directly into the nasal cavity at the lower end of the bony canal, but pierces the nasal mucous membrane very obliquely, so that a *flap* [plica lacrimalis (Hasneri)] of mucous membrane covers the lower border of the opening in the bone, upon which flap the tears first trickle after escaping from the duct proper.

The sac and nasolacrimal duct together constitute the **lacrimal canal**, lined throughout by a continuous mucous membrane. This membrane presents *folds* in some situations, especially near the opening of the ducts above, at the junction of the sac and duct, and at the lower end of the duct. That at the junction of sac and duct is the most important, as it sometimes interferes with the proper flow of tears out of the sac. The total length of the lacrimal canal is roughly 24 mm., half of this being sac, and half nasolacrimal duct. If, however, we reckon as duct the oblique passage through the nasal mucous membrane, this measurement may occasionally be increased by 8 or 10 mm. The lacrimal sac, when distended, measures about 6 mm. from before backward, by 4 mm. transversely. The nasolacrimal duct is practically cylindrical, and has a diameter of about 3 mm., rather less at its junction with the sac, where we find the narrowest part of the whole lacrimal canal.

Development of the Eye

The eye is developed partly from the ectoderm and partly from mesoderm—the retina from a portion of the ectodermal wall of the forebrain on each side; the lens from the superficial ectoderm which surrounds the other structures, and the sclera, cornea (except epithelium) and choroidal coat from the mesoderm.

The process of development is, briefly, as follows (fig. 855): An outgrowth occurs from the ventrolateral aspect on each side of the forebrain, in the form of a hollow vesicle, the *primary optic vesicle* [vesicula ophthalmica]. The lateral surface of the vesicle comes into contact with the surface ectoderm of the head and this epithelium becomes thickened at the area of contact. The superficial portion of the vesicle expands, while its connection with the brain remains slender; becoming depressed on the surface, it forms a cup-shaped hollow, the *secondary optic vesicle* or *optic cup* [caliculus ophthalmicus] the wall of which is formed by two layers, an outer investing layer and an inner inverted one.

The *choroidal fissure* is present almost from the first stages as a cleft on the ventral aspect of both the distal portion of the vesicle, or cup, and of the stalk; it is formed by a longitudinal infolding of the wall of the vesicle. In this cleft is found vascular mesoderm passing to the interior of the hollow of the optic cup. The margins of the cleft meet and fuse, and enclose the vessels to

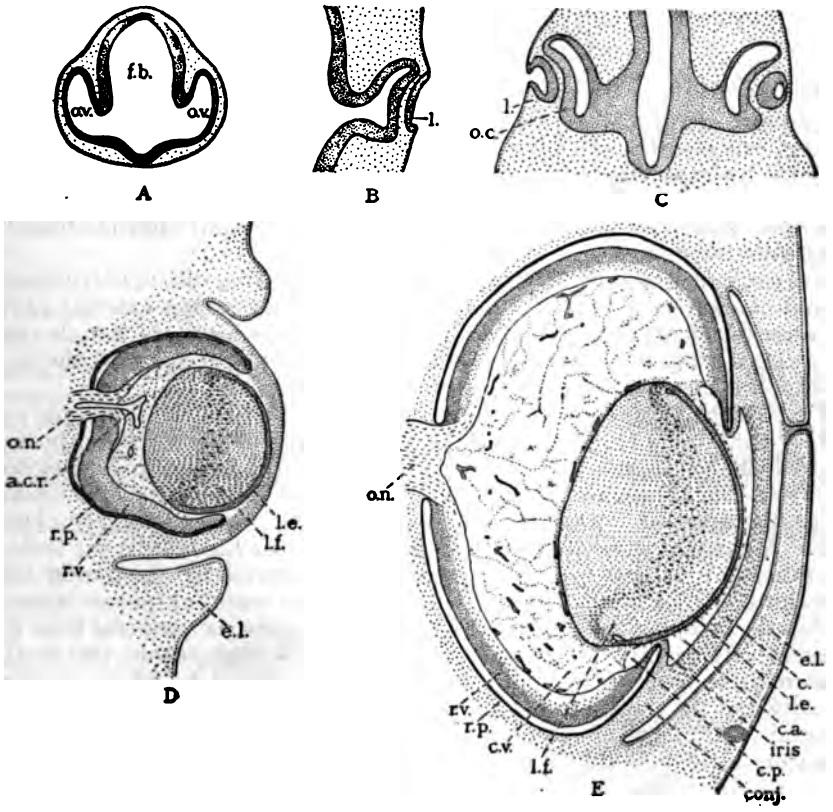
a.c.r., arteria centralis retinæ; c., cornea; c.a., anterior chamber; conj., conjunctiva; c.p. posterior chamber; c. v., corpus vitreum; e. i., eyelid; f. b., forebrain; l., lens; l. c., lens epithelium; l.f., lens fibers; o.c., optic cup; o.v., optic vesicle; r.p., pigmented layer of the retina; r.v., retinal layer of the retina.



the interior—hence the enclosure of the a. centralis retinæ within the optic nerve, and of the hyaloid artery in the interior of the vitreous. Should the margins of the cleft remain separate, the condition known as *coloboma* results.

From the optic cup is formed the whole of the retinal or nervous tunic. This tunic is composed of two layers, with a narrow slit-like interval between them, but the layers are continuous with each other at the margin of the cup. This margin is afterward found, in the fully developed eye, at the pupillary edge of the iris. The outer investing layer forms the pigment layer, and the inner inverted layer gives rise to the other parts of the retina, viz., the pars optica, over the bottom of the cup, the pars ciliaris, in the ciliary region, and the pars iridica, near the margin of the original cup.

The *lens* is formed as a hollow invagination from the surface ectoderm, opposite to the hollow of the optic cup. The margins meet and fuse, enclosing a cavity, and the lens-mass, sinking in more deeply, loses its connection with the surface, and a layer of mesoderm passes in between. At first the lens and the primitive retina are in contact with each other. They gradually draw apart, and the intervening space is filled by the *vitreous body*. The origin of the vitreous is uncertain, but it appears to be developed from the adjacent ectoderm of the optic cup, and in part from the surrounding mesoderm.

The optic cup and the lens are surrounded by mesoderm and from it are formed the structures of the tunica vasculosa in its different parts, viz., choroid, ciliary body and iris, and also the sclera and cornea (excepting the epithelium).

The anterior and posterior chambers are formed by cleavage of the mesoderm, spaces appearing which become filled with fluid. The mesoderm also forms a vascular covering for the [illegible] of the lens, termed the *capsula vasculosa lentis* (pupillary membrane), which disappears from the surface of the lens in the later months of development.

The *eyelids* and *conjunctiva* are formed from the integumentary covering of the eye. The former are mostly skin-folds, which, at first separate, meet and fuse with one another along their margin. Subsequently they become undermined by the ingrowth of epithelium from a central horizontal slit, the rima palpebrarum; the central part of the invading epithelium breaks down, and the free folds are formed.

The *lacrimal gland* is developed from a series of tubular outgrowths from the conjunctival sac.

The lacrimal ducts, sac and nasolacrimal duct are formed by the growth of an ectodermal band which extends into the mesoderm along the nasolacrimal groove. This band loses its primitive connection with the groove, and is reunited to the lid margins by secondary epithelial buds which grow from the primitive band to the lid margin. Similarly a secondary connection is later made with the nasal cavity at the lower end of the duct. The position of the nasolacrimal duct corresponds to the line of union of the nasal and maxillary processes; but the duct does not represent a portion of the cleft between these processes, and is formed secondarily between them.

THE EAR

Under the name of the **ear** [organon auditus] is included not only the structures fashioned to respond to such waves of the air as excite in us a consciousness of hearing, but also the semicircular ducts and their connections, which are the instruments for enabling the effects of gravity and the movements of the head or body as a whole so to influence the functions of the nervous system as to regulate posture and maintain equilibrium, both consciously and unconsciously, i. e., automatically.

The organ consists of three main parts, each possessing distinct structural and functional characters. The first portion, often known as the *external* ear, consists of a receptive organ placed upon the surface of the head, the auricle (pinna), and of a short tube, the external auditory meatus, which leads into the interior and is closed at its deep end by the tympanic membrane.

The second portion, known as the *middle* ear, consists of the tympanic cavity, a small air-containing chamber in the petrous portion of the temporal bone, connected with the nasal part of the pharynx by a tube, the auditory (or Eustachian) tube. From the tympanic chamber a recess passes posteriorly and leads to a cavity in the mastoid portion of the temporal bone, the mastoid or tympanic antrum. A chain of three small bones transmits across the middle ear the effects of the vibrations of the tympanic membrane produced by the sound waves.

The third part, or *internal* ear, which contains the essential sensory apparatus, lies within the complex cavities in the interior of the petrous temporal bone known as the osseous labyrinth. It consists of (1) the utricle and saccule, two small vesicular structures lying in the bony vestibule, and (2) the membranous semicircular ducts and (3) the membranous cochlea, which lie within the corresponding bony canals. Of these the semicircular ducts are concerned with the static or equilibratory sense and the cochlea with hearing.

These structures are filled with fluid, the endolymph, and communicate with one another. They are largely separated from the bony walls by fluid, perilymph, and they are lined by sensory epithelium. Closely related to the epithelial sensory cells are found the terminal branches of the cochlear and vestibular nerves. The to-and-fro movement of the stapes is converted into a wave movement of the endolymph which stimulates the nerve endings.

The description of the three divisions of the ear is taken up in order from the surface inward.

1. THE EXTERNAL EAR

The **external ear** consists of the auricle attached to the side of the head, and the external auditory meatus leading from it to the middle ear (fig. 858).

THE AURICLE

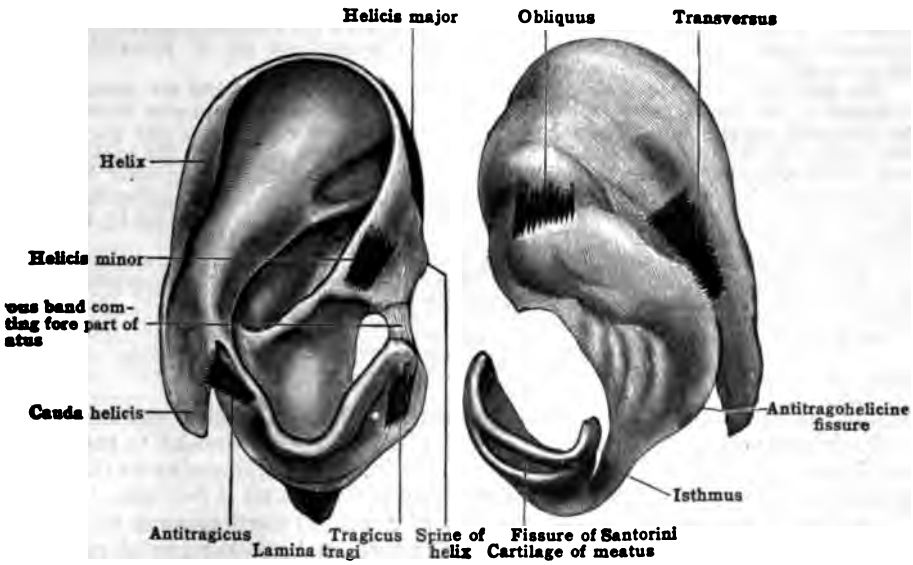
The **auricle** [auricula], or pinna, is an irregular oval plate-like structure which lies upon the lateral surface of the head. It presents a lateral and a medial surface. The lateral surface is irregularly concave (fig. 856). The deepest part of its concavity, situated near the center, is termed the **concha**, and it is partially divided by a prominent oblique ridge, the **crus of the helix**, into a superior part.

ymba conchæ, and a large inferior part, the **cavum conchæ.** The cavum hæ leads into the external auditory meatus, and is bounded anteriorly by a inent process, the **tragus,** which projects posteriorly over the entrance to the us. The tragus is separated from the crus of the helix by a well-marked ession, the **anterior incisure,** and has a small tubercle on it superiorly, the

FIG. 856.—LATERAL SURFACE OF THE LEFT AURICLE.

atragic tubercle. Bounding the cavum conchæ posteriorly and inferiorly is a ction, the **antitragus,** lying opposite, but inferior, to the tragus, and between wo is a deep notch, the **intertragic notch** [incisura intertragica]. A prominent circular ridge, the **anthelix,** bounds the concha posteriorly and supe- y. Inferiorly it is separated from the antitragus by a slight depression,

857.—LATERAL AND MEDIAL SURFACES OF THE CARTILAGE OF THE RIGHT AURICLE AND ITS MUSCLES, ETC.



posterior auricular sulcus. Superiorly the anthelix divides into two ridges, **crura of the anthelix,** and between these is a shallow depression, the **triangular a.** The superior and dorsal margin of the auricle is inverted and forms a ninent rim, the **helix,** which is continued anteriorly into the crus of the helix,

and inferiorly into the **lobule.** An elongated depression, partly overlapped by the helix, termed the **scapha** (scaphoid fossa), separates the helix and the anthelix. Superiorly and posteriorly the free margin of the helix frequently presents a slight projection, the **auricular tubercle** (tubercle of Darwin).

Upon the medial surface of the auricle the depressions of the lateral surface are represented by elevations, viz., the **eminence of the concha,** the **eminence of the scapha,** and the eminence **of the triangular fossa,** respectively; and the elevations by depressed areas, viz., the fossa of the **anthelix, transverse sulcus of the anthelix,** and the **sulcus of the crus of the helix.** The attachment of approximately one-third of the medial surface covers up the two latter depressions. The **cephaloauricular angle,** between the posterior free part of the auricle and the side of the head, averages 20 to 30 degrees.

Structure of the Auricle

The features of the auricle just described are mainly produced by a plate of yellow elastic cartilage, the **auricular cartilage.** In addition to the elevations and depressions already noted, it presents the following additional features. Projecting anteriorly from the helix near the crus is a small tubercle, **spine of the helix** (fig. 857); while the posterior margin of the helix terminates in a pointed tail-like process, the **cauda helicis,** which is separated inferiorly from the antitragus by the deep **antitragohelicine fissure.** Another deep fissure, the **terminal notch** [incisura terminalis auris], separates the cartilage of the auricle from that of the meatus, leaving only a narrow strip, the **isthmus,** connecting the two. The cartilage of the tragus, the **lamina tragi,** is separated from that of the auricle and is attached to the lateral margin of the cartilage of the meatus.

The auricle is covered on both its medial and lateral aspects by skin which closely follows the irregularities of the cartilage. Thus it is tightly bound to the perichondrium of the lateral surface by the subcutaneous areolar tissue, but much more loosely attached to the medial surface, and in the subcutaneous tissue there is little fat except in the lobule, which is made up almost entirely of fat and tough fibrous tissue. **Hairs** are abundant but rudimentary, except in the region of the tragus and antitragus, where they may be large and long, particularly in males and in the aged. **Sebaceous glands** are found on both surfaces, and are especially well developed in the concha and triangular fossa, but **sudoriferous glands** are few and scattered.

Ligaments and muscles.—The auricle is attached to the side of the head by the skin, by the continuity of its cartilage with that of the acoustic meatus, and by certain extrinsic ligaments and muscles. Three ligaments may be distinguished in the connective tissue: **The anterior ligament,** stretching from the zygoma to the helix and tragus; the **superior ligament,** from the superior margin of the bony external acoustic meatus to the spine of the helix; and the **posterior ligament,** from the mastoid process to the eminence of the concha. There are also three extrinsic muscles, the anterior, superior, and posterior auricular (see fig. 372). Six intrinsic muscles are distinguished. These are poorly marked in man and vary much in development. Upon the lateral surface (fig. 857) the **helicis major** stretches from the spine of the helix to the ventral superior margin of the helix; the **helicis minor** overlies the crus helicis: the **tragicus** runs vertically upon the tragus; and the **antitragicus** stretches from the antitragus to the cauda helicis. Upon the medial surface (fig. 857) the **transversus auriculæ** stretches between the eminences of concha and scapha, and the **obliquus** between the eminences of the concha and the triangular fossa. Two small muscles occasionally present are the m. **pyramidalis auriculæ** (Jungi) and the m. incisuræ helicis (Santorini).

The **arteries** are the auricular branch of the posterior auricular and the anterior auricular branches of the superficial temporal arteries. The **veins** are the anterior auricular vein of the posterior facial (temporal) and the auricular branches of the posterior auricular veins. The latter vessels sometimes join the transverse (lateral) sinus through the mastoid emissary vein. The **lymphatics** empty into the anterior, posterior and inferior auricular lymph-nodes. The sensory **nerves** of the auricle are the branches of the great auricular, small occipital (p. 1010, fig. 784), and auriculotemporal (p. 974, fig. 770). The muscles are supplied by the posterior auricular branch of the facial (p. 977, fig. 770).

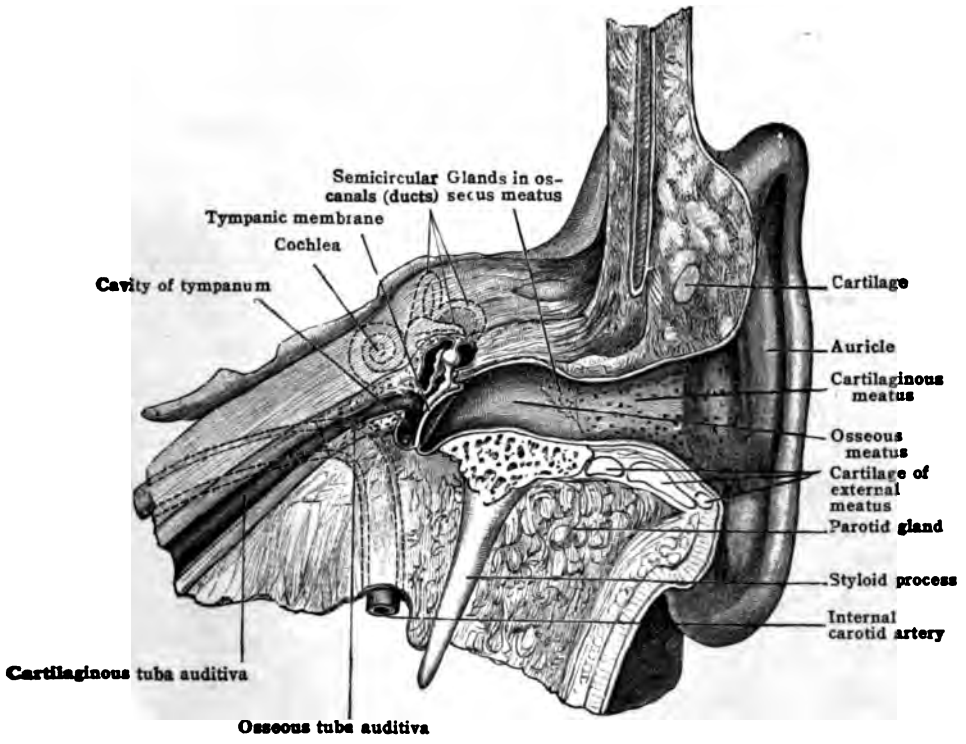
Variations.—There are many variations in the size, shape, and conformation of the auricle and in the cephaloauricular angle. These are associated not only with differences in sex, age, and race, but are also found in individuals of the same family.

THE EXTERNAL ACOUSTIC MEATUS

The **external acoustic (auditory) meatus** [meatus acusticus externus] extends medially and somewhat anteriorly and inferiorly from the concha to the tympanic membrane (fig. 858). It is about 25 mm. (1 in.) long, and, owing to the obliquity of the tympanic membrane, its anterior and inferior wall is 5–6 mm. longer than the posterior and superior. It consists of a lateral **cartilaginous** and a medial **osseous portion.** The canal is slightly curved in both horizontal and vertical directions. Near the auricular end it is convex anteriorly and inferiorly, while at the tympanic end the curve is reversed, and is concave in the same direction. The lumen is irregularly elliptical in outline, the longer axis being vertical at the auricular, but nearly horizontal at its tympanic end. The meatus is constricted at about its center, and also near the tympanum.

Relations.—The *anterior wall* is in relation with the condyle of the mandible medially, and the parotid gland laterally; the *inferior wall* is closely bound to the parotid gland; and *posterior wall* of the bony part is separated by only a thin plate of bone from the mastoid The *superior wall* is separated at its medial end by a thin plate of bone from the epipanic recess, and laterally a thicker layer of bone separates it from the cranial cavity. **Structure of the meatus.**—The walls of the meatus are formed laterally of fibrocartilage medially of bone, lined internally by skin. The cartilage is folded upon itself to form a ove, deficient in its dorsal part, where the edges of the cartilage are united by dense connective tissue. The cartilaginous groove is thus converted into a canal. Medially, the cartilage about one-third of the circumference; laterally, two-thirds. Two fissures (*incisures of torini*) usually occur in its anterior wall (fig. 857). Laterally the cartilage is directly tinuous with the cartilage of the auricle and medially it is firmly connected with the lateral

FIG. 858.—VERTICAL SECTION OF THE MIDDLE AND EXTERNAL EAR.



lip of the osseous portion. The osseous portion, which forms slightly more than half the canal, is formed by the tympanic portion of the temporal bone; it is described in connection with that bone.

The skin of the meatus forms a continuous covering for the canal and tympanic membrane. It is thick in the cartilaginous, but very thin in the bony, part of the meatus, especially near the tympanic end, where it is tightly bound to the periosteum. In the cartilaginous meatus it contains numerous fine hairs and sebaceous glands, but neither hairs nor sebaceous glands are found in the bony meatus. Tubular ceruminous glands, which secrete the cerumen (ear wax), form a nearly continuous layer throughout the cartilaginous, but occur on only a small part of the posterior and superior wall of the bony, meatus. The openings of their ducts appear as dark points to the naked eye (fig. 858).

The arteries are branches from the posterior auricular, superficial temporal, and deep auricular arteries (q. v.). The veins and lymphatics connect with those of the auricle and empty similarly. The nerves are branches from the auriculotemporal and the auricular ramus of the vagus.

2. THE MIDDLE EAR

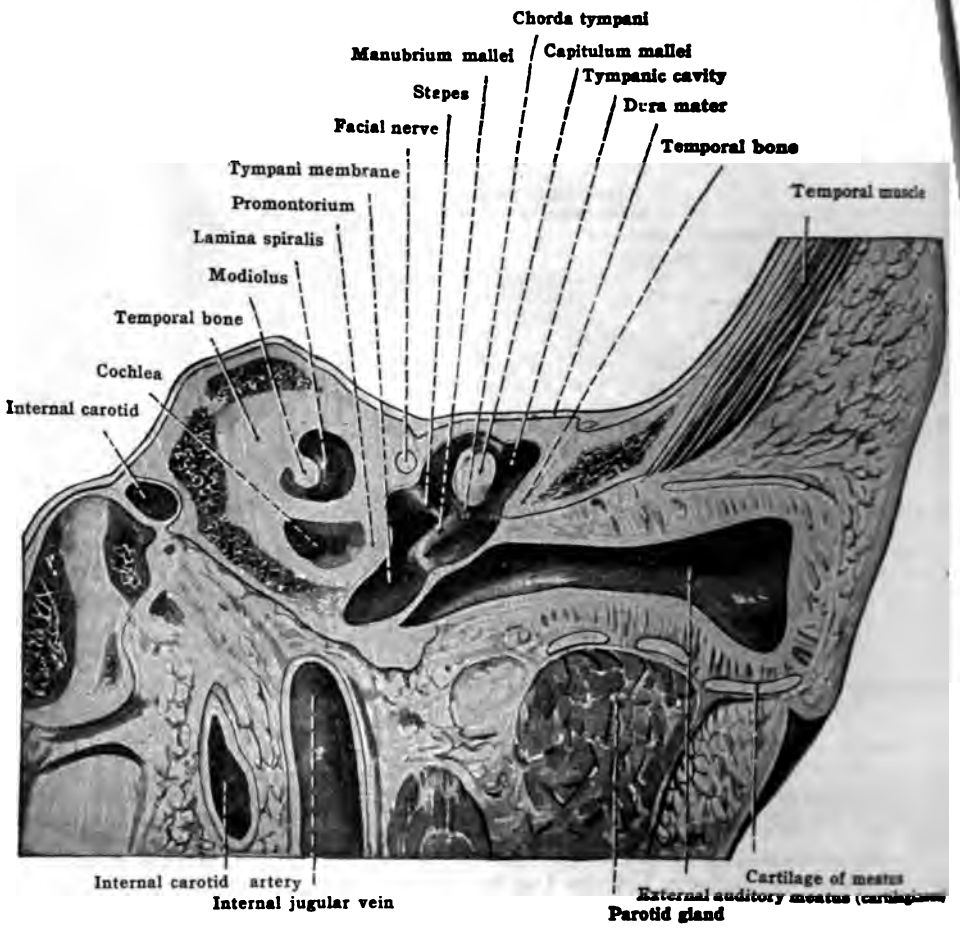
Under the term middle ear there are included the tympanic cavity (tympanum), the tympanic antrum and the auditory (Eustachian) tube. These form a continuous irregular passage, filled with air, and located, for the most part, within the temporal bone. The tympanum is shut off from the external ear by the tympanic membrane; and from the chamber which forms the internal ear by the structures which fill in the cochlear and vestibular fenestræ. It commu-

nicates with the pharynx by the auditory (Eustachian) tube. The structures of the middle ear are of importance, and the study is somewhat difficult, on account of the small size of the structures, the depth at which they lie, and the hard character of the surrounding bone.

The illustrations (figs. 858–860, 862, 863) will help to explain the text and should be constantly referred to. Figs. 859 and 860 are taken from sections traversing the right ear in the coronal planes; while figs. 862, 863 represent dissections.

The parts to be considered in order are the tympanic membrane, the tympanic cavity, the tympanic antrum and the auditory (Eustachian) tube.

FIG. 859.—CORONAL SECTION OF THE RIGHT EAR. (Somewhat enlarged.)



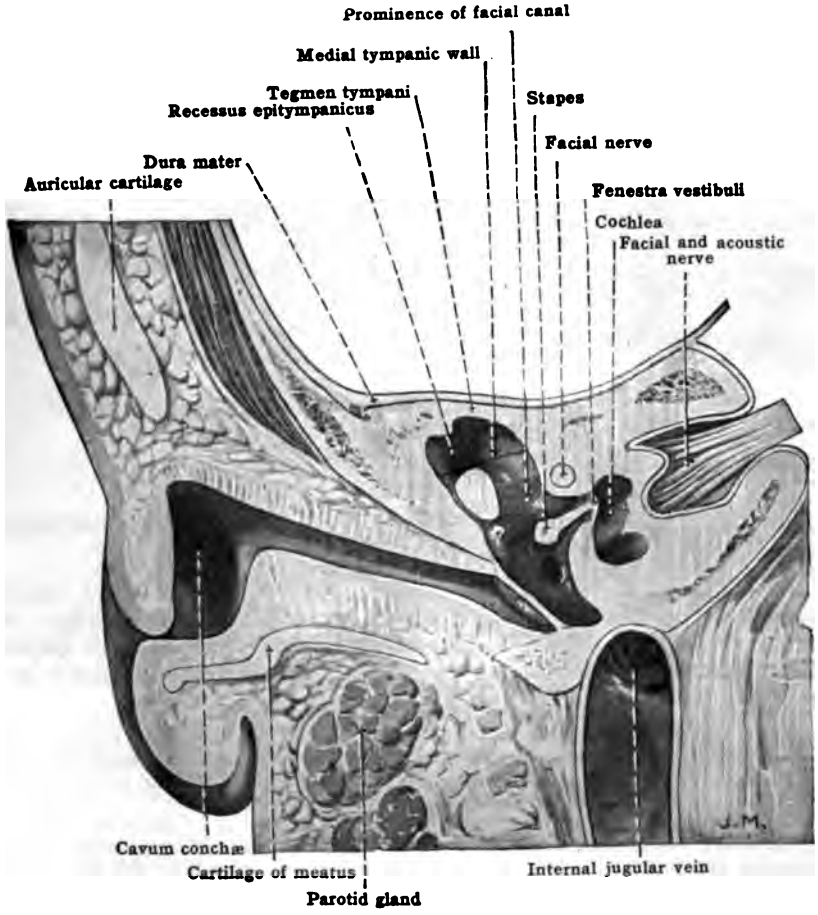
THE TYMPANIC MEMBRANE

The **tympanic membrane** [membrana tympani] (figs. 861, 864) is elliptical in shape, its long axis nearly vertical, measuring 9 to 10 mm., its short axis, 8 to 9 mm. It slopes medially from the superior and posterior to the inferior and anterior wall of the meatus, forming, as a rule, with the superior wall, an angle of 140 degrees. It varies, however, greatly in form, size, and obliquity. Viewed from the meatus, it appears as a semitransparent membrane, which sometimes has a reddish tinge. It is drawn medially by the manubrium of the malleus (fig. 863). The most depressed point at its center, the **umbo, is slightly inferior and posterior** to the center of the membrane, and corresponds to the tip of the manubrium (fig. 861). From it a whitish streak, the **malleolar stria, caused by the manubrium** shining through, passes superiorly toward the circumference. At the superior end of the stria is a slight projection, the **malleolar prominence,** formed by the lateral process of the malleus. From it two folds, **the anterior and posterior**

ce, stretch to the extremities of the tympanic sulcus (fig. 861). The small ngular area of the membrane bounded by the plicæ, is termed the **pars flaccida** rapnell's membrane). It is thin and flaccid, and is attached directly to the trous bone in the tympanic notch (notch of Rivinus). The larger part of the mpanic membrane, the **pars tensa,** is inferior to the plicæ and is tightly stretched. thickened margin, the **limbus,** is attached by a **fibrocartilaginous annulus** the tympanic sulcus, and at the spines of the tympanic ring is continuous with e plicæ.

Structure of the tympanic membrane.—The tympanic membrane is about .1 mm. thick, d consists of four layers. The lateral **cutaneous layer,** relatively thick, is a continuation the skin lining the external auditory meatus. Next to it is a **radiate fibrous layer,** composed

FIG. 860.—CORONAL SECTION OF THE RIGHT EAR. (Somewhat enlarged.)



of connective tissue, the fibers of which are attached to the manubrium of the malleus and radiate from it. Medial to it is the **circular fibrous layer,** which has its fibers arranged concentrically and is especially thick at the circumference. It is closely bound to the radiate layer. **The mucous layer,** which is a continuation of the mucosa of the tympanic cavity, covers the medial surface of the membrane smoothly, except where the manubrium of the malleus causes a projection. The fibrous layers are attached to the fibrocartilaginous ring and are not present in the pars flaccida.

THE TYMPANIC CAVITY

The **tympanic cavity** [cavum tympani], as has been stated, is an air-space, lined with mucous membrane, situated between the external and the internal ear, It is of irregular outline, but, roughly, it is a slit-like cavity, lying in an oblique anteroposterior plane. Its transverse diameter measures only from 2–4 mm., while the vertical and anteroposterior diameters measure about 15 mm. (fig. 863).

It is narrowest at the center, and wider superiorly than inferiorly. The bony walls have already been partly described with the temporal bone, and hence the description given here will refer to the appearance found in the fresh, or macerated condition.

It will be noticed (see fig. 858) that the *floor* of the space is on very much the same horizontal plane as the floor of the external meatus, and the lower margin of the tympanic membrane. The *roof*, on the other hand, lies at a much higher level than the upper margin of that membrane. Hence the cavity may be divided into two regions, a *lower* part, corresponding in extent to the tympanic membrane, and an *upper*, above the upper border of the membrane, known as the *epitympanic recess*. This division forms a definite chamber, and contains the head of the malleus and the body and short process of the incus. It is on the posterior part of this chamber that the communication with the tympanic antrum is found (fig. 1075).

FIG. 861.—LATERAL SURFACE OF THE LEFT MEMBRANA TYMPANI. (Enlarged from life.)

As the shape of the tympanum is irregular, its walls are not everywhere clearly marked off from one another, but there may be recognized (figs. 858 and 864) a **roof**, or **tegmental** wall, a **floor or jugular** wall, a **medial or labyrinthine** wall and a **lateral or membranous** wall, an **anterior or carotid**, and a **posterior or mastoid** boundary or wall.

The roof, or **tegmental wall** (figs. 864, 1075), is formed by a portion of the tegmen tympani, a thin plate of bone which is continued backward to form the roof of the tympanic antrum. This plate is formed by the petrous part of the temporal bone, and at its lateral margin is the petrosquamous suture, where a slight deficiency in the roof may occur.

The floor, or **jugular wall** is very narrow transversely, and is in intimate relation to the internal jugular vein (fig. 860). As shown in fig. 862, the surface is frequently very irregular from stalactite-like projections between which are the tympanic cellulæ (air-cells), while near the back there is occasionally a marked projection corresponding externally to the root of the styloid process.

The posterior or **mastoid wall** presents at its lower part, many additional tympanic cellulæ, and higher up, an elevation, the *pyramidal eminence*, on whose apex is an aperture transmitting the tendon of the stapedius muscle. The fleshy belly of that muscle is contained in a cavity in the interior of the bony pyramid of the posterior wall. Lateral to this is an aperture, the *apertura tympanica canaliculæ chordæ*, through which the chorda tympani nerve enters the tympanum, covered by a reflection of the mucous membrane. Between this opening and the pyramid is a slight elevation; and above it is a fossa, termed the *sinus posterior*. Above this again is a recess, where the posterior ligament of the incus is attached, known as the *fossa incudis*. This portion of the posterior wall forms the boundary of the epitympanic recess. Here the cavity of the tympanum is continued with that of the antrum tympanicum, or mastoid antrum, a large irregular space into which open the mastoid cells (see p. 1125). The boundaries of the orifice are formed above by the tegmen tympani, medially by the prominences of the lateral semicircular canal and facial nerve, and laterally by a plate of bone termed the *scutum*.

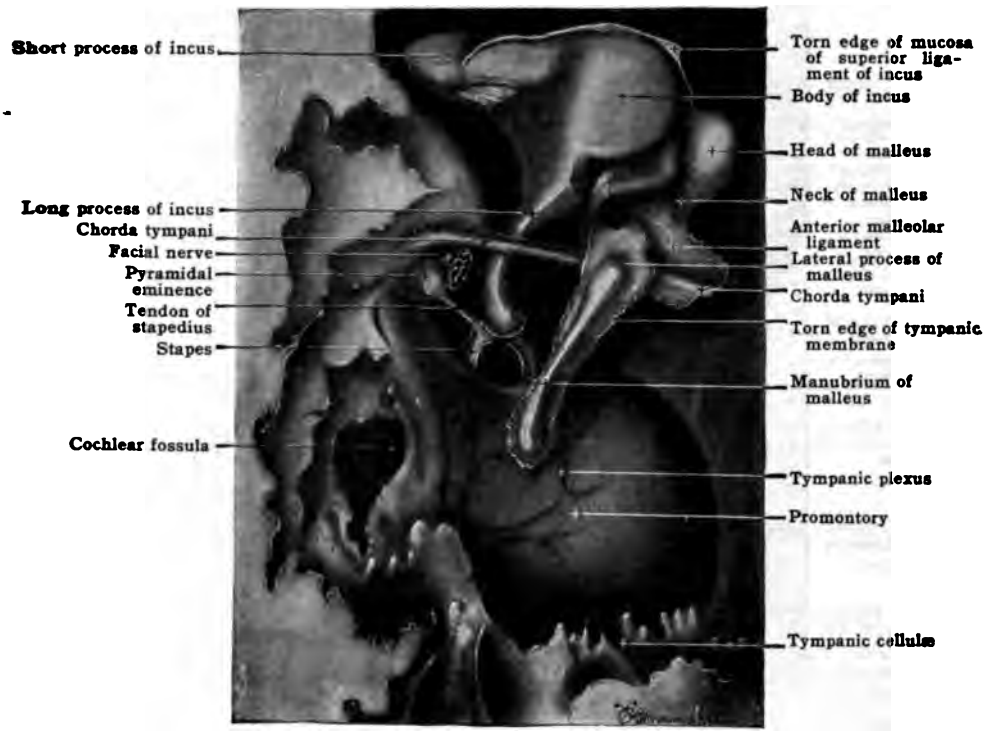
The **carotid (anterior) wall** presents superiorly the *tensor tympani muscle* in its canal, and at a lower level the opening of the *tuba auditiva* (Eustachian tube) (fig. 864) by means of which a direct communication is established into the nasopharynx. Inferiorly, a thin, bony wall, covered with tympanic cellulæ and pierced by the caroticotympanic nerves separates the tympanic cavity from the carotid canal.

The membranous (lateral) wall (fig. 864) is formed mainly by the tympanic membrane, with a small rim of bone to which it is attached, but superiorly the lateral wall of the epitympanic recess is formed by a plate of bone termed the scutum.

The labyrinth (medial) wall (fig. 862) presents inferiorly the *promontory*, produced by the first turn of the cochlea with the *tympanic plexus* (Jacobson's nerve) lodged in grooves upon its surface. Inferior and posterior to the promontory is a depression or fossula at the bottom of which is the *cochlear fenestra* (fenestra rotunda), closed by the *secondary tympanic membrane*, and posterior to the promontory is a smooth projection, the *subiculum of the promontory*, which forms the inferior border of a rather deep depression known as the *tympanic sinus*. Anteriorly and superiorly is the *cochleariform process*, and superiorly and posteriorly are a depression or fossula leading to the *vestibular fenestra* (*fenestra ovalis*), which is closed by the base of the stapes, the prominence of the facial (Fallopian) canal, and the prominence of the lateral semicircular canal, the two latter being formed in the medial wall of the entrance to the mastoid antrum.

The tympanic mucous membrane forms a complete covering for the walls and contents of the tympanic cavity. It is continuous anteriorly with the mucosa of the tuba auditiva (Eustachian tube) and posteriorly with that of the tympanic (mastoid) antrum and mastoid cells.

FIG. 862.—THE LABYRINTH (MEDIAL) WALL OF THE RIGHT TYMPANUM WITH THE TYMPANIC OSSICLES IN POSITION.



It is a thin, transparent, vascular membrane intimately united to the periosteum. As it passes from the walls to the contents of the tympanic cavity, besides covering the ligaments of the malleus and the incus and the tendons of the tensor tympani and stapedius muscles, it forms a number of special folds and pouches.

The **anterior malleolar fold** is reflected from the tympanic membrane over the anterior process and ligament of the malleus and the adjacent part of the chorda tympani, and the **posterior malleolar fold** stretching between the manubrium and the posterior tympanic wall, surrounds the lateral ligament of the malleus and the posterior part of the chorda tympani. Each of these folds presents inferiorly a concave free border, and between them and the tympanic membrane are two blind pouches, the **anterior and posterior malleolar recesses** or pouches of Tröltsch. Connected with the posterior recess is a third cul-de-sac, the **superior recess** of the tympanic membrane, or pouch of Prussak, situated between the pars flaccida of the tympanic membrane and the neck of the malleus. The floor of this recess is formed by the lateral process of the malleus, and is lower than its outlet; therefore, the recess may serve as a pocket in which pus or other fluid may accumulate. A somewhat variable fold of mucosa, the **plica incudis**, passes from the roof of the tympanic cavity to the body and short process of the incus. The body and short process of the incus, the head of the malleus, and this fold incompletely separate off a lateral **cupular portion** of the epitympanic recess, and a **stapedial fold** stretches from the posterior wall of the tympanic cavity and surrounds the stapes, including the oburator membrane, which stretches between its crura. Other inconstant folds have been described. The mucosa of the typanic cavity, except over the tympanic membrane, promontory, and ossicles, is covered by a columnar ciliated epithelium.

Bones.—The tympanic cavity contains three small movable bones, joined together and to the walls of the cavity, and having attached to them special muscles and ligaments. These auditory ossicles form a chain across the tympanic cavity connecting the tympanic membrane and the vestibular (oval) fenestra. They are the **malleus,** the **incus,** and the **stapes,** and are described in the section on OSTEOLOGY. (See p. 148.)

Articulations of the ossicles.—The manubrium and lateral process of the malleus are imbedded in the tympanic membrane. The margin of the irregularly elliptical articular surface on the posterior side of the head of the malleus is bound to the body of the incus by a thin capsular ligament, forming a diarthrodial joint, the **incudomalleolar articulation.** From the inner surface of the capsular ligament, a wedge-shaped rim projects into the joint cavity and incompletely divides it. The long crus of the incus lies parallel to the manubrium of the malleus and on its superior and medial aspect (figs. 862 and 864). It ends in the lenticular

FIG. 863.—THE TYMPANIC CAVITY, ANTERIOR WALL REMOVED.

process. The convex extremity of this fits into the concavity on the head of the stapes, to form a diarthrodial joint, the **incudostapedial articulation.** From its articulation with the incus, the stapes passes almost horizontally across the tympanic cavity to its junction with the medial wall. The cartilage-covered edge of the base is bound to the cartilage-covered rim of the vestibular (oval) fenestra by the annular ligament of the base of the stapes, thus forming the **tympanostapedial syndesmosis.**

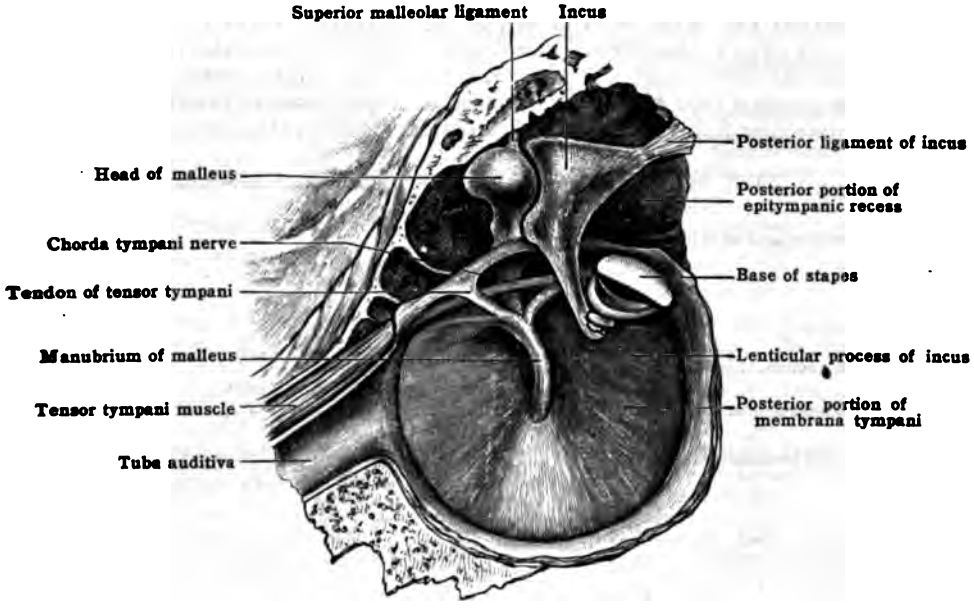
Ligaments of the ossicles.—In addition to the attachment of the manubrium of the malleus and the base of the stapes to the walls of the tympanic cavity, the bones have additional ligamentous attachments. The **superior malleolar ligament** runs almost vertically from the superior wall of the epitympanic recess to the head of the malleus (fig. 863). The **anterior malleolar ligament** extends from the angular spine of the sphenoid bone through the petrotympanic (Glaserian) fissure to the anterior or long process of the malleus, which it surrounds, and is inserted with it into the neck of the malleus. The **lateral malleolar ligament** is short and thick, and runs from the margins of the tympanic notch (notch of Rivinus) to the neck of the malleus (fig. 863). The **posterior ligament of the incus** passes from the fossa on the posterior tympanic wall to the crus brevis of the incus (fig. 864). The **superior ligament** of the incus is little more than mucous membrane; it runs from the tympanic roof to the body of the incus.

Muscles of the ossicles.—Each of the muscles of the ossicles is contained in a bony canal. The **tensor tympani** (fig. 864) is a pinniform muscle about 2 cm. long. It arises from the cartilaginous part of the tuba auditiva (Eustachian tube), from the adjacent part of the great wing of the sphenoid, and from the bony walls of the semicanal which encloses it. It ends in a round tendon which turns almost

right angles over the cochleariform process and passes laterally across the tympanic cavity to be attached to the manubrium of the malleus near the neck. It draws the manubrium medially and tightens the tympanic membrane, and is supplied by the motor division of the trigeminal cranial nerve, through the tensor tympani branch from the otic ganglion. The **stapedius** arises in the interior of the hollow pyramidal eminence. The tendon (fig. 862) escapes through the apex and then turns inferiorly and is inserted on the posterior surface of the neck of the stapes. It draws laterally the ventral border of the base of the stapes and is supplied by the facial nerve.

Vessels and nerves.—The **arteries of the tympanic cavity** are the anterior tympanic from the internal maxillary artery (fig. 495), the stylomastoid from the posterior auricular artery, the superficial petrosal from the middle meningeal artery, the inferior tympanic from the ascending pharyngeal (fig. 490), and the tympanic branch from the internal carotid. The

FIG. 864.—MEDIAL SURFACE OF RIGHT MEMBRANA TYMPANI. (Enlarged.)



veins empty into the superior petrosal sinus, the pterygoid plexus of veins and into the posterior facial (temporomaxillary vein). The **nerves** are the tympanic plexus formed by the tympanic branch of the glossopharyngeal (p. 984), and the inferior and superior caroticotympanic nerves which join the internal carotid plexus of the sympathetic (p. 1065). The small superficial petrosal nerve takes its origin from the tympanic plexus, and the chorda tympani crosses the tympanic cavity from the posterior to the anterior wall (p. 981, figs. 786, 864).

Antrum tympanicum and mastoid cells.—The aperture (*aditus*) in the upper part of the posterior wall of the tympanum leads into the chamber termed the **antrum tympanicum.** This is a comparatively large cavity, of irregular form, lying mainly behind but also somewhat above and lateral to the tympanum, and extends to the medial end of the external acoustic meatus. It is lined by mucous membrane, continuous with that of the tympanic cavity, and into it open the **mastoid cells** (cellulæ mastoideæ). These cells are small, irregular cavities in the interior of the mastoid process and they communicate with one another freely. They vary exceedingly in their size and arrangement. For further details concerning the topography of the middle ear and mastoid region, see pp. 147, 1336).

THE AUDITORY (EUSTACHIAN) TUBE

The **auditory tube** [tuba auditiva] (Eustachian tube) (fig. 858) extends from the carotid (anterior) wall of the tympanic cavity inferiorly, medially, and anteriorly to the pharynx. It is about 37 mm. (1.5 in.)long. In the lateral one-third of its length it has a bony wall, while in the medial two-thirds this wall is cartilaginous. The **osseous part** (see p. 144) begins a tthe **tympanic ostium** on the anterior wall of the tympanic cavity. It is in relation medially adn inferiorly with the carotid canal, and gradually contracts to its irregular medial extremity, which is the narrowest point in the tube, and is termed the **isthmus.**

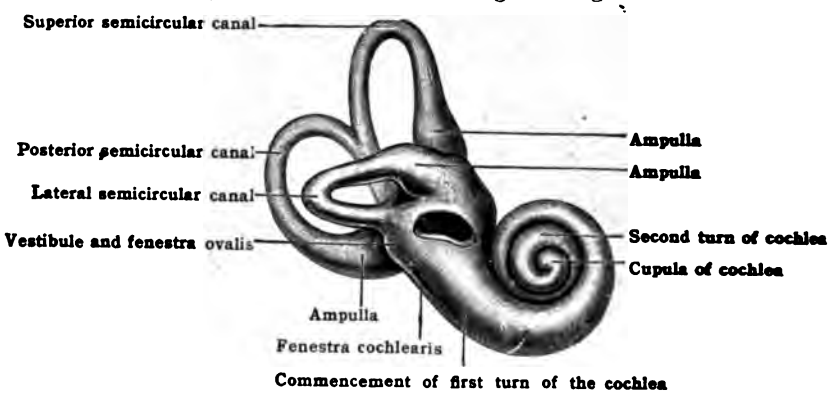
The **cartilaginous part** is firmly attached to the osseous and lies in a sulcus at the base of the angular spiue of the sphenoid bone. It gradually dilates in its passage to the lateral wall of the pharynx, where its opening, **pharyngeal ostium**, is just posterior to the inferior nasal concha and in front of the lateral pharyngeal recess (fossa of Rosenmiller). The walls of the cartilaginous part are formed by a cartilaginous plate which is folded so as to form a trough-like structure, consisting of a medial and a lateral **lamina**, completed inferiorly by a **membranous lamina** formed of connective tissue.

A small portion of the lumen in the superior part of the cartilaginous tube remains permanently open; elsewhere the walls are in contact, except during deglutition, where they are opened by the tensor veli palatini mucles. The mucosa of the osseous part is thin, and firmly attached to the bony wall, but in the cartilaginous part it becomes thicker, looser, and folded, and contains mucous glands, especially near the pharynx, where there is also some adenoid tissue.

3. THE INTERNAL EAR

The **internal ear** [auris interna] is the essential part of the organ of hearing. It consists of a cavity, the osseous labyrinth, contained within the petrous portion of the temporal bone, and enclosing a membranous labyrinth. The **osseous labyrinth** is divided into **cochlea, vestibule,** and **semicircular canals** (see p. 149). The accompanying figures (858, 865, 869) show their position and relations.

FIG. 865.—THE OSSEOUS LABYRINTH OF THE RIGHT SIDE.
(Modified from Soemmerring. Enlarged.)



It will be noticed that the vestibule forms a central chamber, from which the semicircular canals and the cochlea branch off; the former from the superior and dorsal portion, and the latter from the ventral and inferior.

It will further be noticed that the bony wall of this vestibule shows depressions and ridges on its interior, which are associated with parts of the membranous labyrinth, viz., an upper recess for the utricle (fovea hemielliptica) and a lower recess for the saccule (fovea hemispherica). There are openings in the bony wall for the entrance of nerves to the different parts of the membranous labyrinth, and for the transmission of the ductus endolymphaticus, as well as the small openings of the semicircular canals (ducts) and the opening of the cochlear canal (or duct).

The **membranous labyrinth** (figs. 772, 868, 869), in which the cochlear and vestibular nerves end, lies within the osseous labyrinth, the form of which it more or less closely resembles. Thus the membranous semicircular ducts lie within the bony semicircular canals, the membranous cochlear duct within the bony cochlea; while the vestibule contains two small membranous sacs, the utricle and saccule, with their connections. The membranous structures are much smaller in diameter than the osseous, and are partially separated from the bone by an endothelial-lined space which is filled with a fluid, the **perilymph.** The membranes are in contact, however, with the bony wall along their convex margin, and the utricle, saccule and cochlear canals are in contact with the bony walls over the areas where the nerves enter them. The fluid which fills the membranous labyrinth is termed the **endolymph.**

The **utricle** is an oval tubular sac, whose rounded end lies in the superior and dorsal portion of the vestibule. It is here tightly bound to the elliptic recess (fovea hemielliptica) by con-

nective tissue and by the entrance of the filaments of the utricular division of the vestibular nerve as they pass from the superior macula cribrosa to the wall of the utricle. In the anterior part of the interior of the utricle, an oval, whitish, thickened area, **macula acustica utriculi**, marks the terminal distribution of the nerve, and posteriorly the utricle is joined by the orifices of the semicircular ducts.

The **saccule** is a flattened, oval sac, smaller than the utricle, and situated in the anterior and inferior part of the vestibule. It is bound to the spherical recess (fovea hemispherica) by connective tissue and by the saccular division of the vestibular nerve, filaments of which extend from the middle macula cribrosa to the anterior and medial wall of the saccule, to be distributed over a thickened area, **macula acustica sacculi**. Anteriorly and inferiorly the saccule gradually passes into a short canal, the **ductus reuniens**, which connects it with the cochlear duct, and

posteriorly the very small **endolymphatic duct** is attached (fig. 868). This extends through the aqueductus vestibuli to the posterior surface of the petrous portion of the temporal bone, where it ends in a dilated blind pouch, the **endolymphatic sac**, situated just beneath the dura. Just beyond the saccule, the endolymphatic duct is joined at an acute angle by a short canal of minute caliber, the **utriculosaccular duct**, which opens into the utricle through its anterior medial wall and, with the endolymphatic duct, connects it with the saccule.

The **semicircular ducts** (membranous semicircular canals) are situated within the osseous semicircular canals and are, therefore, known as the lateral, superior, and posterior semicircular ducts. They connect with the utricle by five openings, and posterior and superior ducts uniting to form a common crus before their termination. Each duct is less than a third of the diameter of the bony canal, from which it is separated by a large **perilymphatic space**, except along the greater curvature, where it is attached. The ducts are dilated in the bony ampullæ, producing the **lateral, superior,** and **posterior membranous ampullæ**, and on the attached surface of each of these there is a transverse groove, the **ampullary sulcus**, for the ampullary division of the vestibular nerve, and corresponding to the sulcus a ridge, the **ampullary crista**, projects into the

FIG. 867.—INTERIOR OF THE OSSEOUS COCHLEA. (Enlarged.)

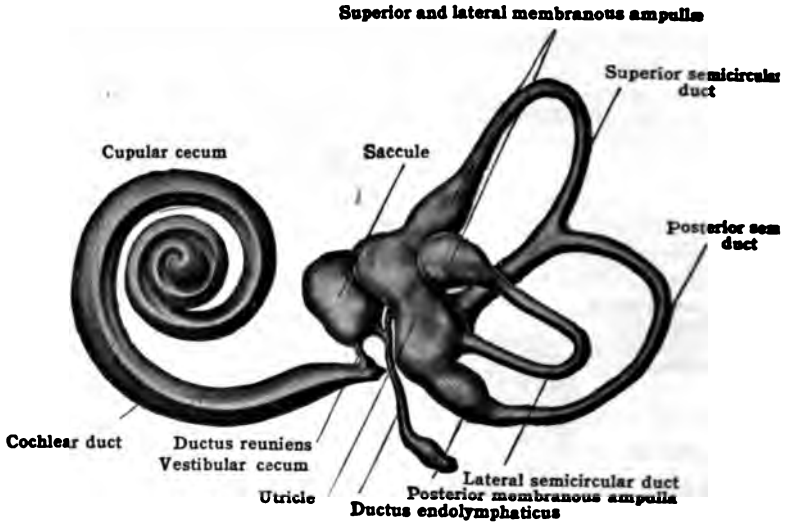
interior. The cristæ in the ampullæ of the membranous semicircular ducts and the maculæ in the saccule and utricle are superficially covered with fine crystals of calcium carbonate, **otoconia** (otoliths).

The **cochlear duct** (membranous cochlea or scala media) begins within the cochlear recess of the vestibule in a blind pouch, the **vestibular cecum**, and traversing the spiral canal of the cochlea, ends just beyond the hamulus of the lamina spiralis in a second blind pouch, the **cupular cecum**. Close to the vestibular cecum it is joined to the saccule by the **ductus reuniens**. It is lined throughout by epithelium and is somewhat triangular in cross-section. Its floor is formed by thickened periosteum over part of the osseous lamina spiralis and by a fibrous membrane, the **lamina basilaris**, which stretches from the free border of the lamina spiralis to a thickening of the periosteum, the **spiral ligament** of the cochlea, on the peripheral wall.

The epithelium of this floor is greatly modified, forming the **spiral organ (organ of Corti)** (fig. 872) in which the fibers of the cochlear nerve terminate. The peripheral wall is formed by the thickened periosteum upon the peripheral wall of the cochlear canal, while the third wall is

formed by a thin **vestibular membrane (membrane of Reissner)** which passes from t ipheral wall to the osseous lamina spiralis near its free margin, forming with the lamina an angle of 45 degrees. The cochlear duct and the osseous spiral lamina divide the spiral canal into two parts, one next to the basilar membrane, the **scala tympani**, and one the vestibular membrane, the **scala vestibuli**. The scala tympani unites with the scala

FIG. 868.—DIAGRAM OF THE LEFT MEMBRANOUS LABYRINTH. (Deaver.)



at the helicotrema, and from the scala tympani a minute canal, the **perilymphatic du** through the cochlear canaliculus and connects with the subarachnoid space. A thi ayer, the **secondary tympanic membrane,** closes the cochlear fenestra (fenestra and thus separates the scala tympani from the tympanic cavity, and the vestibular phatic space (scala vestibuli) is separated from the tympanic cavity by the base of t in the vestibular fenestra (fenestra ovalis).

Vessels and nerves.—The internal auditory artery, (fig. 555), a branch of the basil accompanies the cochlear and vestibular nerve. It supplies the vestibule, semicircul

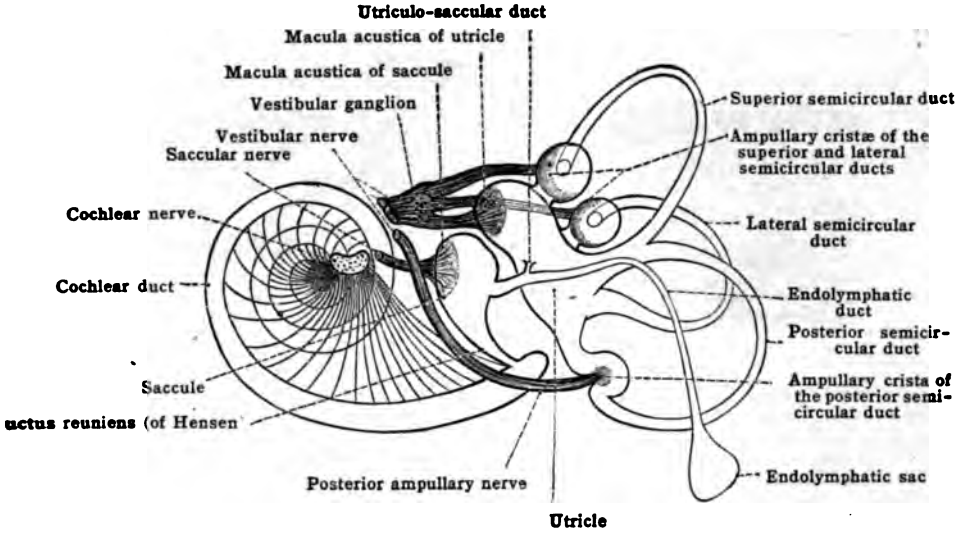
and cochlea, and their membranous contents. The blood is returned by the internal j vein into the inferior petrosal sinus, and by small veins which pass through the cochl vestibular aqueducts to the inferior and superior petrosal sinuses. **The acoustic nerve** figs. 870–872) consists of a vestibular and a cochlear division. **The membranou** ullæ of the semicircular ducts and the acoustic maculæ of the utricle and saccule plied by the vestibular nerve. The spiral organ (organ of Corti) in the cochlear supplied by the cochlear nerve.

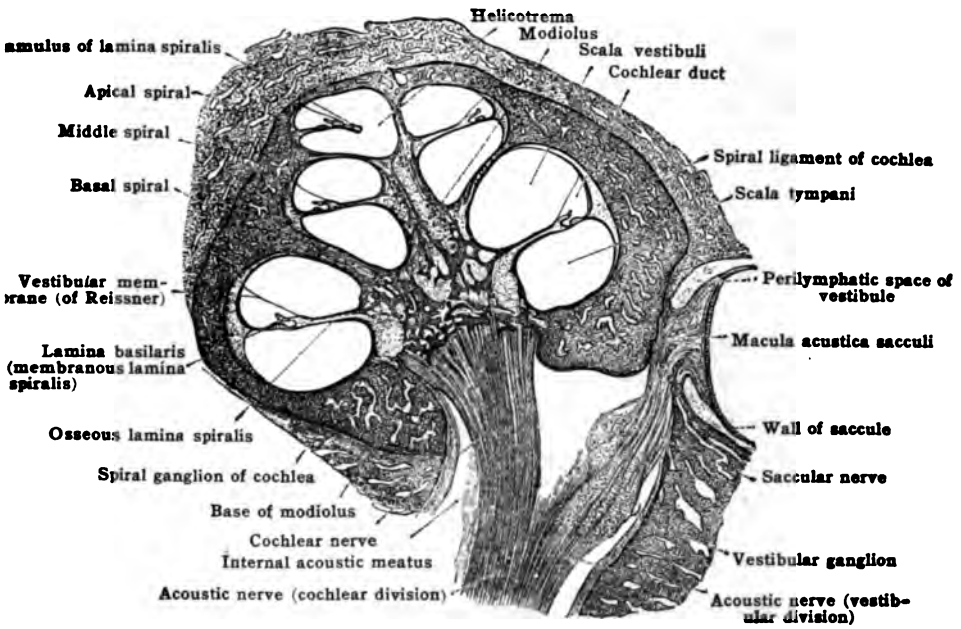
Development of the Ear

The external and middle ears have an origin quite distinct from that of the internal ear, and are to be regarded as portions of the branchial arch apparatus secondarily adapted to auditory purposes. The sensory epithelium lining the internal ear is derived from the otic vesicle, a structure formed from the surface epithelium of the head, while the membrane and bones surrounding it are formed from the mesoderm around the vesicle.

G. 870.—Schematic Representation of the Right Membranous Labyrinth and the Divisions of the Acoustic Nerve. Viewed From behind. (Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



IG. 871.—Axial Section Through the Decalcified Cochlea of a Newborn Child (Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



Internal ear.—The process of development is as follows:—

By invagination from the surface, an ectodermal vesicle, termed the primitive otocyst r otic vesicle, is formed dorsal to the extremity of the second branchial cleft (fig. 820). It is at rst merely a pit on the surface, but eventually it loses its connection with the surface epitheum and sinks into the interior. It then undergoes the alterations in shape and form shown the accompanying fig. 873. The vesicle is at first oval, and at its upper end there is a small

hollow stalk, the recess of the labyrinth, which forms the *ductus endolymphaticus* of t
The ventral and dorsal portions of the cyst become enlarged. From the latter tw
plate-like projections arise, one placed vertically, the other horizontally, and along
margins of these plates are formed the semicircular ducts, the superior and poster
the vertical, and the lateral duct from the horizontal one. The walls of the central par
plate become adherent and the fused areas are then absorbed; when this happens the p
part of each plate assumes the characteristic loop form of the adult semicircular duc
portion of the vesicle lying between the dorsal and ventral enlargements forms the

atrium. It becomes divided into two chambers, an upper dorsal connected with
circular ducts, forming the utricle, and an inferior ventral, the saccule, which is conne
that portion of the ventral expansion from which the cochlea is formed.

The endolymphatic duct retains its connection with the cavity of the vesicle at th
stalk connecting utricle and saccule. The cochlear duct is formed by an outgro
the saccule which becomes coiled in the way shown in fig. 873.

External and middle ear.—The *external auditory meatus* is formed from the o
of the first (external branchial) cleft, and the tympanic membrane from the membra
forms the floor of that pocket and separates it from the corresponding pharyngeal
pouch. Its outer surface is thus formed from ectoderm and the inner from endode
internal pouch gives origin to the tympanic cavity and tuba auditiva.

FIG. 873.—MODELS OF THE LEFT MEMBRANOUS LABYRINTH FROM HUMAN EMB

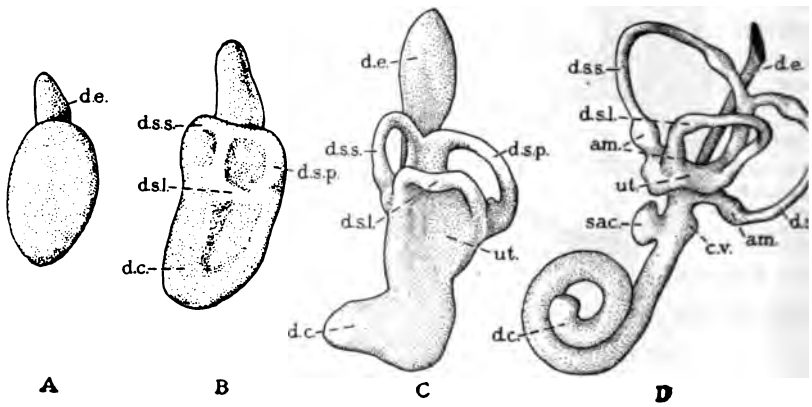
d.e., endolymphatic duct; *d.s.l.*, *d.s.p.*, and *d.s.s.*, lateral, posterior and superior sem
ducts; *sac.*, sacculus; *ut.*, utriculus.



The *auricle* is formed from nodular thickenings of the tissue bounding the outer e
first branchial cleft. Three nodules are formed on the first (mandibular) and thre
second (hyoid) arch. Behind the latter, the free margin of the auricle is formed by a f
of the integument. Later an additional tubercle is formed dorsally between the tw
nodules. From the mandibular nodules are formed mainly the tragus and the crus of th
from the hyoid tubercles the antitragus, the crus of the anthelix and the lobule.

The *auditory ossicles*, and their muscles are formed from the neighboring arches, th
and incus, together with the tensor tympani, being derived from the first arch, while t
and stapedius probably are derived from the second arch.

The *tympanic cavity* is at first quite small, but later increases greatly, partly by the condensation of the loose areolar tissue which underlies its mucous membrane, the auditory ossicles and their muscles being thus apparently brought within the cavity, and partly by the absorption of the neighboring bone. By this latter process the *antrum* and the *tympanic* and *mastoid cells* are formed, all these depressions or cavities being lined by mucous membrane continuous with that of the tympanic cavity.

The ear in the child differs from that of the adult in several important respects, as explained on p. 38.

SECTION X

DIGESTIVE SYSTEM

REVISED FOR THE SIXTH EDITION

BY C. M. JACKSON, M.S., M.D.,

PROFESSOR OF ANATOMY IN THE UNIVERSITY OF MINNESOTA

IN order to furnish the living protoplasm with the materials necessary for energy, growth and repair, a constant supply of food must be provided. Most foods must be rendered soluble, and must undergo certain preliminary chemical changes, in order to render them suitable for absorption and assimilation by the cells of the body. For this preparation of the food-supply, the *digestive system* [apparatus digestorius] is provided, which includes the alimentary canal and certain accessory glands (salivary glands, liver and pancreas). The alimentary canal is divided into a number of successive segments varying in size and structure according to their function. These segments (fig. 874) include the mouth, pharynx, esophagus, stomach, small and large intestines.

Typical structure.—The most important layer of the tubular alimentary canal is the inner *mucous membrane* [tunica mucosa]. From its epithelial lining, the various digestive glands are derived, and through it the process of absorption takes place. The epithelium is supported by a fibrous tunic [lamina propria mucosæ] beneath which is a thin layer of smooth muscle [lamina muscularis mucosæ]. The layer next in importance is the *muscular* coat [tunica muscularis] which propels the contents along the canal. It is typically composed of two layers of smooth (involuntary) muscle, the inner circular and the outer longitudinal in arrangement. Between the mucosa and the muscularis is a loose, fibrous *submucous* layer [tela submucosa], which allows the folds in the mucosa to spread out when the canal is distended. Finally, there is an outer *fibrous* coat [tunica fibrosa], which in the abdominal cavity becomes the smooth *serous* coat [tunica serosa], or visceral layer of the peritoneum, which eliminates friction during movements. The variations in the structure of the alimentary canal in different regions are due chiefly to differences in the mucosa.

Glands.—Since the glands form an important part of the digestive system, the classification of glands in general will be discussed briefly. A gland may be somewhat loosely defined as an organ which elaborates a definite substance which is either a waste product to be eliminated (excreted), or a secretion to be further utilized by the organism. Glands may be divided into (a) *ductless glands* (e. g. spleen, thyroid gland), which pour their secretions directly into the blood or lymph; and (b) *glands with ducts*, which open upon an epithelial surface. Some organs, however, belong in *both* classes (e. g., liver, pancreas).

The glands with ducts (the so-called 'true' glands) are derived from an epithelial surface and may be further subdivided upon the basis of either (1) form or (2) cell-structure of the terminal secretory portions. According to **form**, glands are classified as either *tubular* or *saccular* (alveolar, acinous). Each of these may be either *simple* or *compound* (branched). The compound saccular form is often called *racemose*. Moreover, intermediate forms (tubulo-racemose) occur.

According to **cell-structure** and character of secretion, glands are divided into mucous and serous types. In the *mucous* type, the cells appear larger and lighter when swollen with mucus which is secreted for purposes of lubrication. The goblet-cells of the intestine represent unicellular glands of this type. In the *serous* (or albuminous) type of glands, the cells usually appear somewhat smaller and more deeply stained, with numerous zymogen granules. The secretion is a watery, albuminous fluid, which contains the digestive enzymes. There occurs also a *mixed* type, with separate mucous and serous saccules, or both types of cells may occur in the same saccule (the serous cells as 'demilunes' or 'crescents'). The term *cytogenic* glands is applied to those which produce cells (e.g., gonads and lymphoid organs). In all cases, the epithelial gland cells are supported by a fibrous connective-tissue stroma, which provides a rich vascular and nerve-supply, and forms also an external fibrous sheath or capsule surrounding the entire gland.

Morphology.—The alimentary canal in comparative anatomy is divided into the *headgut* (mouth and pharynx), *foregut* (esophagus and stomach), *midgut* (small intestine), and *hindgut* (large intestine). Embryologically, the midgut corresponds roughly to the portion of the archenteron attached to the yolk-sac, the portions of the archenteron anterior and posterior to the yolk-sac being designated as foregut and hindgut respectively. (See Section I, p. 38).

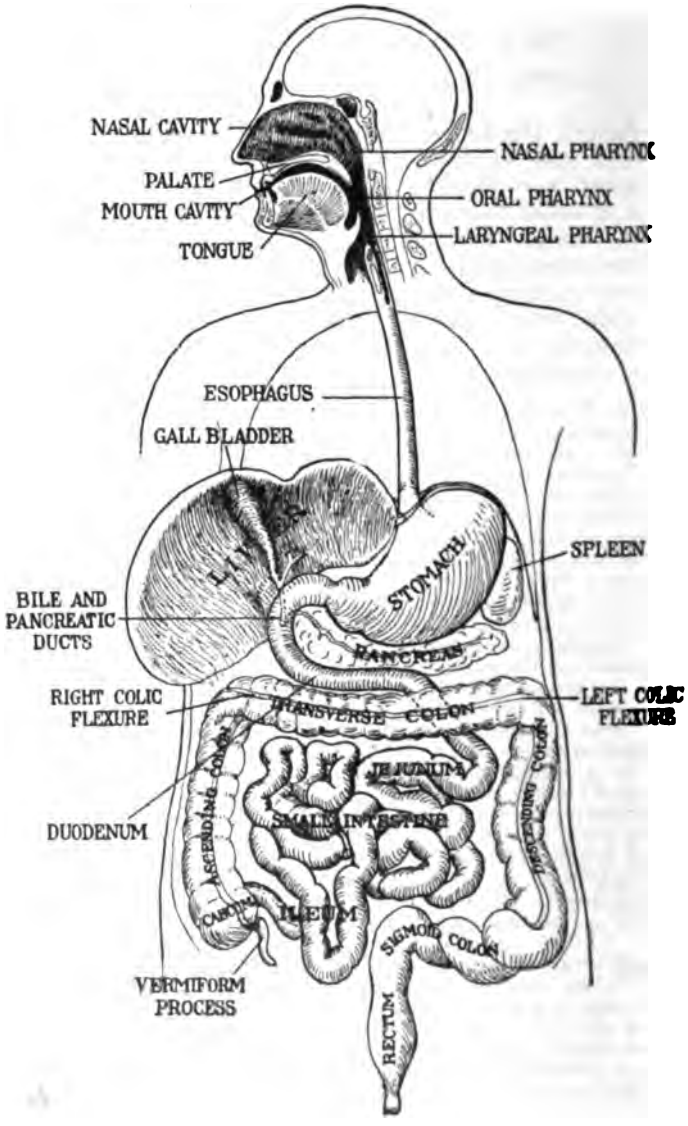
The lining epithelium of the alimentary tract is endodermal, excepting the anal canal and the mouth cavity, which are lined by invaginations of the ectoderm.

In the region of the mouth and pharynx, the digestive and respiratory systems are closely related in position, structure, function and origin. Morphologically, the headgut represents a primitive alimentary-respiratory apparatus.

THE MOUTH

The **oral cavity** [cavum oris] represents the first segment of the alimentary canal. Its walls are exceedingly specialized in structure, corresponding to its manifold functions (mastication, insalivation, taste, speech, etc.).

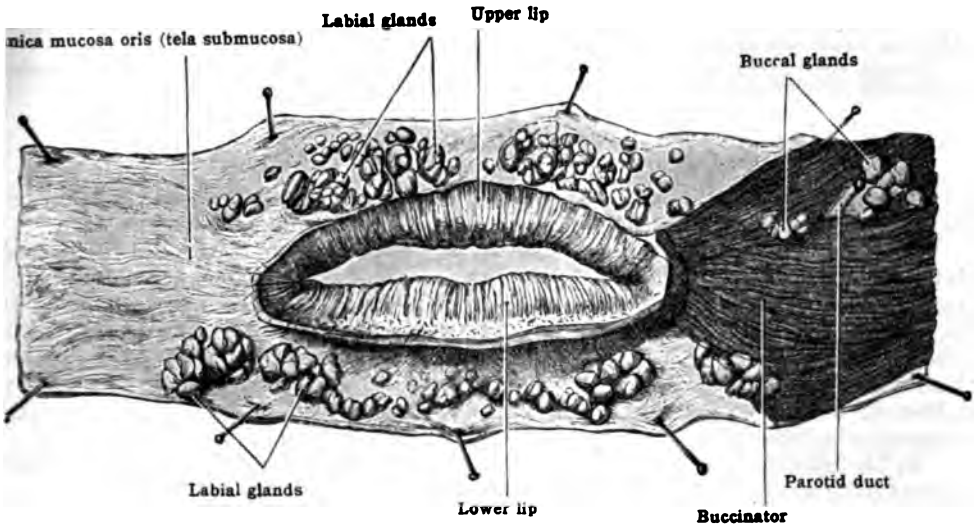
FIG. 874.—DIAGRAM OF THE ALIMENTARY CANAL.



Boundaries.—The oral cavity communicates anteriorly with the exterior through the transverse *oral fissure* [rima oris], and posteriorly with the pharynx through the *isthmus of the fauces* [isthmus faucium]. The *anterolateral walls* are formed by the flexible lips and cheeks. The *roof* is chiefly immovable and is formed by the upper jaw with the hard and soft palate. The movable *floor* is formed by the lower jaw, the tongue and the sublingual region.

Glands.—The *skin* of the lips and cheeks is well supplied with the usual sudoriparous and baceous glands. The mucosa likewise presents two kinds of glands, the sebaceous and the ucous glands. The *sebaceous* glands are relatively few in number and variable, being present about 30 per cent. of cases in the adult (Stieda). They are similar in structure to those of e skin (though not associated with hair-follicles), and when present are visible as small yellow- h bodies in the mucosa. They occur chiefly near the free margins of the lips and along the eek opposite the teeth.

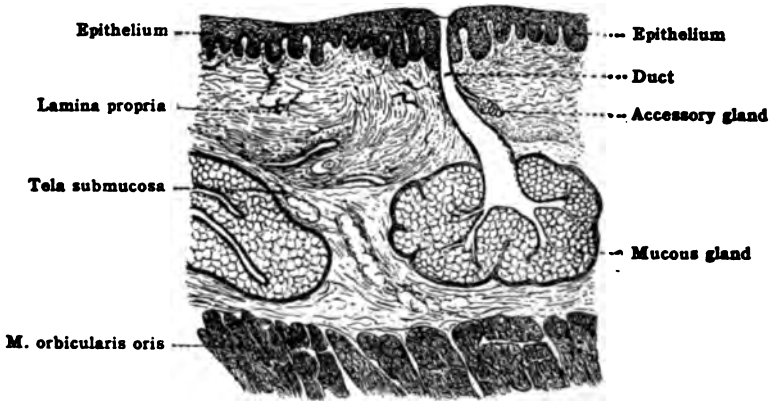
IG. 878.—LABIAL AND BUCCAL GLANDS EXPOSED BY DISSECTION OF THE SKIN FROM IN FRONT. (From Toldt's Atlas.)



The *mucous glands* are much more numerous and constantly present (figs. 878, 879). They .re all of the racemose type. They are variable but small in size, and closely packed together n the submucosa of the lips [glandulæ labiales], where they may easily be felt. Those of the heeks [gl. buccales] are less numerous. A few of them especially in the region of the molar eeth [gl. molares], are placed outside the buccinator. The ducts of the molar glands pierce his muscle near the parotid duct to open on the surface of the mucosa.

Vessels and nerves.—The mucosa of the lips and cheeks has a characteristic reddish hue, on ıccount of the numerous blood-vessels which are visible through the thick but transparent

?IG. 879.—SECTION OF LABIAL MUCOSA, SHOWING GLANDS. × 16. (From Toldt's Atlas.



stratified squamous epithelium (figs. 877, 879). The numerous papillæ of the lamina propria are highly vascular. The *blood-supply* of the lips and cheeks is derived chiefly from the labial (coronary) and buccal arteries. The rich *nerve-supply* (sensory) is from the infraorbital, mental and buccal branches of the trigeminus. The lips are especially sensitive near the rima oris.

Development.—During the second month in the human embryo, ledges of epithelium grow into the substance of the mandibular and the fused frontonasal and maxillary processes. These ledges develop into grooves which separate the upper and the lower lips from the upper and the lower jaws, the grooves forming the oral vestibule.

The philtrum and labial tubercle are said to correspond to the lower part of the frontonasal process. A failure of union between the medial nasal and the maxillary processes presents an arrest of development resulting in the malformation known as 'harelip.'

In the late fetus and newborn, the red portion of the lips consists of an external smooth *pars glabra*, and an inner zone, *pars villosa*, which is covered with numerous villus-like projections. The largest of these reach a length of 1 mm. They also extend backward in an irregular band along the mucosa of the cheek. They disappear during the first few weeks of postnatal life. In the infant, the *corpus adiposum* is especially well developed. On account of its supposed aid as a support for the buccinator in sucking, it has been called the 'sucking pad.'

The sebaceous glands of the mucosa are said not to appear until about the age of puberty.

Variations.—As is well known, the lips and cheeks are exceedingly variable in shape, size and structure in different individuals. There are also characteristic differences according to race and sex in the form and structure of the lips, rima oris, beard, etc. The 'harelip' malformation was mentioned above.

Comparative.—Typical lips are found only in mammals, and are probably organs phylogenetically developed in connection with the process of suckling.

THE PALATE

The **palate** forms the roof of the mouth cavity proper, and consists of two portions, the anterior or hard palate and the posterior or soft palate.

The **hard palate** [palatum durum] (figs. 876, 880) is continuous in front and laterally with the alveolar processes of the maxilla, and gives attachment posteriorly to the soft palate. It separates the mouth from the nasal cavity. It is supported by the palatine process of the maxilla and the horizontal part of the palate bone. The *oral surface* is concave from side to side, and also from before backward. It is covered by a thick, somewhat pale mucosa, which is firmly adherent to the periosteum through the submucosa. The submucosa contains numerous mucous *glands* [gl. palatinæ] (fig. 880), similar to those of the lips.

In the median line of the hard palate is a line or ridge, the *raphe* (fig. 880), terminating anteriorly in the small *incisive papilla*, which corresponds in position to the bony incisive foramen. Anteriorly there occur four to six more or less distinct *transverse ridges* [plicæ palatinæ transversæ]. Near the posterior margin of the hard palate there is on each side of the raphe a small pit (fig. 880), the *foveola palatina*, which is variable and inconstant.

The **soft palate** [palatum molle] (figs. 876, 910) separates the posterior portion of the mouth cavity from the nasal part of the pharynx. It is attached to the hard palate anteriorly and to the pharyngeal wall laterally. The posterior portion or *velum* projects backward and downward into the pharynx. Its free margin presents a median conical projection, the *uvula*, and splits laterally on each side to form two folds, the palatine arches, between which is located the palatine tonsil (fig. 880). The palatine arches and tonsil will be described later in connection with the pharynx.

Structure.—The soft palate is a fold of mucous membrane enclosing a fibrous aponeurosis, muscles, vessels, and nerves. It is marked in the middle line by a raphe indicating the line of junction of the two halves from which it was formed.

The posterior layer of the mucous fold, which is directed toward the cavity of the pharynx, is continuous with the nasal mucous membrane; the anterior layer lies in the posterior boundary of the mouth and is continuous with the mucous membrane of the hard palate. The structure of the mucosa is very similar to that of the lips (fig. 877). Mucous glands are numerous in both layers, but more especially in the anterior, and make up a large portion of the mucosa and submucosa (figs. 879, 880).

The aponeurosis is attached above to the posterior margin of the hard palate; laterally it is continuous with the aponeurotic layer of the pharyngeal wall; below, toward the lower margin of the velum, it gradually disappears. It gives attachment to fibers of the levator veli palatini and the pharyngopalatinus (palatopharyngeus) and to the tendon of the tensor veli palatini.

Muscles.—The muscles of the soft palate are described later (p. 1164) with those of the pharynx, with which they are closely associated.

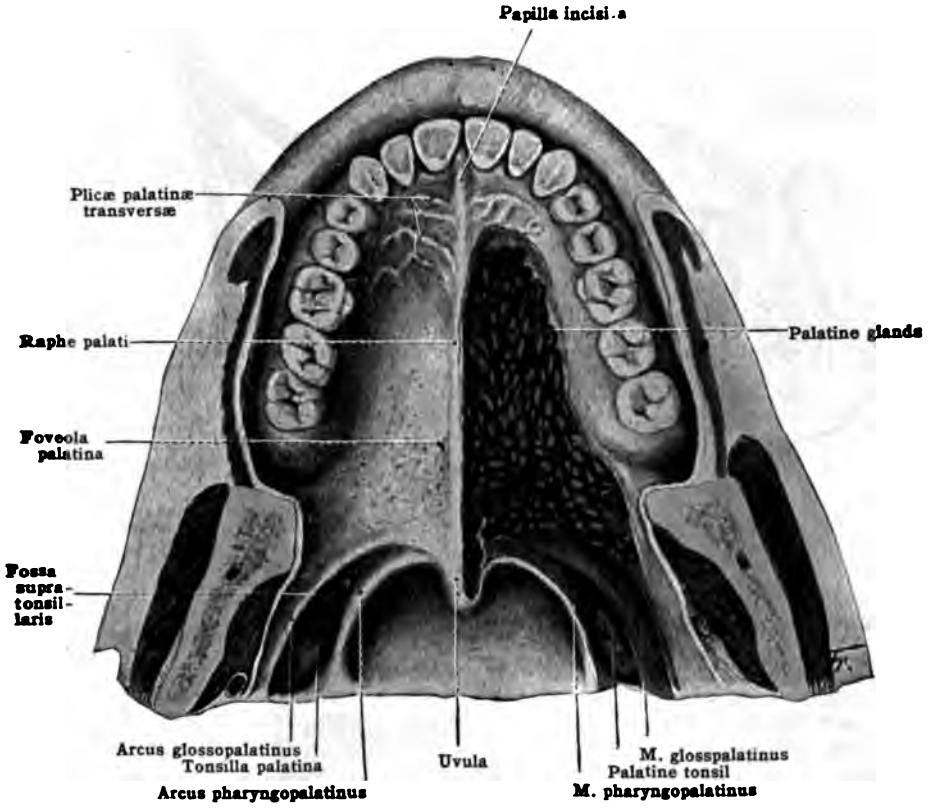
Vessels and nerves.—The arterial supply of the *hard palate* is derived chiefly from the major palatine branches of the internal maxillary. The arteries of the *soft palate* include: (1) Ascending palatine of external maxillary (facial); (2) pharyngeal branches of ascending pharyngeal; (3) twigs from descending palatine of internal maxillary, which enter the smaller palatine canals, are distributed to the soft palate and tonsils, and communicate with the ascending palatine of the external maxillary (facial) artery; (4) lingual artery, by twigs from the dorsal branch.

The *sensory nerves* to the palate are derived chiefly from the trigeminus through the sphenopalatine ganglion. The hard palate is supplied by the nasopalatine and anterior palatine branches; the soft palate chiefly by the middle and posterior palatine branches. The *motor* nerves will be mentioned later in connection with the muscles.

The development of the palate.—The development of the *palatine shelves* is described on p. 38. The incisive foramen indicates the place of meeting of the premaxilla and palate shelves, which closes the primitive communication between the oral and the nasal cavity. A lack of union of the palate shelves presents an arrest of development known as cleft palate. The *uvula* is similarly formed by the union of the posterior ends of the palatine shelves, and a failure to unite may produce a bifid uvula. The transverse *palatine ridges* are better developed in the infant than in the adult, and may assist in holding the nipple in sucking.

Variations.—*Cleft palate* and *bifid uvula* were mentioned above. The transverse *palatine ridges* are quite variable in number and prominence. On each side of the *incisive papilla* there is often found a small pit or shallow tube, a vestige of the embryonal incisive canal (Merkel). Sometimes there is instead a single median pit, representing the lower end of the incisive (Stenson's) canal. These pits are remnants of the primitive embryonic communication between mouth and nasal cavities.

FIG. 880.—ROOF OF MOUTH, SHOWING HARD AND SOFT PALATE DISSECTED ON ONE SIDE (Rauber-Kopsch.)



Comparative.—The palate is absent in fishes. In amphibia, the nasal cavities open directly into the primitive mouth cavity. In some birds, the palate shelves fail to unite, leaving a normal cleft palate. The incisive (Stenson's) canal remains open permanently in some mammals (e.g., ruminants), bifurcating above and thus placing the mouth cavity in communication with the nasal cavity on each side in the vicinity of Jacobson's organ. The transverse palatine ridges are much better developed among many mammals, especially the carnivora.

THE TONGUE
